Preface

The purpose of this handbook, originally published in 1984, was to provide a comprehensive review of current clinical descriptions, research, and theories of psychopathology. Descriptive psychopathology is a field that forms the foundation of clinical practice and research in clinical psychology, psychiatry, psychiatric social work, psychiatric nursing, and allied professions in mental health. Since the 1st edition, the editors have devised and updated a handbook to cover both general and specific topics in psychopathology that would be useful to researchers, practitioners, and graduate or other advanced students in the mental health and behavioral medicine professions. To implement this plan, we have very carefully chosen colleagues whom we respect for their expertise in particular fields. These authors include both clinicians and researchers who have outstanding national reputations, as well as more junior behavioral scientists and clinicians who, in our opinion, will achieve similar recognition in the future. The excellent chapters in this book lead us to believe that we have chosen wisely. We would like to express our appreciation to these authors for their outstanding contributions and cooperation.

This 3rd edition of the handbook was updated to include the most recent changes in the official diagnostic manual, the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV), and two chapters were added to address schizophrenia, a topic of resurgent interest. The remaining chapters have been revised to reflect recent changes in research and theories. The authors were asked to provide a comprehensive overview of their topics rather than focusing on their own research or theoretical biases. Furthermore, emphasis has been placed on clinical description, research, and theoretical implications, rather than remedial or therapeutic procedures, although these topics are discussed briefly in some chapters.

The volume is divided into six major parts. Part 1 is an overview of various theoretical and methodological issues in psychopathology. In Part 2, the traditional areas of abnormal behavior, including the neurotic and psychotic disorders, are discussed. In Part 3, the personality disorders are described, reflecting the increased attention to these disorders. Part 4 covers the disorders associated with social and situational problems, and Part 5 focuses on disorders linked to physical trauma and medical illness. Parts 4 and 5 could have also been labeled Behavioral Medicine 1 and 2 because they include topics in behavioral medicine and health psychology. Part 6 describes disorders arising in specific life stages.

The editors express appreciation to Jay Allen and Garnett Stokes, Heads of the Department of Psychology at the University of Georgia, John Church, Director, and the Psychology staff of the Veterans Affairs Medical Center in New Orleans, other administrators, faculty, and graduate students at the University of Georgia, and Alan D. Kaye and

Randolph B. Schiffer, Chairmen of the Departments of Anesthesiology and Neuropsychiatry and Behavioral Science at Texas Tech University Health Sciences Center, whose cooperation and support made this project possible. We also thank Albert N. Allain, Jr., whose diligence kept this project together, and Mariclaire Cloutier, our sponsoring editor at Kluwer Academic/Plenum Publishers, who has offered ongoing encouragement during this effort. Additionally, the courtesy of publishers and authors who gave permission to include copyright material in this volume is acknowledged gratefully.

Contents

PART I. ISSUES IN PSYCHOPATHOLOGY

<i>Chapter 1</i>	The Classification of Abnormal Behavior: An Overview	3
	<i>Henry E. Adams, Kristin A. Luscher, and Jeffrey A. Bernat</i>	
<i>Chapter 2</i>	Methodological Issues in Clinical Diagnosis	29
	<i>Sol L. Garfield</i>	
<i>Chapter 3</i>	Behavior Genetic Approaches to the Study of Psychopathology	53
	<i>Soo Hyun Rhee, Sarah A. Feignon, Jessica L. Bar, Yukiharu Hadeishi, and Irwin D. Waldman</i>	
<i>Chapter 4</i>	Biological Variables in Psychopathology: A Psychobiological Perspective	85
	<i>Don C. Fowles</i>	
<i>Chapter 5</i>	Culture, Ethnicity, and Psychopathology	105
	<i>Jeanne L. Tsai, James N. Butcher, Ricardo F. Muñoz, and Kelly Vitousek</i>	

PART II. NEUROTIC AND PSYCHOTIC DISORDERS

<i>Chapter 6</i>	Generalized Anxiety Disorders, Panic Disorders, and Phobias	131
	<i>Ronald M. Rapee and David H. Barlow</i>	
<i>Chapter 7</i>	Obsessive-Compulsive Disorder	155
	<i>Samuel M. Turner, Deborah C. Beidel, Melinda A. Stanley, and Nancy Heiser</i>	

<i>Chapter 8</i>	Posttraumatic Stress Disorder	183
	<i>John A. Fairbank, Lori Ebert, and Juesta M. Caddell</i>

CHAPTER 1

The Classification of Abnormal Behavior: An Overview

Henry E. Adams, Kristen A. Luscher,
and Jeffrey A. Bernat

Introduction

From the beginnings of life, as organisms attempt to understand their environment, they seek to organize a vast array of incoming stimuli. The recognition of similarities and the ordering of objects into sets on the basis of their relationships are primordial classificatory abilities that begin at a crude level but grow ever more discriminating as the organism matures. Even before the advent of *Homo sapiens*, classification ability must have been a component of fitness in biological evolution (Sokal, 1974). The acquisition of language by humans is clearly the most sophisticated example of this classificatory phenomenon in nature, for it is through learning words that we can select, evaluate, and categorize much of the information that bombards us in everyday life. In short, for human beings, words are classification; a sound or combination of sounds (or its representation in print) communicates a specific meaning (Davies, 1970). Because we possess this type of communication, we can discriminate a multitude of stimuli into categories that allow us to process, store, and act

on additional information at a level that no other organism can approach.

In the same way that lay persons use these categories to group concepts in an organized and common language, scientists, too, must have a means of communicating with each other. Their language requires even greater clarity and precision if knowledge is to be enhanced. Scientific classification systems use their own common language to organize and integrate data in a particular field and to work toward the goal of developing scientific principles and laws. It should be clear, then, that a science can develop only so far as it can classify the information in its field (Adams, 1981). Sartorius (1988) (p.14) highlighted the importance of classification when he stated that

no other intellectual act is of equal importance: if our classification of things and people in the world around us were to collapse, the world would cease to exist as a coherent and organized environment and would become a nebulous agglomeration of rubbish—matter, people, and things out of place.

The early stage in the development of a classification system should be guided by naturalistic and experimental observations rather than theoretical postures, despite the claims of some psychologists (Follette & Houts, 1996). In this way, scientific verification of theories and hypotheses generates the facts that can then be integrated into the development of an increasingly sophisticated classification scheme (Adams, Doster, & Calhoun, 1977). Unfortunately, in the study of abnormal

behavior, the trend has long been to place the cart before the horse. Early efforts in the field have followed the medical model, which views abnormal behavior as a form of illness; specific symptoms are aggregated into patterns of clinical syndromes. Identifying these syndromes is termed *diagnosis*, which is defined as the use of specific taxonomic schemes or classification systems to identify illness. Other classification systems have been proposed, but these, too, have been based on theoretical concepts of the nature of abnormal behavior, such as trait theory (McLemore & Benjamin, 1979) and behaviorism (Bandura, 1968). Defining aberrant behavior on the basis of questionable theoretical beliefs has led to much confusion in the development of adequate classification systems. Furthermore, the self-fulfilling prophecies inherent in this type of approach have made it next to impossible to determine which of the competing theories best explains these disorders (Wakefield, 1998).

The goal of any system designed to classify behavior is that the assignment of an individual or a response pattern to allocation on a dimension or certain category permits useful statements about the behavior based on membership in that category. Classification should imply further information about the individual or the behavior, including prediction in terms of social interaction, response to treatment, and future behavior (Quay & Werry, 1979).

It should be noted that the classification of individuals, particularly the type that involves the diagnosis of deviant behavior, is considered questionable by some mental health professionals. For instance, Rogers (1951) stated that categorizing people is unnatural, arbitrary, and unnecessary. In his view, abnormal behavior is caused by certain ways of perceiving one's present circumstances; thus, only the person knows the complete dynamics of his or her own perceptions and behavior. Further, Rogers felt that classifying interferes with treatment by hampering communication between the therapist and the client. Thomas Szasz, one of the more vocal opponents of classification, bluntly stated that "classifiers should be classified, people should not be" (Szasz, 1961, p. 37). Indeed, he felt that the doctor-patient relationship fostered by the traditional medical model—in which a "sick" person is classified according to his or her particular "illness"—fosters an inappropriate dependency on the part of the person seeking treatment, who is supposed to be learning to be more responsible

and independent in psychotherapy, not merely having a disease "cured."

Similar arguments against classification have involved the assumption that each individual or each response pattern is unique, and therefore classification is rendered meaningless. However, a science searches for common elements in events to integrate them into a conceptual scheme, and psychology is no exception (Adams et al., 1977). Its classification schemes are conceptual models that seek commonalities in responses or individuals. It is true that the uniqueness of each individual cannot be accounted for in a conceptual model of classification, because the classification of abnormal behavior implies the categorization of maladaptive responses for future use in predicting proper treatment protocols. For example, a physician classifies a person who has a serious heart condition with regard to the type of ailment and the seriousness of the disease; the classification is based on a complaint, and for all practical purposes, the uniqueness of the individual is set aside until the maladaptive response is remedied.

The justification of a particular model of classification is determined by how accurately the model facilitates the prediction, control, and understanding of the response. If there are not common elements in behavioral patterns, then these goals cannot be accomplished. This is not to say that the uniqueness of the individual is irrelevant—far from it! Recognizing the individuality of each human being has been a cornerstone of medicine throughout history. However, little can be done for the individual without referring to general principles. It is these principles that allow a diagnosis, and as Cawley (1983) stated,

The diagnostic statement represents the point of contact between the experience of the individual patient and the relevant collective knowledge and its organization. The diagnosis is the link which enables the individual to benefit from what is already known, and also allows the assimilation of the individual's data into the collective store. (p. 773)

It must be noted, too, that the debate over classifying abnormal behavior is scientific and has political overtones as well. Much of the criticism of the medical model has resulted from competition between various mental health professions (Schacht & Nathan, 1977), a competition in which psychiatry has remained dominant. The medical model has been used to justify the preeminent role of physicians in treating mental disorders; if people exhibiting abnormal behavior are "ill," then they require treatment by a medical doctor. Current

trends in society—that seem to label any persistent, maladaptive behavior a “disease”—indicate that the public is implicitly endorsing the medical model. As the cost of health care rises and competition among service providers increases, these issues are likely to take on increasing importance. Consider, for instance, the professional implications of the latest revision of the American Psychiatric Association’s *Diagnostic and Statistical Manual*, which changed the label of Axis III from “physical disorders” to “other medical disorders” (Widiger, Frances, Pincus, & Davis, 1990), indicating that the medical model continues to have an overarching presence.

In summary, the primary purpose of classification is to develop a means of communication among scientists and/or clinicians for the purpose of scientific research. Other purposes served by classification include information retrieval, description, and prediction (Blashfield & Draguns, 1976). In the initial stages, classification should not attempt to explain a phenomenon, but only to identify and describe it (Adams et al., 1977). Historically, classification attempts in psychopathology have evolved out of the observations of clinicians working with individuals who exhibited daily aberrant behavior, so that the immediate requirements have seldom permitted systematic investigation. The clinician begins by noticing the regularity with which certain characteristics occur together and conceptualizing them as a diagnostic entity. These various entities then gain some degree of consensual validation, particularly in the clinical setting, and subsequently become codified into a classification system (Quay & Werry, 1979). This process does not occur in a political vacuum, however, and can be influenced by conceptual as well as empirical considerations. This chapter provides an overview of the principles of classification of abnormal behavior, normative behavior, a definition of abnormal behavior, the relationship between measurement and classification, evaluation and models of classification, and current classification systems used in the study of abnormal psychology.

Principles of Classification

A classification scheme attempts to divide natural phenomena into mutually exclusive as well as exhaustive subsets. As mentioned previously, the first purpose of classifying is to permit accurate

communication that will allow developing, explaining, predicting, or controlling the events that constitute a particular phenomenon. To accomplish this goal, certain rules must be followed regarding the development of a conceptual scheme for classification. When psychologists attempt to classify their observations, they must keep in mind the conceptual nature of their efforts—for example, the idea of concept formation, which in reality is simply a model of natural events that simplifies the complex phenomena under study.

Because classification systems are first and foremost communication devices, it is vital that the characteristics defining a category be clearly detailed and described. The scientific or data language is the basic prerequisite for any classification scheme, and complex concepts need to be operationally defined so that measurement of the attributes of a particular category is possible (Bergmann, 1957). In the initial stages of developing a classification system, it is probably best to begin with what has been called *alpha taxonomy* or *lower order categories* (Bruner, Goodnow, & Austin, 1965; Kety, 1965; Mayr, 1952; Plutchik, 1968; Robins, 1966; Stengel, 1959). In essence, the construction of an alpha taxonomy requires a thorough description of the observable attributes of a phenomenon within a specific set. It should be demonstrated that the pattern exists with a cluster of covarying characteristics that are consistent over time and can be observed by various methods. As many subsets as possible should be constructed, so that all aspects of the phenomenon being classified may be included. The reliability of these subsets is greatly affected by the degree of care taken in specifying the definable aspects of the subsets and by how mutually exclusive they are.

Another important aspect of developing classification schemes is the unit used to assign an event to a given category or subcategory. Unfortunately, in the area of abnormal behavior, these units have tended to be abstract (e.g., personality structures, traits, or defense mechanisms rather than observations). An example is the first two editions of the American Psychiatric Association’s (APA, 1952, 1968) *Diagnostic and Statistical Manual*, which were saturated with psychoanalytic terms and concepts. This problem has since been largely eliminated in subsequent versions. Classification units should be simple, capable of being observed, and amenable to measurement techniques. It will be argued that the appropriate units for classifying abnormal behavior are responses and their param-

eters. Furthermore, categories and subcategories of an adequate classification scheme of abnormal behavior should consist of response patterns or dimension of response patterns rather than individual persons as units of measurement. The advantage to this approach can be seen, for example, in using the more response-specific phrase *person with alcohol dependence* rather than labeling the person as *alcoholic* with its sweeping implications.

Ideally, the defining properties of subsets should establish which properties at what values are necessary prerequisites for membership in that particular class. It should be noted that when categories require only some group of attributes in some value, therefore allowing the same attribute to cause a phenomenon to be classified in more than one subset, then the categories are said to be *disjunctive*. Disjunctive categories can cause confusion about the way an event should be classified, and ultimately, problems of lower reliability, redundant categories, and decreased ability to identify specific etiologies and treatments may result. For example, if an individual exhibits depressed mood and depressed mood is a defining characteristic for a number of categories (e.g., schizoaffective disorder, dysthymic disorder, and major depressive disorder), the person could be given any of these diagnoses. The disjunctive categories in DSM-III (APA, 1980) led to considerable overlap in symptomatology (Kass, Skodol, Charles, Spitzer, & Williams, 1985; Pfohl, Coryell, Zimmerman, & Stangl, 1986; Widiger, Trull, Hurt, Clarkin, & Frances, 1987). The DSM-III-R and DSM-IV (APA, 1987, 1994) attempted to reduce the problems inherent in disjunctive categories by deleting some of the overlapping items. For instance, idealization/devaluation was deleted from narcissistic personality disorder and angry outbursts/tantrums deleted from histrionic personality disorder because these were not central features and both items overlapped borderline personality disorder. This was an attempt to pursue more *conjunctive* categories, in which rules specify the intrinsic attributes and specific levels thereof necessary for a phenomenon to qualify for membership in a particular class or category. However, there are still considerable problems in the DSM-IV because it typically uses such terminology as the patient has to exhibit "six to ten of the following symptoms," a method that ensures disjunctive categories.

Conjunctive categories are one alternative to the problems inherent when disjunctive categories

are used. In this case, the absence of one or more attributes or a change in value of the attribute(s) would disqualify the phenomenon from membership. The end result is more homogeneous categories, which allows more precise scientific communication. Another benefit of this type of category is that borderline cases are clearly specified. For these reasons, conjunctive categories should be most useful scientifically. Unfortunately, they can be quite difficult to obtain. It appears that most naturally occurring categories (e.g., furniture, birds, or fruit) tend to be rather fuzzy sets with heterogeneous membership, overlapping boundaries, and many borderline cases (Mervis & Rosch, 1981; Wittgenstein, 1953). Natural categories are characterized by a set of correlated features that are imperfectly related to category membership (i.e., the defining features are not singly necessary). Some members of the category possess all of the defining features, but many—if not most—do not (Wittgenstein, 1953). Indeed, in the sciences of biology, zoology, and archaeology, the criteria tend to be polythetic (requiring only a specified number of a larger set of items, as in the DSM-IV) rather than nomothetic (requiring that all items are present).

In the field of abnormal behavior, growing awareness of the difficulties in striving for homogeneous syndromes with distinct boundaries led to major revisions in the DSM-III, III-R, and IV (APA, 1980, 1987, 1994). As Widiger, Frances, Spitzer, and Williams (1988) noted, the nomothetic nature of many of the DSM-III and III-R's criteria sets were overly restrictive, whereas the adoption of polythetic criteria for all disorders in DSM-III-R (and IV) improved reliability by not requiring the presence of every item in every disorder for making a diagnosis. Reliability was further improved by deleting some overlapping items, though this can become problematic if it cuts too big a swath through the essential features of related conditions. Many of the personality disorders, for example, inherently correlate with each other and necessarily share overlapping behaviors or characteristics. Thus, it is realistic to acknowledge this at a basic level. Consider social withdrawal, which is shared by avoidant, schizoid, and schizotypal personality disorders. Deleting this feature from one or two of these categories would improve differentiation but would virtually eliminate clinical usefulness.

It can be seen, then, that there are advantages and disadvantages to both disjunctive and con-

junctive categories. Although the ideal scientific approach would be conjunctive, the reality of nature as well as practical considerations are moving the field toward polythetic and somewhat disjunctive criteria to emphasize the validity of categories (Spitzer & Williams, 1980). As noted before, however, efforts are continuing to work toward eliminating nonessential overlap to arrive at more homogeneous categories (as required in a conjunctive approach).

Another important principle of classification is the requirement to use a single classifying principle. Classification schemes dealing with human behavior have the option of sorting behaviors according to observed behavior, the cause of behavior patterns (etiology), development over time (prognosis), or response to treatment. Although ideally there should be classification schemes for all of these parameters of human behavior, initially they should be independent to avoid conceptual contamination. The descriptive classification of behavior, for example, should not include the causes of a particular behavior pattern as part of its defining factors.

In the early stages of a psychological science, behavior, etiology, and response to treatment should be classified independently, and a specific type of behavior should be related to a specific etiology on the basis of empirical facts or research. This results in a higher order of classification, termed *beta taxonomy* by Bruner et al. (1965), and through this approach the relational categories can then be empirically related to a particular treatment approach. A good example of this type of development is the identification of syphilis, which was followed by the demonstration that it is caused by spirochetes, and then by the development of penicillin to treat the disorder.

If an empirical relationship among behavior, etiology, prognosis, and response to treatment can be established, then a more scientific classification system results. On the other hand, if this approach is not adopted, and behavior, as well as the presumed causes of the behavior, is used in classification, then criterion contamination results. One good way to reduce criterion contamination is by using a multiaxial system that classifies behavior on one axis, etiological factors on a second axis, and so forth.

In summary, several principles of classification are important, including the use of adequate terminology or data language, simple classification units, conjunctive categories (as far as possible),

and a single classification principle. Inadequate terminology, overly disjunctive categories, and preconceived notions about etiology that influence the development of a classification system will result in difficulties in the system's reliability and validity.

Defining Abnormal Behavior

Attempts to define abnormal, deviant, disordered, or psychopathological behavior in psychology have largely been disastrous, although this process is necessary to develop a classification system. Any number of attempts ranging from statistical to theoretical positions have been made; all cause more confusion than clarification. One possible solution to this problem is Wakefield's (1992a,b) notion of "harmful dysfunction," which is similar to the definition used by the DSM-IV.

A definition of abnormal behavior should be quite distinct from models or theories of behavior or abnormal behavior, contrary to the claims of Follette and Houts (1996). A definition of abnormal behavior is used to identify the domain (i.e., what it is) that theories or models attempt to explain (i.e., the causes or mechanisms of the disorder). Abnormal behavior defined in terms of a theory or causal model eliminates the possibility of empirically evaluating the theory or contrasting it with other explanations or theories of the behavior. If abnormal behavior is "mental illness," then by definition only a medical model is an appropriate explanation. Other definitions such as a "learned habit" or "residual deviance" cause similar problems. To avoid tautology, universal, plausible, "atheoretical" definitions and diagnostic criteria were important goals of individuals who devised the recent diagnostic and statistical manuals (i.e., DSM-III, DSM-III-R, and DSM-IV) (APA, 1980, 1987, 1994; Spitzer & Williams, 1983; Wakefield, 1992a,b).

Wakefield's analysis of the concept of disorder is one possible solution to this problem. He states, "a disorder exists when the failure of a person's internal mechanisms to perform their functions, as designed by nature, impinges harmfully on the person's well-being, as defined by social values and meaning" (Wakefield, 1992a, p.373). The "harmful dysfunction" notion is similar to the definition of disorder used by the DSM-IV. It requires two necessary conditions for a diagnosis of a disorder: "dysfunction" and "negative conse-

quences.” This definition addresses a number of vexing problems in defining abnormal behavior. We shall address a few of them.

Mental Disorders: Scientific Concepts or Value Judgments?

It is true that many forms of abnormal behavior are normative concepts based on value judgments. Most mental disorders are negative conditions that justify social concerns, but defining them in terms of pure value judgments allows classifying many socially disapproved behaviors as disorders when they clearly are not. Incarcerated Soviet dissidents, “childhood masturbation disorder,” *drapetomania* (slaves running away from their masters), or other socially deviant behavior, which violated social norms of the time or a particular culture, are clearly not disorders. In spite of Houts and Follette’s (1998) claim that abnormal behavior is, first and foremost, a social judgment, this cannot and should not be the case because this means that disorders can become a method of social control associated with repression of unpopular behavior, as was done in Russia. Recent controversies about “self-defeating personalities” (Caplan, 1988) and homosexuality (Bayer & Spitzer, 1982) clearly illustrate this problem.

Similarly, if disorder is defined as a “dysfunction” in purely scientific terms, there are serious limitations. For example, a person in our culture who hears voices that others do not is assumed to have a disorder of cognitive processing. But, what about prophets, saints, and holy men who hear voices in other cultures or subcultures. Are they suffering from mental disorders? The point is that some internal malfunctions do not cause harm to the individual nor do they cause harm to others. Thus, to consider the dysfunction a mental disorder it must be harmful to the individual or society. A hybrid definition where the behavior represents both a dysfunction (i.e., a scientific concept) and harm (i.e., a value concept) is necessary to label a condition as a mental disorder. Both components are necessary, and neither is sufficient alone.

Mental Disorders: External Behavior or Internal Mechanisms

Two frequent criticisms of Wakefield’s concept of internal mechanisms are that the notion is both

“mentalistic” (a term that drives strict behaviorists crazy) and biological. Most psychologists would agree that what goes on inside a person is important. However, important scientific methods and procedures must be considered when dealing with “unobservable” events. Operational definitions and similar procedures have facilitated the cognitive revolution in psychology, which is interested, primarily, in unobservable events. Not even the most radical behaviorist would deny the importance of internal mechanisms insofar as they are addressed scientifically. Consider, for example, the topics of memory, information processing, and similar areas of important recent cognitive research. Are we to dismiss these advances as mentalistic? The criticism of internal mechanisms as biological or genetic is also nonsensical. Few cognitive psychologists who deal constantly with internal mechanisms would label their explanations of these mechanisms as biological or genetic. Internal mechanisms can be created by environmental events and learning, as well as by biological factors. Internal does not necessarily mean biological. A person with a memory disorder may not exhibit obvious behavior that indicates this problem, and a “fine-grained analysis with all neuropsychological tests” may be necessary to detect the problem. Further, the memory deficit may be psychological or biological. There are numerous other examples.

On occasions, labeling a person as “disordered” when the problem resides in the environment is a mistake. For example, the loss of loved ones will cause people to look like they are depressed, but when a suitable time has passed, they again appear normal. The point is that a depressive disorder resides in the person and is due to the disruption of a normal mechanism, such as the emotional response system. This does not mean that environmental events cannot cause disruption of internal events. They can and do. Posttraumatic stress disorder is one such example. There are numerous other conditions caused by a malignant environment or an interaction of a malignant environment and biological predispositions.

Internal dysfunctions must be demonstrated by careful evaluation of environmental events, behavior, and internal functions. This process is called *case formulation*. Not all abnormal behavior is a disorder. This distinction is important legally (e.g., is the individual innocent because of mental disorder?) and socially (is oversensitivity

to a Black person due to a politically repressive environment or a disorder such as “paranoia”?).

Disorders: Mental or Medical?

A widespread controversy involves the medical model of mental illness as a “disease.” Interestingly, definitions of disease or illness have the same conceptual difficulties in disentangling a scientific or neutral definition from value statements as definitions of abnormal behavior. All disorders are usually undesirable and harmful according to social values, but disorders are more than just values. They are failures of internal mechanisms that maintain coping behavior as well as psychological and physiological adjustment. The general concept of disorder applies to both mental and physical conditions, whereas the notion of internal mechanism refers to both physical structures and functioning as well as mental structures and functioning such as memory, perception, and other psychological systems that we shall discuss later. In the former case, the disorder is labeled a physical disorder, and in the latter case a mental disorder. The former involves the physiological response systems, and the latter the psychological response systems.

The overlap of the two types of disorders causes confusion among lay people as well as professionals. For example, cancer can cause severe depression, but it should be a “mental disorder” only if the physical illness has caused a dysfunction of the internal psychological mechanisms that control emotional behavior. If that is the case, then the individual has both a physical and mental disorder. The reverse can also occur. A mental disorder, such as alcohol abuse, can cause a physical disorder (i.e., liver damage). Physical and mental disorders can occur together or separately, but it is important to understand that they are different conditions. The relationship of the two conditions has instigated the growth and development of behavioral medicine and health psychology.

Mental Disorders: What Are Dysfunctions?

A dysfunction is a failure of some mechanism to perform its natural function as designed by nature. For example, the natural function of the heart is to pump blood; the natural function of perception is

to convey information about the environment; the natural function of emotions is to avoid harm and enhance pleasure. A mechanism may have other characteristics as well, such as the heart producing sounds. However, pumping blood is the natural function of the heart even though it has other characteristics, such as sounds, which may be helpful in diagnosing heart conditions.

The clause “as designed by nature” is the evolutionary explanation of the structure, existence, and activity of the organ or mechanism. In other words, mechanisms that contributed to the organism’s coping and reproductive success over successive generations increased in frequency or were “naturally selected” and exist in today’s organism (Buss, 1999). This evolutionary explanation is bound to cause criticism; however, determining how these organs and mechanisms came to be is not central to this notion. The fact that such organs and mechanisms exist is sufficient.

The major difficulty is that we know a great deal about physiological mechanisms and structures because of the basic research into normal functioning conducted by biological scientists. This is the basis of modern medicine, which uses the basic research to understand physical disorders and treatment. Physicians know what normal physiological functioning is and usually they can quickly spot a deviation from this normalcy. Psychology, on the other hand, is in a great state of ignorance regarding the causes of normal psychological functioning or its related mechanisms. To make matters worse, psychological practitioners are typically ignorant of basic research in psychology and fail to use the wealth of basic research available to them in clinical problems. As a group, clinical psychologists, particularly private practitioners, have disowned basic research, which has stifled advancements in applying basic knowledge.

Normal Behavior and Psychopathology

A major question that has plagued the field of abnormal behavior is, what are the criteria for abnormal behavior (or psychopathology, mental illness, or a similar term)? Perhaps a clue to the answer can be seen in the medical profession, that can diagnose physical illness or disease fairly accurately. In the history of developing successful

Table 1. Response Systems in the Behavior Classification System

Response Systems	Definition	Response Categories	Examples of Variations as Diagnosed by DSM-II and DSM-III
Emotional	Activity of tissues and organs innervated by the autonomic nervous system that is associated with specific behavior patterns and subjective experience of an individual	Anxiety Euphoria/dysphoria Anger/affection	DSM-II—Anxiety neuroses, phobic neuroses, depressive neuroses, explosive personality DSM-III—Affective disorders, anxiety disorders, impulse disorders (anger), anxiety disorders of childhood or adolescence, intermittent explosive disorder
Sensory/perceptual	Activities involving detection, discrimination, and recognition of environmental stimuli	Visual Auditory Gustatory Vestibular Visceral Olfactory Kinesthetic Cutaneous	DSM-II—Hysterical neuroses, conversion type (sensory) DSM-III—Somatoform disorders (sensory)
Cognitive	Behaviors involving the processing of information	Information selection Information retrieval Conceptualization Reasoning	DSM-II—Hysterical neuroses, dissociative type; depersonalization neuroses; obsessive-compulsive neuroses (obsessions); hypochondriacal neuroses DSM-III—Dissociative disorders
Motor	Activity of the muscles and glands involved in physical activities but exclusive of the meaning or content of those activities	Oculomotor Facial Throat Head Limb Trunk	DSM-II—Hysterical neuroses, conversion type (motor); obsessive-compulsive neuroses (motor rituals); tic; psychomotor disorders; speech disorders DSM-III—Obsessive-compulsive disorders (motor rituals); speech disorders; stereotyped movement disorders
Biological needs	Behaviors associated with basic body needs arising from specific biochemical conditions or unusually strong peripheral stimulation that can impair the well-being or health of the individual if not satisfied	Hunger Thirst Elimination Sex Sleep Respiration Harm avoidance	DMS-II—Neurasthenic neuroses; asthenic personality; sexual deviations; disorders of sleep; feeding disturbances; enuresis; encopresis DSM-III—Psychosexual dysfunctions; paraphilias; other sexual disorders; sleep disorders; eating disorders; enuresis; encopresis
Acquired biological needs	Acquired physical dependencies (intake of substances into the body that change the biochemistry of the physiological systems so that the presence of these substances is required to avoid physiological or psychological distress)		DSM-II—Alcoholism, drug dependence DSM-III—Substance use disorders

Table 1. (Continued)

Response Systems	Definition	Response Categories	Examples of Variations as Diagnosed by DSM-II and DSM-III
Social	Reciprocal actions of two or more individuals	Aggression/ submission Dependency/ independency Altruism/ selfishness Conformity/ deviations	DSM-II and DSM-III—Personality disorders in adults and children
Complex variations	Functional interaction of two or more response systems		DSM-II and DSM-III—Mental retardation (functional); schizophrenia; paranoid states; pervasive developmental disorders, including infantile autism; major affective disorders

diagnostic procedures in medicine, a primary prerequisite has been a fairly precise knowledge of what constitutes normal anatomy and physiological functioning. In other words, before physicians can diagnose illness or disease, they must know the population parameters of “normal” biological functioning. The fact that an understanding of normal behavior is a prerequisite to identify and investigate abnormal behavior seems to have been all but ignored in developing classification systems for abnormal behavior. A classification scheme of normal behavior must be developed, and normative data must be obtained before one can empirically establish what constitutes deviant, abnormal, or unusual behavior.

Adams et al. (1977) developed such a preliminary scheme for classifying normal behavior. This taxonomy is organized around the notion of response systems, as may be seen in Table 1. The taxonomy is based on the assumption that various types of observable responses (behavior) can be grouped into categories that represent fairly homogeneous independent response systems. In this sense, it is similar to normal physiological systems or the taxonomy used by biologists, with such categories as the cardiovascular, gastrointestinal, nervous, and musculoskeletal. Although it can be argued that the response systems proposed by Adams et al. are not independent of each other and that they interact, resulting in somewhat arbitrary

divisions, note that the taxonomies of biological functioning and anatomy are also interrelated. Studying the interrelationships of biological systems, as well as the systems themselves, has proved useful to biological scientists and should provide similar knowledge to psychological scientists, so that they too can attempt to organize behavior into subsystems of responses.

Because the psychological response system of Adams et al. (1977) is based on units of behavior or responses, some professionals may assume that it is a classification system based on the theoretical position of behaviorism. This was not the aim of this scheme, and the assumption that the primitive units of observation in psychology are responses or response patterns does not imply a behavioral orientation. Most mental health professionals, including humanists, behaviorists, psychodynamic theorists, and those who are biologically oriented, would agree that the study of human beings begins with the observation of their behavior. The implications and explanations of that observed behavior constitute the various theoretical orientations. It is imperative that an adequate classification system precede the development of these theories. Although the temporal order is often confused in actual practice, the sequence of the development of a science involves classification, then measurement, and then theories as a basic prerequisite for knowledge.

Once there is some idea of the parameters of normal behavior and the way it varies as a function of age, sex, cultural groups, and similar features, then the question of what constitutes abnormal behavior can be more appropriately addressed (Costello, 1980; Lefkowitz & Burton, 1978). Essentially, psychopathology can be defined by two methods: the class model and the multivariate, dimensional, or quantitative model.

The *multivariate model* assumes that all behavior can be placed on a continuum; one example would be intelligence. When some behaviors, such as depression and anxiety, become so exaggerated that their intensity is exhibited by only a small fraction of the population, then psychopathology may be demarcated. In this sense, a disorder such as depression or anxiety is diagnosed in the same way as hypertension in medical classification. When these responses reach a certain frequency, intensity, and duration, they are labeled pathological. Note that to use this criterion, it is necessary to have the population parameters or, in less suitable situations, clinical knowledge of the attribute and to make some judgment about where the limits should be, a judgment that is somewhat arbitrary. Selecting the appropriate limits can be aided by knowledge of the consequences of the extremes of behavior. It is also necessary to know the environmental aspects and other related circumstances of these behaviors (stimulus parameters) to make such a decision. The loss of a loved one, for example, is typically assessed with an increase in depression of high intensity, but of limited duration. Epidemiological inquiry and the notion of prevalence are the key concepts in this approach, although it is important to keep in mind Costello's (1980) warning that merely because behavior patterns are frequent does not mean that they are normal or acceptable. For example, posttraumatic stress disorder is a frequent, albeit arguably "abnormal," response to traumatic events. The dimensional approach to classification is the essence of this method, which assumes that a particular aberrant response is dimensional (i.e., everyone has the characteristic to some degree).

In addition, establishing that a particular behavioral pattern is deviant or statistically rare is only the first step in developing a classification scheme for psychopathology (Adams, 1981; Costello, 1980). The second step is to demonstrate that these behavior patterns are clinically significant and

cause objective or subjective distress to the individual or to others (see Wakefield, 1992a,b). Two general criteria can be used in arriving at this decision. The first has been called the *criterion of labeled deviance*. Under this criterion, deviant behavior or psychopathology is defined by behavior patterns that violate social norms. This criterion varies as a function of local conventions and changes from society to society, from time to time, and even from place to place. An example of this relativity is homosexuality. In DSM-I and DSM-II, homosexuality was considered a form of mental illness. In DSM-III-R and IV, however, it is not. For example, homosexuality is barely referenced at all in DSM-III-R and IV, where "persistent and marked distress about sexual orientation" is cited as an example under the category "sexual disorders not otherwise specified."

The second criterion is the *criterion of adjustment*. This criterion is based on how well individuals cope with their environments and is, within limits, independent of culture, because it is keyed only to the satisfaction of one's biological and/or social needs and one's ability to survive. These two criteria can conflict with each other; for instance, hardworking executives may meet all the deviance criteria of normality but would qualify as abnormal in terms of the adjustment criterion if their hard work has caused a potentially life-threatening stress disorder. Another case would be a young man whose draft resistance during the war in Vietnam qualified him as deviant in terms of social norms but who, alive and well in Canada, is normal by the adjustment criterion. Therefore, it is obvious that what is perceived as normal behavior may depend on which criterion is used, and it should be clear that these criteria differ. However, it is also apparent that when an individual satisfies both criteria, the label of psychopathology is greatly enhanced. The validity of these judgments of abnormality must be established by research efforts.

Another approach to classification is the *class or qualitative difference model*, which assumes that some psychopathological disorders do not occur in the normal population. For example, some disease processes (e.g., cancer or syphilis) do not vary in degree in all people, even in a mild form. Such diseases are either present or absent. Because it is difficult to conceive of any response—even a loosening of associations—that does not occur at some time to some extent in most people,

the classification categories and subcategories in psychopathology must refer to a constellation of responses that are functionally related, so that they have simultaneous and/or consecutive variation within a given subset of the population. Even though each response may occur in some form in the normal population, these responses do not covary in the same manner as in the deviant subset, or they may be independent of one another.

Note that this type of classification scheme requires careful determination of the relationship of the constellation of responses. A good example is schizophrenia. Earlier definitions of schizophrenia required that the individual exhibit the fundamental symptoms of altered associations, altered affect, ambivalence, and autism. At one time or another, all of us have demonstrated any or all of these responses to some degree. However, it is doubtful that the four symptoms covary together in the normal population, and this covariation permits us to use the label of schizophrenia and to assume that it does not occur in the normal population.

According to this approach, if it is assumed that there is such a phenomenon known as schizophrenia that does not occur in the normal population, then such a phenomenon needs to be demonstrated or verified before it can be used as a classificatory concept. This prerequisite is often neglected, and the hypothesis that there is a pathological condition known as schizophrenia is transformed into the fact that an entity known as schizophrenia exists. This is known as the process of *reification*. The question as to whether there is such a phenomenon as schizophrenia has received scant attention, and as a number of theorists have noted, the phenomenon of schizophrenia may well be a figment of psychologists' and psychiatrists' imaginations (Laing, 1960; Sarbin, 1967; Szasz, 1966). Carson (1996 and in this book) has been particularly critical of the DSM-IV and its tendency toward an Aristotelian mode of thought. Further, there are even those who feel that it is unimportant whether such entities exist. Kendell (1983) found the "truth value" of classificatory schemata irrelevant and emphasized instead their heuristic value. He stated that "diagnostic terms are no more than convenient labels for arbitrary groupings of clinical phenomena" and that these are "concepts justified only by their usefulness" (p. 51).

The point is that deviant behavior should be

assumed dimensional, something we all have to some degree—like blood pressure—unless otherwise demonstrated. To verify that a disorder is categorical (i.e., limited to some people but not others), it must be demonstrated by research evidence. In a recent development, Meehl and his colleagues (Meehl & Golden, 1982, Waller & Meehl, 1998) described taxometric procedures that can determine if a classification category is typological (i.e., class or latent class, taxonic) or dimensional/continuous. The procedure is too complicated to describe in detail here, but it is obviously a method that should resolve many classification controversies in the argument about whether a disorder is a category or a dimensional variable. This procedure has the potential to revolutionize classification if it is used.

In summary, adequate knowledge of normal behavior and behavioral norms are necessary prerequisites for establishing a reliable and valid classification system for psychopathology. Then, either the class or quantitative methods can be used to establish categories of psychopathology.

Classification and Measurement

In the initial stages of developing a classification system, observations comprise a classification scheme. If the categories or subcategories are adequately defined, then the next step in the process is measuring the attributes. Measurement is the technological implementation of a classification scheme; in psychology, it involves assessing behavior or response patterns. Which response should be measured is determined by the definition of the particular category or subcategory, and measurement involves operationally defining the category so that the presence or absence of the attribute or its magnitude and duration can be determined.

Several points are relevant to measuring both normal and abnormal behavior for diagnostic purposes. On a practical level, clinicians should devise a standardized psychological examination similar to the physical examination administered by physicians. This examination should inspect an individual's response systems and include a specific examination of the person's emotions, sensory-perceptual processes, cognitive processes, motor behavior, biological needs, acquired biological needs (addictions), and social behavior. This exam could be conducted by a standardized interview or,

in some cases, by rapid screening tests to determine if a more thorough examination of a particular aspect of the individual's behavior is indicated. Omnibus personality inventories, such as the Minnesota Multiphasic Personality Inventory-II (MMPI-2) and problem checklists have been used for similar purposes or as screening devices. Unfortunately, these are not satisfactory because they fail to detect problems that are obvious by simple observation (e.g., obesity, tics, or substance abuse), give few clues to more precise assessment, are often cumbersome methods of determining the obvious (e.g., whether someone is hallucinating), and are based on theoretical propositions (e.g., trait theories) that can impede an objective evaluation of the problem.

Furthermore, the psychological exam should indicate what particular aspect of the individual's behavior is aberrant, not whether the individual is aberrant. Such a screening procedure should lead to specific tests or examinations for specific problem behaviors. Thus, if it were suspected that an individual was demonstrating a thought disorder, a more thorough examination of information processing could be conducted, perhaps by means of the situations or tests used in research programs such as that by Shakow (1977). On the other hand, if there were no indication that the individual was experiencing sexual problems, then it would be foolish and an invasion of privacy to conduct an extensive examination of the individual's sexual orientation and behavior. For the practicing clinician concerned with a variety of diagnostic problems, there is a serious need to organize and develop a series of different tests to evaluate different disorders and a need for some type of standardized psychological examination.

The procedure for diagnosing specific problems should attempt to assess all three channels of behavior: cognitive, behavioral, and physiological. Adequate assessment should include the individual's subjective report (both self-monitoring and self-reporting), behavioral observation or behavioral analogue tests, and when possible, physiological indexes, such as those used in assessing aberrant sexual behavior (Tollison & Adams, 1979). Even though they are crude and imperfect, behavioral avoidance tests that are used to detect phobic behavior are an example of the way specific disorders should be evaluated. In this procedure, an individual is placed in an appropriate situation where a subjective report, observation of

approach or avoidance behavior, and psychophysiological indexes of autonomic arousal can all be obtained. Similar experimental procedures already present in the literature could be modified and adapted to detect and evaluate other specific disorders.

Because of the appeal of rapid screening devices and the influence of personality and trait theory, the role of stimulus variables and the environmental context of behavior has traditionally been ignored. Typically, every individual in an assessment situation is exposed to a standard set of stimuli (e.g., test items or ink blots), and it has been assumed that behavior exhibited in this situation allows predicting behavior in other situations. Unfortunately, this assumption has proven questionable. The constructive controversy, elicited by the work of Mischel (1968, 1973) on situationalism versus trait approaches to behavior, has indicated the naivete of that assumption and clearly has shown that situational or stimulus factors must be considered in assessing behavior. That situations often determine behavior is obvious to even the casual observer; it is not difficult to imagine oneself as aggressive with Pee-Wee Herman and being extremely considerate of Clint Eastwood's "Dirty Harry."

Therefore, to make meaningful observations and inferences, one must consider two aspects of stimulus variables. First, the intensity of the stimulus must be varied, and then the change in response must be observed. For example, a phobic individual may exhibit fear upon entering a room containing a caged snake. Even a normal individual may exhibit the same response if the intensity is increased by requiring the person to handle the snake. Second, the variation in stimulus situations is also crucial. A person with a snake phobia may show little anxiety in New York City but may be greatly handicapped on an overgrown, rocky hillside. An interesting implication of the situational-versus-trait argument has been suggested by Adams (1981) and Marrioto and Paul (1975): Individuals who do not vary their behavior as situations change, and thus appear to be more "trait like," may be more psychologically disturbed than people who have the more common pattern of varying their behavior as a function of stimulus situations. In any case, a basic factor in adequate assessment is that stimulus factors (the independent variables) must be manipulated if one is to observe changes in responses (the dependent variables).

Thus, adequate measurement for assessment involves a stimulus-organism-response-consequences (S-O-R-C) approach. The stimulus content and intensity can be varied as independent variables, whereas responses can be viewed as dependent variables. The organismic variable, which includes age, sex, activity levels, and so forth, can be viewed as modulating variables, which may directly influence the S-R relationship. The consequences of behavior are, strictly speaking, more relevant to etiological classification because consequences give a clue to the development and maintenance of a behavior pattern. Perhaps, at this stage of the game, consequences should not be considered in assigning behavior patterns to classification categories because confusion of the occurrence of a disorder with its cause results in a self-fulfilling prophecy. Currently, it seems that the more we know, the more we learn how rare are complete and specific associations between a disorder's etiology, symptomatology, and consequences (Cawley, 1983). On the other hand, if it has been empirically demonstrated that a particular behavior is a direct function of a certain consequence of the behavior, then it is legitimate to use it as a classification attribute.

A similar argument can be made with respect to personality traits, often used to classify types of behavior disorders. This is not usually advisable except in classifying dysfunctions of social behavior or personality disorders. For example, people with obsessive-compulsive personality traits may or may not demonstrate compulsive rituals, such as hand washing. Therefore, this personality type should not be used as an attribute for classifying behavior in a category of obsessive-compulsive disorders. This type of trait is an extraclassificatory correlate of behavior and is not an intrinsic attribute of the behavior disorder. Consequently, it should not be used to classify a behavior pattern. If it is used in this way, it often leads to a great deal of confusion.

There are a number of parametric issues that must be addressed when devising suitable measuring instruments for classification purposes, including reliability, validity, demand characteristics, and similar issues. These are important and complex issues that cannot be adequately addressed in the limited space of this chapter. For further information in these areas, the reader is referred to more relevant references and textbooks (e.g., Anastasi & Urbina, 1997).

Evaluation and Methods of Classification

Classification research for the development of classification schemes requires a framework for describing the approach to and evaluating classification schemes. In evaluation, there are four major aspects that are very important in producing a reliable and valid classification system (Skinner, 1981):

1. The classification system should be reliable and consistent from user to user (interrater agreement) and within the same user over different time periods (stability).
2. The system should describe the domains of behaviors it encompasses. This aspect of a classification system always involves a trade-off between the extent of coverage and the precision of measurement. A good example of broad coverage is the series of *APA Diagnostic and Statistic Manuals* that include behavioral disorders and organic conditions, as well as numerous mental disorders.
3. The system should have descriptive validity, which is the degree to which the categories within it are homogenous with respect to their relative attributes (e.g., symptoms, personality constructs, biographical data, and other defining attributes of the categories).
4. The system should have predictive and clinical validity, which addresses the question of whether classification predicts other variables and whether the predicted variables are clinically significant, respectively.

As a framework for clinical research, the three-states paradigm described by Skinner (1981), evolving from the work of Loevinger (1957), is a useful model and is shown in Figure 1. The theoretical formulation should lead to hypotheses that are open to empirical evaluation so that the classification system can be shown capable of scientific evaluation. As Popper (1972) has noted, a scientific theory is only useful if it suggests repudiation rather than truth. Thus, a classification system should include a precise definition of each type of functional relationship among the various subtypes (i.e., a nomological network), a method of explicating the development and etiology of the disorders, a description of the prognosis, the appropriate treatment interventions, and a discussion of the population for which the classification oc-

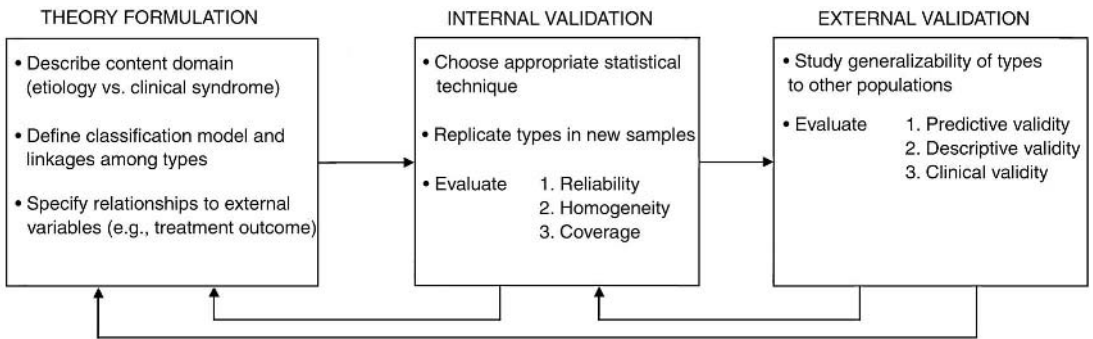

Figure 1. Framework for classification research. (From *Toward the integration of classification theory and methods* by H. A. Skinner, 1981, *Journal of Abnormal Psychology*, 90, 70. Copyright 1981 by the American Psychological Association. Reprinted by permission.)

curs. Irrefutable theories and classification systems that cannot be evaluated are of little value to the scientific clinician.

The content domain should describe clearly the variables on which the classification is based. In other words, is the individual or the behavior placed in a category on the basis of clinical symptoms (aberrant behavior), the course of the disorder, its etiology, or some combination of these variables? The two major competing classification variables are behavior and etiology. However, any system that uses both variables to classify a disorder hopelessly confounds the issue of whether a certain etiological factor causes a specific type of deviant behavior. There is considerable argument that the use of etiology as a method of classifying behavior is premature and that the description of behavior is most appropriate for the current state of the science (Zigler & Phillips, 1961).

The validity of this argument has been recognized in DSM-III, III-R, and IV, which reversed the trend toward classification by etiology in favor of more descriptive, observational notions. Klerman, Vaillant, Spitzer, and Michels (1984) clearly indicated the reasons for the reversal, stating that the reliance on descriptive rather than etiological criteria “represents a strategic mode of dealing with the frustrating reality that, for most of the disorders we treat, there is only limited evidence for their etiologies.” The obvious solution would be to construct one classification system for abnormal behavior and a second for etiology, in accordance with Hempel’s (1965) view of logical empiricism, which holds that we can claim to

understand concepts scientifically only if we are able (1) to describe them and (2) to explain or predict them through general laws and theories. An example of etiological classification is Zubin and Spring’s (1977) description of six approaches to the classification of schizophrenia: the ecological, developmental, learning, genetic, internal, and neurophysiological models. Their variables are categories of etiology and are similar to the classification system described by Hebb (1966) and shown in Table 2.

When using two classification systems, it is possible to demonstrate by research that a specific behavior type is associated with specific kinds of etiology. This type of research leads to refinements in classification systems. As a matter of fact, a multiaxial system—similar to that introduced in DSM-III, in which the clinical syndrome is diagnosed separately from its etiology—would be one possible step toward that end (Essen-Moller, 1973). Nevertheless, it must be emphasized that scientific documentation rather than theoretical speculation is the only method by which a classification scheme can use both etiology and behavior (or symptoms) in a classification system.

There are basically three types of structural models that can be used to develop a classification system. The first is the hierarchical model that classifies individuals into subsets that are themselves successively classified into groups at a higher level in the hierarchy (see Fig. 2). One example is schizophrenia, which in the figure is subdivided into acute or chronic types and then further subdivided into various subtypes, like

Table 2. Classes of Causal Factors in Human Behavior

No.	Class	Source, Mode of Action, etc.
I	Genetic	Physiological properties of the fertilized ovum
II	Chemical, prenatal	Nutritive or toxic influence in the uterine environment
III	Chemical, postnatal	Nutritive or toxic influence: food, water, oxygen, drugs, etc.
IV	Sensory, constant	Pre- and postnatal experience normally inevitable for all members of the species
V	Sensory, variable	Experience that varies from one member of the species to another
VI	Traumatic	Physical events tending to destroy cells: an "abnormal" class of events to which an animal might conceivably never be exposed, unlike Factors I to V

hebephrenic (disorganized), catatonic, and paranoid, where each category is distinct from other subcategories but all share characteristics at higher levels. For instance, all subsets of schizophrenia would include the defining attributes of schizophrenia, such as disorders of cognition. Another example is the four-tiered system of Foulds and Bedford (1975), which begins with neurosis and personality disorders and progresses up the hierarchy to depression, mania, and paranoia; schizophrenia; and organic brain syndromes. These classes are ordered in terms of increasing severity and assume that a person with symptoms of a given class necessarily has the symptoms of all of the lower classes in the hierarchy.

Another approach is to use categorical systems, which assume that individuals can be classified into discrete classes that are seen as internally coherent but distinct from each other. This was the primary approach adopted in DSM-III, DSM-III-R, and DSM-IV. An example of this type is the cluster analysis depicted in Figure 3.

The third method is the dimensional system, which orders individuals along axes in a multi-dimensional scale. This has been the most common method employed in personality research, perhaps because the literature in this area has failed to establish any sharp boundaries between personality styles or between adaptive and maladaptive traits (Eysenck, Wakefield, & Friedman,

1983). An example of this approach is the three-dimensional model of DSM-III personality disorders developed by Widiger et al. (1987), which identified these disorders along the dimensions of social involvement, assertiveness, and acting-out behavior (see Fig. 4). A more recent alternative is the translation of the DSM-IV personality disorders along the dimensions of the five-factor model of personality (Widiger, Trull, Clarkin, Sanderson, & Costa, 1994).

Dimensional models provide more flexible, specific, and comprehensive information, whereas categorical models tend to be Procrustean, to lose information, and to result in many classificatory dilemmas for borderline cases (Kendell, 1975; Strauss, 1975). If one accepts these advantages, however, one is still confronted with the difficult question of which dimensions to choose in defining these disorders. Figure 4 demonstrates one option. Still another dimensional approach is the circumplex, a circular model in which disorders that appear across from each other are considered opposites, whereas disorders that are next to each

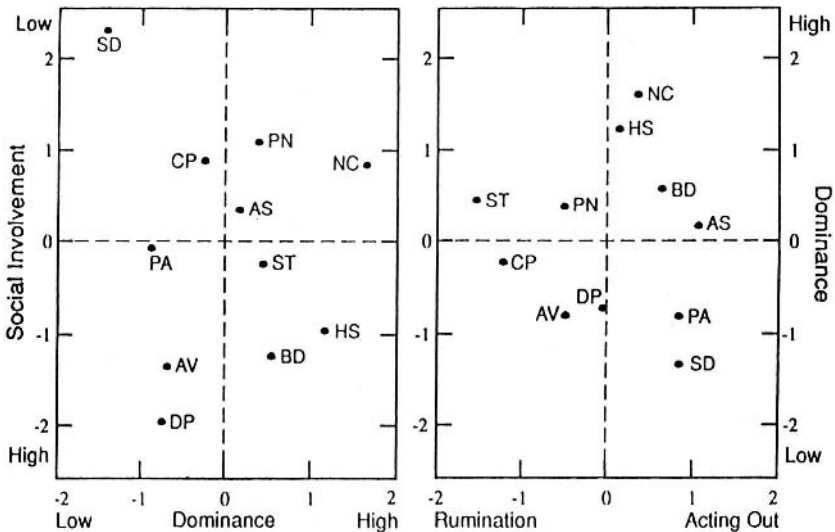

Figure 4. A three-dimensional model of classification of DSM-III personality disorders. Placement of DSM-III personality disorders along three dimensions. Numbers along axes are stimulus coordinates. SD = schizoid; CP = compulsive; PN = paranoid; NC = narcissitic; AS = antisocial; PA = passive-aggressive; AV = avoidant; DP = dependent; ST = schizotypal; HS = histrionic; and BD = borderline. other are considered similar. An example of a circumplex for personality disorders proposed by Wiggins (1982) is depicted in Figure 5.

Cantor, Smith, French, and Mezzich (1980) objected to the traditional view of classification, which places attributes in distinct categories on the basis of necessary and sufficient defining features. They further discussed how the classical view assumes a particular relationship between categories. For example, if two categories have a subset relationship, the defining features of the more abstract category are included or nested in those of the subset. To illustrate, the defining features of schizophrenia are also included in the subset of paranoid schizophrenia. Thus, in a categorization system, according to the classic view, the features of any higher level category should occur in every subset of that category. Cantor and her colleagues pointed out that there are a number of difficulties with this approach. They claimed that the classical view suffers from a failure to specify defining features for most categories, the existence of borderline cases, the heterogeneity of the members of a category with respect to their features, the variation among category members with respect to their typicality and ease of categorization, and less than perfect nesting of a general category's features among its subsets.

What Cantor et al. suggested as a solution to these problems is *prototype categorization*, where an ideal type is specified in terms of its features, but it is assumed that the features in most cases need only be similar, not necessarily identical. Attributes need only be correlated with category membership and need not be necessary and sufficient. In other words, if there are four features of a category such as histrionic personality disorder, an individual could have two, three, or four of the features and still be labeled histrionic. Thus, the features are not defining but correlational. This type of approach, as Cantor and her colleagues mentioned, eliminates the existence of borderline cases and causes heterogeneity of categories. It does not require perfect nesting of a general category's features in the subset, and, they claimed, prototypes make sense of variations in typicality. This point was expanded upon by Schwartz and Wiggins (1987), who stated that by depicting the perfect case, the "ideal types" permit us to pinpoint in specific terms the areas that require further inquiry. For any given disorder, deviations from the pure case—the ideal case—should spur the clinician to focus on these omissions (or additions) as indicative of the uniqueness of the individual within the framework of the general disorder. In short, framed in terms of ideal types, the clini-

cian's inquiry is given shape and direction in a heuristic manner, without regard to a truth value, in a practical effort to understand a person's problems.

This lack of truth or falsity, however, makes prototypes (or ideal types) problematic from a scientific point of view, because it may violate Popper's (1972) doctrine of the ability to falsify a hypothesis. Furthermore, the fact that the criticisms by Cantor et al. (1980) of the traditional view (existence of borderline cases, inability to specify defining features, the heterogeneity of the members of a category, and less than perfect nesting of a general category's features) are in themselves the criteria used to evaluate classification systems that further violate Popper's doctrine. Schwartz and Wiggins (1987) disputed this criticism, stating that the ideal type guides the clinician to particular beliefs about an individual that are themselves falsifiable with respect to that particular patient. In essence, however, advocates of this approach are abandoning the logical empiricism that has guided science for more than 100 years in favor of practical considerations. This approach aggravates the situation described by Birley (1975), who maintained that psychiatry is already littered with a mixture of irrefutable theories, including classification systems, that explain a great deal and refutable theories that explain very little.

More complex models of classification may solve the problem that some behavioral disorders differ in kind and others in degree from normal behavior. The multiaxial diagnostic system, for example, is a hybrid model that allows evaluating an individual in terms of several different domains. Each of the domains is assessed quasi-independently of the others, but together they represent a more comprehensive evaluation than when an evaluation is limited to one mental disorder (Williams, 1985). The use of various domains permits a class-quantitative structure in which quantitative dimensions are superimposed on qualitative categories (Mezzich, 1979). For example, Axes I and II of the DSM-IV allow differentiations on qualitative dimensions, whereas Axes IV and V (which indicate severity of psychosocial stressors and global assessment of functioning) are quantitative.

Another interesting approach is the Radex that integrates dimensions and spheroids (Degerman, 1972). An example is the vector model of disease

described by Sneath (1975): Disease states are represented by a swarm of points around the origin (which represents health) in dimensional space. As people become ill, they move away from the origin; the length of the vector (or the distance from the origin) indicates a symptom's severity, and the direction of the vector indicates the type of disease.

In terms of the internal validation (see Fig. 1) of a classification scheme, some decision should be made about the appropriate statistical techniques, usually such multivariate statistical methods as factor or cluster analysis. If the disorder is assumed to be categorical, then Meehl's taxonomic methods should be used to establish this fact empirically. There are a number of other methods that can be used, but as Skinner (1981) indicated, there is no real way of evaluating which statistical procedure is more appropriate. Indeed, few would disagree that thus far factor analysis and discriminant functions have yielded few new insights. However, Zubin (1984) reminded us that statistical treatment lies in the realm of verification rather than discovery and that therefore statistics are still important to scientists. In any case, internal validation would also involve replicating the types in other samples of the population and evaluating the reliability, the homogeneity, and the coverage of the system. External validation in this framework would involve studies of the generalizability of types to the overall population, the predictive validity of the categories, the descriptive or content validity of the disorders, and the clinical usefulness of the system.

Current Classification Systems

There has been a variety of attempts to devise a classification system for abnormal behavior, from several different theoretical viewpoints. This section is a brief overview of a behavioral approach, a psychometric approach, and the psychiatric approach, as evidenced by the developmental history of the DSM-IV.

A Social Learning Taxonomy

Albert Bandura (1968) delineated a social learning model for classifying psychological dysfunctions as an alternative to the medical or disease model. In essence, a social learning taxonomy of

psychopathology observes the interaction between behavioral predispositions (subject variables) and stimulus events. An analysis of this type, according to Bandura, can help to explain the acquisition and maintenance of deviant response patterns and to guide therapeutic processes. His taxonomic scheme treats mediating events as intervening variables, which are related to manipulable stimulus variables and their response sequences by well-defined laws. Abnormal behavior is seen as the learning of maladaptive behavioral response patterns that can be directly modified by the stimulus variables that affect both the mediating and terminal behavior. In this type of theoretical orientation, no underlying pathology needs to be modified or removed; the behavior itself is changed.

In this view, the conditions that maintain deviant behavior are a function of the environmental contingencies of which the individual is a part. A social learning taxonomy then, necessarily “highlights the reciprocal relationship between stimulus events and behavioral variables” (Bandura, 1968, p. 298). The taxonomic scheme that Bandura proposed for abnormal behavior is based on six distinct patterns of deviant behavior: (1) behavioral deficits, (2) defective stimulus control of behavior, (3) inappropriate stimulus control of behavior, (4) defective or inappropriate incentive systems, (5) aversive behavioral repertoires, and (6) aversive self-reinforcing systems. Each of these will be discussed briefly.

Behavioral Deficits. Some persons are considered maladjusted because of a lack of the requisite skills for coping effectively with the social, academic, and vocational demands of their environment. These individuals receive insufficient rewards and may receive punishment because of their deficits. Inadequate modeling and insufficient or poorly managed reinforcements are likely to produce behavioral deficits. Individuals who have poor social skills (personality disorders) may be viewed as examples of this disorder.

Defective Stimulus Control of Behavior. Individuals may possess adequate repertoires of responses that enable them to receive positive reinforcement from the environment, but they may behave inappropriately and go unreinforced because of an inability to discriminate among important stimuli. Defective stimulus control is due to faulty social training or to a breakdown of previously established discriminative behavior.

Schizophrenic behavior, such as failure to respond to social cues, may be an example of this disorder. **Inappropriate Stimulus Control of Behavior.** Maladaptive responses may arise from formerly innocuous and inappropriate stimuli that have acquired the capacity to elicit highly intense emotional reactions. This category involves autonomic reactivity and the physiological response. Disorders are reflected in a wide variety of somatic complaints, including muscular tension, anxiety, phobia, insomnia, fatigue, gastrointestinal disorders, and cardiovascular disturbances. Control of the previously innocuous stimuli is brought about through aversive and vicarious classical conditioning.

Defective or Inappropriate Incentive Systems. Maladaptive behavior may be due in large part to the fact that certain potentially harmful or culturally prohibited stimuli have very strong positive reinforcing functions for the individual. Sexual deviations, such as fetishism and transvestism, are examples of these maladaptive patterns. Various types of drug abuse and their reinforcing pharmacological aspects are other examples. These response patterns are learned through reinforcement and modeling.

Aversive Behavioral Repertoires. In this category, an individual engages in behavior that generates aversive consequences to others. Individuals in this category include children who are very aggressive, annoying, or attention seeking; children who show clinging dependence; and adolescents or adults who engage in antisocial activities or other forms of socially disruptive behavior. Aversive behavioral patterns are learned patterns of response to stress, frustration, and other forms of emotional arousal, originating from the observation of adult and peer models who provide the developing child with ample opportunities to observe their frustration reactions in different stimulus situations (Bandura, 1968, p. 322). Bandura’s modeling experiment with a “Bobo” doll and children imitating aggression are examples of this type of behavioral repertoire (Bandura & Ross, 1963).

Aversive Self-Reinforcing Systems. In contrast to the external reinforcing stimuli highlighted previously, this group implies self-administered reinforcers. Self-reinforcement may be contingent upon performance that is indicative of personal merit or achievement. Self-administered positive and negative stimuli are powerful incentives for

learning and are effective reinforcers in maintaining behavior in humans. A good example of this type of disorder is depression.

Although Bandura's taxonomic schemata demonstrated the strong influence of social learning upon behavior, a major problem with this approach is that a person's psychopathology may be classified on the basis of behavior (behavioral deficits), etiology (defective stimulus control), or inferred states (aversive self-reinforcing systems). To further aggravate this problem, a given "individual's learning history may have produced deficient behavioral responses, avoidant response patterns under inappropriate stimulus control, and a powerful aversive self-reinforcement system" (Bandura, 1968, p. 334). Thus, this system violates the principle of a single classification variable and hopelessly confuses the issue of an empirical determination of the cause or causes of a given behavior pattern. Is compulsive hand washing a response pattern caused by social learning? Research has not been able to establish definitely the etiological components of this behavior; therefore, should they be established by definition?

A very serious problem is that social learning theory is theoretical. Consequently, such a system biases any attempt to test social learning theory against competing explanations. A circular argument always occurs when a specific theory of behavior is evaluated by measurement procedures developed from that theory. Systems of classification and their concomitant measurement procedures must be independent of specific theories of behavior to allow an objective evaluation of competing theories.

Interpersonal Diagnosis

McLemore and Benjamin (1979) proposed an interpersonal behavior taxonomy, based on their contention that useful aspects of psychiatric diagnostic schemata are psychosocial and that most diagnoses of "functional mental disorders" are made on the basis of observed interpersonal behavior. Interpersonal is described as what "one person does, overtly or covertly, in relation to another person who, in some sense, is the object of this behavior" (Leary, 1957, p. 4). McLemore and Benjamin claim that interpersonal taxonomy would be more useful in understanding and treating psychological difficulties and that it may also help to identify constructive factors in human development, thereby enhancing efforts to prevent the appearance of behavior disorders.

The concept of interpersonal diagnosis was developed by Timothy Leary in 1957. This interpersonal system concerned itself with "the impact one person has or makes with others" and allows for the "interaction of psychological pressures among the different levels of personality." Benjamin (1974) expanded this idea to develop a clinical classification model of social behavior known as the *structural analysis of social behavior* (SASB). In this circumplex type of analysis, three diamonds are used to express interpersonal, self, and intrapsychic (or introjected other to self) quadrants (Fig. 6). Horizontal axes on all three diamonds concern love-hate affiliations, and a vertical axis outlines interdependence with maximum independence at the top. An advantage of this model is that it has been tested with certain types of circumplex analysis, factor analysis, and autocorrelational methods, and fairly high reliabilities have been demonstrated. An interpersonal nosology is emphasized by McLemore and Benjamin to ameliorate the complicated business of how one person (the therapist) is best advised to behave toward another person (the client) to improve the latter's life (via successful psychotherapy). It allows assessing interpersonal functioning, with an additional provision that interpersonal experiences may be internalized. A more complete discussion and appropriate references can be found in Benjamin (1996).

The major assumption of this approach is that personality traits are substrates that cause all normal or abnormal behavior. Thus, personality (interpersonal interaction) is human psychology, and aberrant behavior reflects an aberrant personality. McLemore and Benjamin agree with Szasz (1966) that only social and interpersonal behavior is diagnosed and classified. The social category is seen as a window through which to view the other domains of human functioning. Other processes that affect or derive from social behavior are critical, and McLemore and Benjamin (1979) believe that the "object of one's social behavior may be oneself." They further state that social behavior "regardless of its causes or correlates" is more accessible to the psychologists' (or psychotherapist's) interventions (pp. 25-26).

There are serious questions about the validity of these assumptions. It is not at all clear that conditions such as tics, stuttering, phobias, compulsive rituals, obesity, and sleep disorders can be viewed as disorders of interpersonal relations or maladaptive styles of interacting. Even though a number of conditions, such as the personality disorders, may

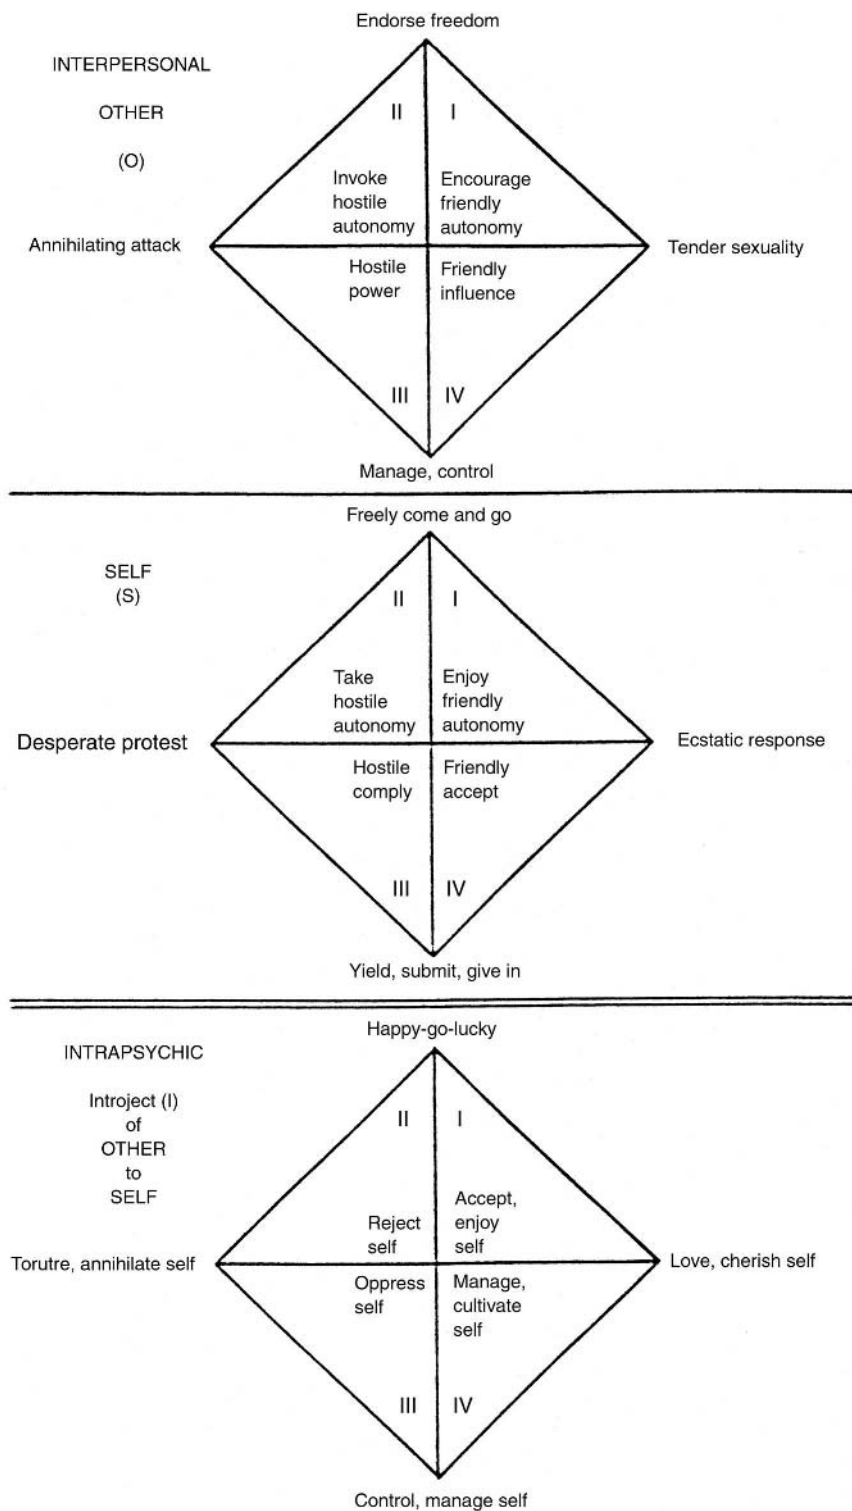

Figure 6. Benjamin's structural analysis of social behavior. (From Structural analysis of differentiation failure by L. S. Benjamin, 1979, *Psychiatry*, 42, 4. Copyright 1979 by the William Alanson White Psychiatric Foundation. Reprinted by permission.)

reflect aberrant interpersonal interactions, the assumption that all psychopathology is similarly based is certainly open to debate. This assumption is the primary difficulty with this system, although other criticisms have been voiced as well, such as those regarding the use of terms like introjection.

Psychiatric Approaches

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-III, DSM-III-R, and IV)*.

The first two editions of the American Psychiatric Association's (1952, 1968) classification scheme were uniformly unsatisfactory and subject to valid theoretical and practical criticism. Begelman (1976) summarized a number of published articles and derived a fairly comprehensive list of criticisms.

In response to these criticisms and concurrent with resurgent emphasis on the medical foundations of psychiatry, a third edition of the Diagnostic and Statistical Manual was published in 1980. DSM-III had a more complex system than previous editions, encompassing twice as many separate diagnostic descriptions as DSM-II. It was developed to reflect the current state of knowledge regarding mental disorders by (1) allowing clear and brief professional communication to facilitate inquiry, (2) providing a guide to current differentiated treatments, (3) providing information concerning likely outcomes with and without treatment, (4) reflecting the current level of knowledge of etiology and pathophysiology, and (5) meeting the needs of practitioners and administrators in a wide variety of settings (Schacht & Nathan, 1977).

DSM-III corrected many problems inherent in DSM-II. First, DSM-III was not heavily influenced by any given theoretical position except the assumption that aberrant behavior is an illness. Second, it adopted a more operational language and required that specific criteria be met before an individual was diagnosed. This latter aspect led to more homogeneous categories and helped reduce disjunctive categories.

The attempt to develop an empirical classification was continued with the development of the DSM IV. In essence, thirteen workgroups, each chaired by a member of the task force whose members were appointed by the Board of Trustees of the American Psychiatric Association, reviewed the data on various subgroups of disorders to modify the criteria of DSM III and III-R, if

necessary, or to develop new criteria for each type of disorder. These empirical reviews were intended to resolve issues of criteria and clinical controversies by a comprehensive overview of the relevant research by a scholar who was, hopefully, neutral on these issues. We think it is fair to say that this produced some good and useful review but did not resolve many of the controversies because there are many "gaps" in the literature and because of the more fundamental problem of the assumptions made by this classification model, as vociferously and frequently discussed by Robert Carson (Carson, 1996). Nevertheless, the culmination of these literature reviews and data re-analyses was the DSM-IV sourcebooks. These books presented the major diagnostic issues, as well as options for dealing with them, and encouraged critical and constructive comments. The next stage was to perform focused field trials to determine the reliability/validity of the revised criteria and to address some of the issues raised by the literature reviews. A DSM-IV draft criteria was then published to invite reviews and comments which led to the publication of the DSM-IV. It has to be admitted that a great deal of work and thought went into the final version. Although certainly not perfect nor acceptable to some, this classification system is much better than our earlier efforts.

The major innovation introduced in DSM-III, III-R, and IV's psychiatric diagnostic classification is the use of five dimensions or axes, which are designed for planning treatment and predicting outcome, as well as in categorizing and classifying (Schacht & Nathan, 1977). Some minor modifications in the multiaxial system were implemented in the 1987 revision (DSM-III-R) and in DSM-IV. These axes will be described as covered in the DSM-IV.

Axis I: Clinical Disorders and Other Conditions That May Be a Focus of Clinical Attention. This axis is used to designate behavioral patterns associated with such abnormal states as schizophrenia, bipolar affective disorder, or dysthymic disorder. It covers all of the psychological disorders except the personality disorders and mental retardation. An individual may have more than one of these disorders and all should be reported. The principal reason for the visit should be labeled as the "Principal Diagnosis."

Axis II: Personality Disorders and Mental Retardation. This axis was used in the DSM-III to designate specific developmental disorders,

such as learning disabilities in children and adolescents, as well as personality disorders in adults. In DSM-III-R, mental retardation was removed from Axis I to Axis II at the suggestion of Kendell (1983) and others who felt that the changes to Axis II would better distinguish “lifelong and stable handicaps” and restrict them to a single axis. In the DSM-IV, developmental disorders have been placed on Axis I, and Axis II is reserved for personality disorders and mental retardation. This change was an improvement.

A major difficulty with Axis II is low reliability and much overlap or comorbidity among the categories. Recently, two very innovative studies of the classification of personality disorders were conducted by Westen and Shedler (1999a,b). They noted that the assessment of personality disorders has relied almost exclusively on self-report inventories and assessed DSM-IV categories and criteria, which limits their utility in making meaningful revisions of these criteria. They devised an assessment tool, the Shedler–Westen Assessment Procedure or the SWAP-200, where the clinicians rated their patients on 200 items. These items included descriptions such as “has an exaggerated sense of self-importance,” “seeks to be the center of attention,” “tends to feel helpless, powerless, or at the mercy of forces outside his/her control,” and a number of similar items from a variety of clinical sources. A Q-sort technique was used in which the statements (i.e., items) were printed on separate index cards. The clinician then sorted the cards into eight categories where the first category (assigned a value of “0”) contained statements judged irrelevant or inapplicable to the patient and the last category (assigned a value of “7”) contained statements that were highly relevant or applicable to the individual. The Q-sort technique required that the clinician assign a specific number of statements to each category. For example, with the Swap-200, the clinicians must place eight items into category 7 (i.e., the most relevant items), ten items into category 6 (i.e., the next most relevant items), and so on until all items have been exhausted and assigned to specific categories. Clinicians then rated a hypothetical prototypical patient who exhibited a histrionic personality disorder, which allowed the development of a *diagnostic prototype* (see Cantor et al., 1980). Then they rated actual patients with specific personality disorders. A composite description of the patients could then be developed. The correlation between the composite description and the diag-

nostic prototype yielded a personality disorder score (ten disorders currently in Axis II, four disorders in the appendix or previous versions of the DSM, and a prototype of a healthy, functioning person). The personality score obtained indicated how closely the patient “matched” the diagnostic protocol for each personality disorder. Their results show high divergence and discrimination in a variety of criteria.

Using this methodology, Westen and Shedler (1999b) developed an empirical classification system of personality disorder taxonomy. Their analysis found eleven naturally occurring diagnostic categories, some of which resemble current DSM-IV personality categories, whereas others do not. In some cases, the DSM-IV categories place dissimilar cases in the same categories and in other cases made diagnostic distinctions when none actually existed. The empirically derived system is more faithful to the clinical data and eliminated much of the comorbidity in their categories. Thus, the system proposed by Westen and Shedler eliminates much of the difficulty resulting from comorbidity that plagues the current classification system for personality disorders proposed by the DSM-IV. These are the categories that resulted from the classification system proposed by Westen and Shedler:

1. Dysphoric personality disorder
 - Subtypes
 - A. Avoidant
 - B. Dysphoric (essentially a high functioning neurotic)
 - C. Emotionally dysregulated (similar to the borderline personality disorder)
 - D. Dependent masochistic
 - E. Dysphoric: Hostile-external (similar to passive-aggressive personality disorder)
2. Antisocial personality disorder
3. Schizoid personality disorder
4. Paranoid personality disorder
5. Obsessional personality disorder
6. Histrionic personality disorder
7. Narcissistic personality disorder

These important studies conducted by Westen and Shedler have great relevance for developing a more adequate classification system and should be extended to Axis I disorders to determine if the methodology generalizes to this set of disorders. It is an important wedding of basic research and clinical activity.

Axis III: General Medical Conditions. This axis provides a way for clinicians to indicate any current physical conditions that they consider relevant to understanding or treating patients. Although Kendell (1983) urged that this axis be revised to include "all etiological factors, both proven and suspected, to purge the first two axes of all etiological implications" (p. 87), it was not revised for DSM-III-R or IV. Inclusion of this axis in no way implies that clinicians are expected to evaluate their patients physically, for most mental health practitioners (including psychiatrists) do not conduct physical examinations or make physical diagnoses. Nonetheless, a verbal screening for notable physical problems should be included as part of any clinician's comprehensive evaluation (Williams, 1985).

Axis IV: Psychosocial and Environmental Problems. This axis is for reporting psychosocial and environmental problems that may affect the diagnosis, treatment, and prognosis of the disorder. This axis changed considerably from the DSM-III and III-R and allows the examiner to note the presence of psychosocial stressors (e.g., poverty) that have contributed to the development or exacerbation of the disorder.

Axis V: Global Assessment of Functioning. This axis had the largest revision in DSM-III-R. In DSM-III, it was labeled "highest level of adaptive functioning in the past year" and used a seven-point scale to assess adaptive functioning in terms of social relationships, occupational performance, and use of leisure time. The primary use of this scale was considered its potential prognostic validity, and DSM-III-R expanded the clinician's ability to judge this area by specifying that the individual be assessed for current functioning as well as level of functioning during the past year. Comparing the two ratings is said to reflect both the current need for treatment and the degree of deviation from the individual's premorbid functioning. In the DSM-IV, the patient is rated on a scale that gives the clinician's judgment of the overall level of function from 0–100. However the GAF may reflect current functioning, functioning at discharge, or functioning in the past (i.e., GAF = 75 (past year) and GAF = 85 (current)). Thus, a DSM-IV diagnosis might look like this: Axis I = 305.00, alcohol abuse; Axis II = 301.6 Dependent Personality Disorder; Axis IV = Unemployed; Axis V = 65 (current).

The choice of these five axes was made after careful consideration. Williams (1985) noted that

the committee sought to make the system comprehensive yet practical enough for routine clinical use. This limited the number of axes that could be included, although various authors have proposed separate axes for such areas as intelligence (Rutter, Shaffer, & Shepherd, 1975), substance abuse (Treece, 1982), family factors (Fleck, 1983), and response to treatment (Schacht & Nathan, 1977).

It is apparent that, despite its flaws, the DSM-IV and its successors represent a decided improvement over previous efforts. This system came about in response to the resurgence of the neo-Kraepelian movement in psychiatry—and hence continues to overemphasize the medical model—but at least criteria now exist that can be operationally evaluated. It is hoped that the heuristic value of the DSM series will lead to continued advancement in classifying abnormal behavior.

Summary

Tremendous progress in classifying abnormal behavior has been made in the past 25 years. With the advent of DSM-III and its multiaxial system, along with the purging of psychodynamic theory from classification in favor of operational definitions, we now have a much improved classification scheme. Nonetheless, there is still room for improvement within that system, including a more open-minded evaluation of the feasibility of the medical model, as opposed to a classification system based on classification theory and models, and more empirically based decision making. The latter is expected to occur as the literature base expands, and perhaps future systems will be revolutionary not so much for their changes but for their demonstrations of the validity of earlier schemata.

In addition to new classification systems, the atmosphere regarding classification and the ensuing dialogues concerning methods, principles, and models of classification are very positive indications that we will have a better understanding of classification schemes in the future. We are also likely to continue proceeding toward more accurate classification based on truly scientific principles of behavior.

CHAPTER 2

Methodological Issues in Clinical Diagnosis

Sol L. Garfield

Introduction

Clinical appraisal and diagnosis in health-related disciplines are clearly of great importance. No one seriously advocates providing treatment before some kind of diagnostic appraisal has been made to guide the treatment. Furthermore, particularly in the medical specialty of psychiatry, as new knowledge has been secured and new theories developed, diagnoses and diagnostic approaches have been modified, new diagnoses added, and old ones discarded. In some instances the descriptive symptomatic patterns of the disorder is little changed, but its official clinical diagnosis or categorization is changed as a result of newer conceptualizations and points of view. Such developments have occurred with particular frequency in the period from 1980 to 1994 with official publication of three new *Diagnostic and Statistical Manuals of Mental Disorders* by the American Psychiatric Association (1980, 1987, 1994).

Therefore, clinical diagnoses are not invariant, and problems in this area have been topics of discussion and controversy over the years. Disagreements have stemmed from differences in disciplinary orientation, theoretical considerations,

and interpretations of research data concerning the reliability and validity of clinical diagnosis. The issues generated are complex and have important research and practical implications for the entire field of psychopathology. Consequently, methodological problems in this area are not mere academic concerns but directly affect all professional disciplines in the area of psychopathology and, thus, the actual treatment and disposition of those individuals whose difficulties are considered psychopathological. Furthermore, although official systems of diagnosis or nosology may show significant changes over time, the basic methodological issues involved remain very much the same and require careful consideration in evaluating any formalized classification system.

Clinical Diagnosis: Some Possible Meanings

Before discussing some of the methodological problems and issues in clinical diagnosis, it is important to discuss briefly the possible meanings or interpretations attached to this term. Traditionally, clinical diagnosis has referred to discovering, describing, and designating a specific illness or disease. Deriving from the field of medicine, it has been closely identified with medical conceptions of disease entities. The Funk & Wagnalls *New College Standard Dictionary* (1950) gives the following as the first definition for the word diagnosis: "The art or act of discriminating between

Sol L. Garfield • Department of Psychology, Washington University, St. Louis, Missouri 63130.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

diseases and distinguishing them by their characteristics." Webster's Unabridged Dictionary (1979) defines diagnosis as "the act or process of deciding the nature of a diseased condition by examination."

Thus, diagnosis has been based on the disease entity concept used in medicine. Within this orientation, clinical diagnosis is of great importance, for appropriate treatment depends on the correct diagnosis. Medicine, based on scientific advances in such basic areas as biochemistry, genetics, microbiology, and comparable advances in instrumentation and equipment, has used the disease entity model with success. Many illnesses have been identified in terms of symptomatology, course of illness, prognosis, and possible causes. Treatments for a number of these illnesses subsequently have been discovered or developed. Consequently, the correct clinical diagnosis may lead to the selection and administration of an appropriate and effective treatment.

Psychiatry, the branch of medicine concerned with psychopathology, has modeled itself after the practices of the parent field. Various neurologists and psychiatrists during the latter part of the nineteenth century and thereafter identified specific mental illnesses which they discovered or described, for example, general paresis, Korsakoff's syndrome, and Alzheimer's disease. This process has been relatively more successful in organic or neurological disorders where both the symptomatology and the course of the disorder can be more successfully described and the etiology more clearly ascertained. This, however, has not kept psychiatrists from describing and designating forms of mental illness which do not always fit the disease entity model successfully. Since the time that catatonia and hebephrenia were identified as separate types of mental illness more than 100 years ago, numerous designations and classifications have been devised by psychiatrists, individually or in organized groups (Zilboorg & Henry, 1941). Some categories, particularly those with a known etiology or course, have withstood the test of time. Others, however, have appeared on the diagnostic stage for an interval of time, and have then disappeared or were replaced. Dementia praecox, conceived by Kraepelin to incorporate the separate diagnoses of catatonia, hebephrenia, and paranoia, has given way to schizophrenia. The latter, in turn, has undergone several modifications and transformations, and questions are still raised

about its diagnostic classification (Carson, 1996; Carson & Sanislow, 1993). In the latest revision of the official diagnostic manual of the American Psychiatric Association (1994), DSM-IV, thirteen new diagnoses were added, and eight were deleted.

In addition to changes in nosologies and designations of disease over time, different classifications or diagnostic schemes were promulgated during the same period. Thus, diagnostic schemes and specific diagnostic terms in psychiatry reflect the views of individuals and also of committees or groups of individuals who participated in the diagnostic classification process. For such reasons, both individual and group values and interests may influence the diagnostic system formally adopted at a given time. This point is mentioned to emphasize that the creation and adoption of a diagnostic system is not a result of scientific research *per se*. In more recent times, even economic considerations deriving from third-party payments have played a possible role in retaining or adding selected diagnoses.

In any event, diagnoses or diagnostic labels have been used in psychiatry, in conformance with medical views concerning illness and disease, to designate various types of psychopathology or deviant behavior. Because the care and treatment of disturbed individuals was gradually entrusted to the medical profession, such individuals also tended to be viewed as mentally ill, and their deviant behaviors, thoughts, and moods were considered symptoms of mental illness. This has had a number of important theoretical, practical, and research implications. Although our primary concern in this chapter is with methodological issues and problems, it is worth commenting here on some of the broader implications of using clinical diagnosis in the mental health field.

Clearly, accurate diagnosis of illness or disease is an important prerequisite for selecting the most efficacious treatment. In severe illness, incorrect diagnosis may have serious consequences, including death. As medical science has advanced and as greater knowledge of disease has been accumulated, more effective diagnostic and treatment procedures have also been developed. The net result has been improved medical service. Thus, the concept of disease has worked well in medicine. However, when applied to psychiatry and psychopathology, the results have not been quite as successful.

One obvious problem with psychiatric diagnostic systems is the difficulty in deciding what is mental illness and what is not. For example, in the DSM II diagnostic system of the American Psychiatric Association (American Psychiatric Association, 1968), homosexuality was at first included as a mental disorder and then later was excluded. In DSM III, many new diagnostic categories were added, including such new disorders as pathological gambling and developmental reading disorders. In fact, the number of officially diagnosable disorders has increased markedly over the years. For example, DSM-I, published in 1952, listed slightly more than 100 disorders (American Psychiatric Association). DSM-II, published in 1968, contained more than 180 distinct psychiatric disorders, DSM-III in 1980 included more than 260 disorders (Kazdin, 1986), and both DSM-III-R (1987) and DSM IV (1994) have more; DSM-IV leads with 357 disorders. This large increase in the number of specific mental disorders reflects changes in characterizing, delineating, and approaching the formal listing of types of psychopathology and is not an epidemic of new and strange disorders.

At present, it is difficult to know if the increase in the currently available psychiatric diagnoses facilitates the process of diagnosis and subsequent treatment or if the diagnostic task has become more complicated and overly cumbersome. The slim diagnostic manuals of DSM I and DSM II have been replaced by the heavier tomes of DSM III, DSM III-R, and DSM IV. DSM-I consisted of 130 small pages, and DSM-II had 134 similar pages. However, the three most recent diagnostic manuals have increased noticeably; DSM-IV is far and away the largest with 886 pages. In a rather humorous publication, Blashfield and Fuller (1996) used regression estimates based on data from past editions of the DSM to make predictions about DSM V. On the basis of their analysis, DSM V will have 390 disorders and the estimated number of pages is 1026. It is still not clear if bigger is better. Guze (1995) in reviewing DSM-IV was both "impressed by and worried about the phenomenal growth in the number of diagnoses now recommended ... (because) few of the hundreds of diagnoses have been satisfactorily validated" (p. 1228).

In any event, it is apparent that there are difficulties in deciding what are diagnosable mental disorders and that such decisions have important social consequences. There is still some stigma

associated with being mentally ill, but sometimes there also are more positive effects—for example, individuals may be provided treatment and avoid punishment. In a previous publication, for example, I raised some question about the appropriateness of listing "pathological gambling" as a mental disorder in DSM-III and mentioned that it had been used by a defense counsel on behalf of a defendant in a federal court trial (Garfield, 1986). However, in this case, the jury did not consider this defense acceptable and found the defendant guilty of kidnapping and auto theft. This may have been noted by those involved in preparing DSM-III-R because the following cautionary statement is contained in the introduction to DSM-III-R:

It is to be understood that inclusion here, for clinical and research purposes, of a diagnostic category such as Pathological Gambling or Pedophilia does not imply that the condition meets legal or other nonmedical criteria for what constitutes mental disease, mental disorder, or mental disability. (American Psychiatric Association, 1987, p. XXIX).

This statement is also included in the introduction to DSM-IV (p. XXVII).

Apart from such issues, there is the fact that the diagnostic categories or disorders included in conventional diagnostic systems are not really comparable. On the one hand, as already mentioned, there are neurological or organic brain disorders that more clearly resemble what is usually termed illness in other fields of medicine. However, at the same time, there are a variety of other designated disorders that are quite different. Schizophrenia, for example, has been considered a major form of mental illness for many years. However, whether it is one disease or many or whether it is caused primarily by genetic, biological, or psychosocial factors, or by all three, is still not known. One critical review even states that schizophrenia is not a valid object of scientific inquiry and casts doubt on the reliability, construct validity, predictive validity, and "aetiological specificity of the schizophrenia diagnosis" (Bentall, Jackson, & Pilgrim, 1988, p. 303). The less severe forms of psychological disturbance are even more difficult to equate with medical conceptions of illness. For example, phobias, compulsions, anxieties, and similar problems are less like illnesses and more like variations from normative behaviors. In such behaviors or disorders, the distinction between discrete disorders or illnesses and behavioral patterns that can be viewed as more extreme variations on a continuum of normal behaviors be-

comes rather blurred. The DSMs, however, are based on a categorical system rather than on a continuous or dimensional one.

Therefore, there are different bases for the definition and classification of the different diagnostic categories. Some are based on known etiologies, some are organically caused, and some can be diagnosed systematically and reliably. Others are somewhat diffuse diagnoses in which the cause, course, and symptom pattern of the illness is cloaked in ambiguity. This is another way of saying that some may resemble traditional types of disease entities, but that others do not. Although clinical diagnosis has traditionally referred to medical conceptions of disease, the apparent difficulties in applying such conceptions to many of the problems of psychopathology encountered in clinical work has led to dissatisfaction with such diagnostic systems, particularly by psychologists (Adams, 1952; Carson, 1997; Eysenck, 1986; Follette & Houts, 1996; Garfield, 1974, 1986). Some of these difficulties will be discussed later. Other attempts to appraise psychological disorders, however, can be mentioned briefly at this point.

Individuals with psychodynamic or interpersonal orientations have been more concerned with ideographic means of personality appraisal or diagnosis. Traditional psychiatric categories of diagnosis were viewed as too broad and of relatively little help in understanding the individual's problems and in planning a program of treatment. The focus was on appraising the personality dynamics of the individual client with an emphasis on unconscious conflicts and defenses rather than on the diagnostic label that might be attached to the client. However, relatively less emphasis recently on psychoanalytic theory and increased emphasis on biological factors in psychiatry may also have played a role in the recent changes.

Various other schemes have been developed, but they have not received wide clinical usage (Adams & Cassidy, 1993). For example, attempts to apply factor analysis to the results of psychological tests and rating scales have been made to identify more refined and reliable categories of psychopathology. The Inpatient Multidimensional Psychiatric Scale (Lorr, Klett, McNair, & Lasky, 1966) is one illustration of such an approach. Twelve specific syndromes were identified by factor analysis that reflected specific patterns of disturbance such as Excitement, Paranoid Projection, Perceptual Distortion, and Motor Disturbance. Al-

though this scale was used in the past in research on chemotherapy, it has not been used much for regular clinical diagnosis. Nevertheless, such measures allow for dimensional studies of psychopathology that could provide more information than a categorical system like that used in psychiatric diagnosis.

Similarly, related statistical approaches such as cluster analysis have also been used to classify or designate types of psychopathology. However, much of this research has been criticized as mainly descriptive in approach. "Too often, a clustering algorithm has been applied to a convenient data set as an end in itself. Few attempts have been made to determine whether the derived types have prognostic value with respect to treatment outcome or to integrate the types with previous research" (Skinner, 1986). Lorr (1986) also reports in a review that cluster analytic studies do not consistently offer support for the existing psychiatric diagnostic categories.

Reference can also be made to the activities of clinical psychologists in diagnosis. Because of the primacy of psychiatry in diagnosing and treating psychopathology and disordered behavior, clinical psychologists who worked in medical installations, tended to follow the conventional diagnostic nosology. Most clinical staff conferences tended to center around discussions of the "correct" diagnosis. In some settings, the clinical director made the official diagnosis (diagnosis by authority). In other settings, the final diagnosis was reached by majority vote (diagnosis by democratic methods). I have no research data to report on which procedure was more efficacious.

However, with the expansion of the field in the post-World War II era and with the creation of nonmedically dominated clinical centers, dissatisfaction with psychiatric diagnosis on the part of a number of psychologists was apparent. Many psychologists preferred to use the term, assessment, rather than diagnosis, and to focus on the problems, strengths, and deficiencies of the client or patient, rather than on bestowing a diagnostic label. This is a broader concept than the more traditional psychiatric diagnostic concept and is not tied to a disease model. Thus, the terms diagnostic appraisal or assessment tended to be favored over the term, diagnosis. In a survey reported a few years after the publication of DSM-III, only a small number of psychologists reported a preference for using DSM-III over other methods of

diagnosis (Smith & Kraft, 1983). However, in recent years, with third party payments usually tied to formal psychiatric diagnoses, there has been much less criticism from practicing clinical psychologists. There has also been a noticeable increase in the forms of psychotherapy developed for specific psychiatric diagnostic groups, and psychologists have played a leading role in this development (Chambles & Hollon, 1998; Garfield, 1998).

Thus, as noted, the term, diagnosis, may be used in somewhat different ways and with somewhat different meanings even though it has been traditionally associated with medicine and conceptions of disease. In the past, psychologists have favored a broader conception of assessment in which both the strengths and weaknesses of the individual evaluated were emphasized and less emphasis was placed on psychiatric diagnosis. However, relative improvements in recent diagnostic manuals and the importance of diagnosis for third-party payers has changed the situation for at least a number of clinical psychologists.

Reliability and Validity of Clinical Diagnosis

As indicated, clinical diagnosis usually results in a specific categorization or label. After the patient has been appraised, the clinician offers a diagnosis (e.g., schizophrenia, paranoid type). If the diagnosis reflects a specific disease process that is known and understood, there is a reasonable probability that most diagnosticians might agree on the correct diagnosis. However, if the diagnostic category lacks preciseness and covers a moderate variety of behaviors, the reliability of the diagnosis may be impaired. This is of some importance for both practice and research. For example, if a specific treatment is indicated for a given disorder, a misdiagnosis may lead to improper treatment. In research investigations, unreliable diagnoses for the subjects studied may lead to unreliable or invalid results. Thus, the reliability of the diagnosis is of some consequence; most of the research in the past has not secured high agreement among psychiatrists who provided diagnoses on the same group of subjects (Ash, 1949; Beck, Ward, Mendelson, Mock, & Erbaugh, 1962; Blashfield, 1973; Hunt, Wittson, & Hunt, 1953; Kreitman, 1961; Kuriansky, Deming, & Gurland, 1974; Malamud,

1946; Spitzer & Fleiss, 1974). Although several of these studies have flaws, they do illustrate the problem of the lack of reliability in psychiatric diagnosis. The percentage of agreement between two psychiatrists for specific subtype diagnosis, excluding organic brain syndromes, varied from 6 to 57% in one study (Schmidt & Fonda, 1956). In a study of three psychiatrists who worked in the same hospital with comparable groups of patients, one of the psychiatrists diagnosed two-thirds of his patients as schizophrenic, compared with 22 and 29% by the other two psychiatrists (Pasanick, Dinitz, & Lefton, 1959). Anyone who has worked for a time in a psychiatric hospital has had the opportunity to observe the diagnostic preferences and biases of other staff members.

Other examples of the possible unreliability of psychiatric diagnosis can be found in differences in proportions or distribution of diagnoses over time and in different countries or geographic locations. Kramer (1965), for example, collected data that showed large variations over time in first admission rates to state mental hospitals in the United States for different diagnoses. The rates of schizophrenic admissions were 17.2, 22.0, and 25.3 per 100,000 for the years 1940, 1950, and 1960, respectively. The 1960 rate of admission for patients diagnosed as schizophrenic exceeded the 1940 rate by 47%. The rates of affective psychosis, on the other hand, showed a steady decline from 11.2 to 9.5 to 7.4 for the same periods, or a decline of 33.9%. Does this represent a real increase in rates of admission for schizophrenia and a real decrease in such rates for affective psychosis, or does this reflect inconsistency in applying diagnostic criteria? Similar questions can be raised concerning other diagnoses for which large differences in rates of admission are observed. "The large increases in the rates for the psychoneuroses, personality disorders, and alcoholic addictions raise questions as to whether they represent true increases in rates of admission for these diagnostic groups or differences in diagnostic fads and criteria or other factors that lead mental hospital psychiatrists to place nonpsychotic diagnoses on increasing numbers of patients" (Kramer, 1965, pp. 104–105).

It is reasonably clear from the kinds of data mentioned before, as well as from studies comparing psychiatric diagnoses obtained in different countries, that unreliability in diagnosis has constituted a problem of some importance. It is cer-

tainly a serious problem for research on psychopathology. If there is limited reliability for the diagnostic groups studied, the results secured for any investigation may lack stability, and replication and generalization of results will be difficult. Clinically, lack of reliability may lead to incorrect diagnosis and treatment. As a result of faulty diagnosis, individuals may be socially stigmatized or inappropriately institutionalized. Thus, reliability of diagnosis is not merely an academic issue, even though our concern here with methodological issues may pertain more directly to problems of research in psychopathology.

Although the reliability of clinical diagnosis is important, there is also the matter of the validity of the diagnoses secured. Reliability, although necessary, does not guarantee validity. As emphasized in a critical review, "Even if the reliability of schizophrenia could be assured, therefore, the validity of the concept would require further demonstration" (Bentall, Jackson, & Pilgrim, 1988, p. 306). The importance of the validity of clinical diagnoses in psychiatry, however, has not received very much research attention, perhaps because of the difficulties in securing adequate criteria for evaluative purposes. How does one decide if a diagnosis of anxiety disorder or schizophrenia is valid? In essence, in evaluating disorders without physical components or clearly known etiologies, one must rely on clinical judgments or psychological tests, which in turn have been based largely on clinical judgments. In the absence of some standard or accepted criteria against which to evaluate clinical diagnoses, the process of validation is difficult and thus somewhat neglected. Reliability, by contrast, is much easier to appraise and has received increased attention in the preparation of DSM-IV.

Nevertheless, the problem of validity remains. It may not be viewed as of great importance when there are no treatments of proven worth or preventive strategies for different diagnostic categories. However, where different and effective treatments or methods of prevention are available, the validity of differential diagnosis becomes important. It is, however, always significant for studies of particular types of disorders and may be particularly so for certain types of research.

One kind of research in which the validity of clinical diagnoses is of great importance is that conducted with subjects at high risk for schizophrenia. Although the problem of low reliability

of psychiatric diagnoses can be overcome with competent and specially trained diagnosticians who are provided with accurate and detailed information and with structured interview guidelines, the matter of validity is more complex and difficult. Nevertheless, "For high-risk researchers, the issue of the predictive validity of the diagnoses of schizophrenia is of central importance" (Hanson, Gotterman, & Meehl, 1977, p. 576).

The Recent DSMs-III, III-R, AND IV

As already noted, there has been considerable activity in recent years in forming new psychiatric diagnostic systems. Three revised diagnostic manuals have been published in just 14 years. Furthermore, these manuals were considerably larger than their predecessors, and the approach and methods for producing them differed in important ways. These new diagnostic manuals manifest a definite sensitivity to the criticisms made of the older systems. The authors have been particularly sensitive to issues of definition and reliability, and the new diagnostic systems have stimulated a considerable amount of research (McReynolds, 1989; Millon & Klerman, 1986; Sutker & Adams, 1993). Some of these studies are reviewed here briefly, mainly to illustrate methodological issues.

In many respects, DSM-III was a radical departure from its predecessors. Its authors attempted to avoid any theoretical partisanship or controversies, and they also attempted to emphasize operational criteria and descriptive psychopathology. "These criteria are based, for the most part, on manifest descriptive psychopathology, rather than inferences or criteria from presumed causation or etiology, whether this causation be psychodynamic, social, or biological. The exception to this is the category of organic disorders whose etiology is established as caused by central nervous system pathology" (Klerman, 1986, p. 5). However, this distinction for organic disorders was omitted in DSM-IV. "The term 'organic mental disorders' has been eliminated from DSM-IV because it implies that the other disorders in the manual do not have an 'organic' component" (American Psychiatric Association, 1994, p. 776). This change appears to reflect political-guild issues more than diagnostic ones (Follette & Houts, 1996), and I will say no more about it here.

Although some have criticized the deliberate

avoidance of a theoretical approach to diagnosis (Follette & Houts, 1996; Skinner, 1986), the authors of DSM-III, as well as DSM-III-R and IV, emphasized the need for accurate description and reliability of diagnosis and even carried out reliability studies, particularly for DSM-IV. Let us now turn to some studies of reliability and related issues.

In one study, twenty psychiatrists made independent diagnoses on twenty-four actual case histories of childhood psychiatric disorders (Cantwell, Russell, Mattison, & Will, 1979). The average agreement of these clinicians with the authors' consensus on the expected DSM-III diagnosis was just less than 50%. In another report on this study, the average agreement between the psychiatrists on their most common diagnosis (they were allowed more than one) was 57% for DSM-II and 54% for DSM-III (Mattison, Cantwell, Russell, & Will, 1979). Interrater agreement for DSM-III reached 80% for only four of the twenty-four cases; the best results were obtained for diagnoses of mental retardation. Noteworthy disagreement was noted in both systems for anxiety disorders, complex cases, and in the subtypes of depression.

The lack of agreement among the different diagnostic systems and the fact that they tend to select different samples of subjects for the same diagnostic category has also been noted by others (Endicott, Nee, Fleiss, Cohen, Williams, & Simon, 1982; Fenton, Mosher, & Matthews, 1981). In the study by Endicott et al. (1982) of diagnostic criteria for schizophrenia, six well-known systems were used to evaluate newly admitted patients including the Research Diagnostic Criteria (RDC) (Spitzer, Endicott, & Robins, 1975), the Feighner Criteria (Feighner, Robins, Guze, Woodruff, Winokur, & Munoz, 1972), and DSM-III. "The most salient finding of the study is that the systems vary greatly in the rates at which they make the diagnosis of schizophrenia" (Endicott et al., 1982, p. 888). The percentage of cases diagnosed as cases with schizophrenia ranged from 3.6 to 26%, a sevenfold difference, although most systems showed acceptable rater reliability. "The disparity illustrates the degree of difficulty associated with the diagnosis of schizophrenia and in the concept of schizophrenia ..." (Endicott et al., p. 888).

A somewhat similar study of forty-six cases of schizophrenia was reported by Klein (1982) who compared seven diagnostic systems including most of those evaluated by Endicott et al. (1982).

These patients had to have a hospital diagnosis of schizophrenia based on DSM-II, a score of four or more on the New Haven Schizophrenic Index (As-trachan et al., 1972), and be under age 56 with no evidence of organic brain damage, toxic psychosis, drug abuse, and the like. The DSM-III correlated .89 with the Feighner Criteria and .84 with the RDC, diagnostic systems which were models for it. However, its correlations with the remaining four scales were considerably lower. Use of the DSM-III led to diagnosis of 28% of the sample as cases of schizophrenia; the range was 24 to 63% for the other diagnostic systems. Furthermore, only nine of the forty-four patients were diagnosed by all seven systems as either cases of schizophrenia ($N = 3$) or as not such cases ($N = 6$).

Somewhat comparable findings were reported in a more recent study (Hill et al., 1996). "The aim of this study was to determine the extent to which diagnoses of schizophrenia from forensic sources can be seen to meet formal diagnostic criteria through use of both a structured undiagnostic approach and a multidagnostic chart review based on case histories" (p. 534). Each of the eighty-three subjects had a recorded diagnosis of schizophrenia at coronal autopsy. Thirty one percent did not meet the criteria for any of the five diagnostic systems, 68.7% met criteria for at least one system, and 20.5% met the criteria for all five diagnostic systems. Agreement ranged from 42.2% for the Feighner criteria to 63.9% for DSM-III-R.

Although it seems reasonably clear that DSM-III, DSM-III-R, and DSM-IV are more precise in their delineation of many mental disorders than was true of DSM-II and that the reliability of diagnosis has been enhanced in many instances, some important problems remain. The lack of comparability of diagnostic systems has already been noted, and this clearly presents problems for both research and practice. If everyone adhered to one diagnostic system exclusively, then perhaps this problem would be less serious. However, when new official systems are introduced within a period as brief as seven years, the comparability and meaningfulness of clinical diagnosis becomes more problematic. DSM-IV, for example, was being prepared while research studies on DSM-III-R were still underway. Thus, although the DSM-IV Task Force profited from the research and data sets resulting from DSM-III, it could have learned more by awaiting additional research based on DSM-III-R.

In the introductory section of the DSM-III-R manual, it is stated that the American Psychiatric Association decided in 1983 to work on a revision of DSM-III for several reasons. Data from new studies were inconsistent with some of the diagnostic criteria. "In addition, despite extensive field testing of the DSM-III diagnostic criteria before their official adoption, experience with them since their publication had revealed, as expected, many instances in which the criteria were not entirely clear, were inconsistent across categories, or were even contradictory" (American Psychiatric Association, 1987, p. XVII). Therefore, a thorough review was instituted, and the required modifications were made. Although the revised DSM-III essentially follows the same overall scheme and rationale as the original, some modifications were made and comparisons of the two diagnostic systems have been reported. Some examples of the problems encountered follow.

One study attempted to evaluate the reliability, sensitivity, and specificity of DSM-III and DSM-III-R criteria for the category of autism in relation to each other and to the clinical diagnoses made (Volkmar, Bregman, Cohen, & Cicchetti, 1988). The subjects were fifty-two individuals diagnosed as autistic and sixty-two considered developmentally disordered but not autistic. The reliability of the specific criteria tended to be high. The DSM-III criteria were judged more specific but less sensitive than the DSM-III-R criteria. As a result, the investigators concluded that the diagnostic concept of autism has been greatly broadened in the revised system.

In the light of the preceding paragraph, it is of interest to list the changes made for autistic disorder in DSM-IV:

Autistic Disorder. The DSM-III-R defining features (impaired social interaction, communication, and stereotyped patterns of behavior) are retained in DSM-IV, but the individual items and the overall diagnostic algorithm have been modified to (1) improve clinical utility by reducing the number of items from 16 to 12 and by increasing the clarity of individual items; (2) increase compatibility with the ICD-10 Diagnostic Criteria for Research; and (3) narrow the definition of caseness so that it conforms more closely with clinical judgment, DSM-III, and ICD-10. In addition an "age of onset" requirement (before age 3 years in DSM-IV), which had been dropped in DSM-III-R, has been reinstated to conform to clinical usage and to increase the homogeneity of this category. (American Psychiatric Association, 1994, p. 774)

Another problem in clinical diagnosis is illustrated in a study of the differential diagnosis of

attention deficit disorder (ADD) and conduct disorder using conditional probabilities (Milich, Widiger, & Landau, 1987). Although these two disorders are considered separate disorders, there has been a substantial overlap in symptoms. Using a standardized interview designed to represent the diagnostic criteria contained in DSM-III, seventy-six boys referred to a psychiatric outpatient clinic were evaluated and the conditional probabilities and base rates of the symptoms for both disorders were ascertained. The results indicated that the symptom with the highest covariation with the specific disorder was not always the most useful in diagnosis. Furthermore, some symptoms are most useful as inclusion criteria, whereas some are most useful as exclusion criteria. The authors also point out that the interview used was based on DSM-III and that the application of different diagnostic criteria could change the pattern of results obtained. This, of course, is always a problem when diagnostic criteria are revised and new systems instituted. A final important point made by these investigators is that the symptom criteria offered for ADD in DSM-III-R are weighted equally "whereas the results of the present study suggest that some symptoms are more effective inclusion criteria than others. In addition, the DSM-III-R offers only inclusion criteria and makes no attempt to use symptoms as exclusion criteria" (Milich, Widiger, & Landau, 1987, p. 766).

Because of space limitations, only a few other studies can be mentioned. The introduction of many new diagnoses obviously created many new potential problems, among them, estimating the incidence of specific disorders. For example, "In the years since 1980, bulimia has gone from being virtually unknown to being described by some medical investigators as a 'major public health problem' (Pope, Hudson, & Yurgelun-Todd, 1984) and being designated by one prominent nonmedical leader of contemporary female opinion as a disorder of 'epidemic proportions'" (Ben-Tovin, 1988, p. 1000). This author also states that "The use of DSM-III-R seems likely to lead to a dramatic decline in the diagnosis and prevalence of bulimia" (Ben-Tovin, 1988, p. 1002).

Somewhat comparable comparisons have been reported by others. In one study of the definitions of schizophrenia for 532 inpatients treated and reevaluated 15 years later, the use of DSM-III-R reduced the number of patients diagnosed with schizophrenia by 10%. However, the DSM-III di-

agnosed patients included and excluded by DSM-III-R did not differ in terms of demographic, pre-morbid, or long-term outcome characteristics. The authors of this report emphasized that in the absence of improved validity, frequent changes in diagnostic systems were likely to impede research progress (Fenton, McGlashan, & Heinsen, 1988). Zimmerman (1988) also expressed his doubts that new changes in such a short time would actually improve the practice of psychiatry.

A number of clinical researchers have published various critiques of some of the diagnostic categories listed in the new classification systems. Aronson (1987) stated that the definition of panic attack in DSM-III lacks precision and that the overlap with other disorders raises questions about what is a distinct psychiatric disorder. Leavitt and Tsuang (1988) reviewed the literature on schizoaffective disorder and concluded that "Until there is greater agreement on the criteria for and the meaning of schizoaffective disorder, reports on treatment results will not be generalizable" (p. 935). In DSM-IV, the criteria set for schizoaffective disorder "has been changed to focus on an uninterrupted episode of illness rather than on the lifetime pattern of symptoms" (American Psychiatric Association, 1994, p. 779).

Obviously, there are significant differences in validity and reliability of diagnosis among diagnostic categories. In recent years, some of the personality diagnoses such as narcissistic personality disorder or borderline personality disorder have been popularized by several psychoanalytically oriented clinicians and, in part due to this, have been included as distinct disorders in the official nomenclature. Although a *definite* diagnosis of a *borderline* condition has always seemed rather illogical to me, apparently it is no problem to many people. However, as some have noted, the category of borderline personality disorder has been used to include a variety of pathological behaviors. "Exhibiting almost all of the clinical attributes known to descriptive psychopathology, borderline conditions lend themselves to a simplistic, if not perverse, form of diagnostic logic, that is, patients who display a potpourri of clinical indices, especially where symptomatic relationships are unclear or seem inconsistent, must perforce be borderlines" (Millon, 1988).

The use of a multi-axial system has also led to an increase in what has been termed "comorbidity," having two or more concurrent diagnoses. Axis I

in DSM-IV, Clinical Disorders, contains most of the more traditional psychiatric diagnoses, whereas Axis II includes only Personality Disorders and Mental Retardation. In DSM-III, it was originally stated that "This separation ensures that consideration is given to the possible presence of disorders that are frequently overlooked when attention is directed to the usually more florid Axis I disorder" (American Psychiatric Association, 1980, p. 23). However, it appears that personality disorders are diagnosed quite frequently as either a primary diagnosis or as a secondary diagnosis. In a recent critical appraisal of the use of the terms of *comorbidity* or *comorbid* in psychopathology research, Lilienfeld, Waldman, & Israel (1994) indicated the growth in their use. After appearing only twice in 1986, "the number of journal abstracts or titles containing these terms increased to 21 in 1987, 43 in 1988, 97 in 1989, 147 in 1990, 192 in 1991, 191 in 1992, and 243 in 1993" (Lilienfeld et al., 1994, p. 71). This trend raises some question concerning the use of traditional views of medical diagnosis in psychopathology and "implicitly assumes a categorical model of diagnosis that may be inappropriate for personality disorders ..." (Lilienfeld et al., 1994, p. 79).

In a study of more than 200 adults at risk of AIDS, multiple diagnoses of personality disorder were recorded for most individuals with any DSM-III-R Axis II diagnosis. Almost half of the subjects with a diagnosis in one personality cluster also had a concurrent diagnosis in another cluster (Jacobsberg, Francis, & Perry, 1995). A study of the comorbidity of alcoholism and personality disorders in a clinical population of 366 patients also obtained comparable findings. There was extensive overlap between Axis I disorders and personality disorders, as well as among personality disorders themselves (Morgenstern, Langenbucher, Lubovue, & Miller, 1997). In another study of 118 gay men conducted to investigate the stability of personality disorder, it was reported that diagnoses of personality disorders had low stability over a 2-year period (Johnson et al., 1997). A study of seventy-eight adult outpatients with attention deficit hyperactive disorder evaluated by standard tests showed high comorbidity with current depressive disorder, antisocial personality disorder, and alcohol and drug abuse dependence (Downey, Stanton, Pomerleau, & Giordani, 1997). In a sample of 716 opioid abusers, psychiatric comorbidity was documented in 47% of the sample based on a

DSM-III-R diagnostic assessment. Such comorbidity was especially noted for personality and mood disorders for both sexes (Brooner, King, Kidorf, Schmidt, & Bigelow, 1997). There have been additional studies published on this issue, but there is no need to review them here. As Robins (1994) commented, "When standardized interviews demonstrate that a single patient qualifies for an unreasonable number of diagnoses, that should motivate the field to rethink this proliferation of categories" (p. 94).

Thus, the categorical delineation of psychiatric disorders presents problems for meaningful diagnosis. Dumont (1984), for example, feels strongly that psychiatry errs in attempting to divide all abnormal behavior into discrete illness categories. He believes that labels such as "hyperactivity" and "learning disorders" for children "are a capricious and arbitrary drawing of lines through a spectrum of behavioral, intellectual, emotional, and social disabilities" (Dumont, 1984, p. 326). Marmor (1983) in discussing systems thinking in psychiatry also emphasizes "that the growing tendency to think in terms of distinct and sharply demarcated phenomenological entities, as exemplified in DSM-III, deserves some skeptical evaluation despite its usefulness pragmatically" (p. 834). Although categorization may be simpler to handle than a dimensional approach, a combination of the two suggested by Lorr (1986) and by McReynolds (1989) may be more meaningful in the long run and provide more information as well as potentially greater predictive power. Others also suggest that the use of both psychometric and fixed diagnostic criteria could lead to a better and more valid definition of schizophrenia (Moldin, Gottesman, & Erlenmeyer-Kimling, 1987). However, despite such criticisms, as well as others (Carson, 1996, 1997; Follette & Houts, 1996; Millon, 1991; Sarbin, 1997), the neo-Kraepelinian model has continued to be used.

Research Issues and Problems

As already mentioned, problems pertaining to the reliability and validity of diagnosis are of definite importance for research in psychopathology. Research results based on inadequately diagnosed patients are of dubious value. However, there are other considerations that are equally important. One frequent and serious problem pertains to the

specific sample of subjects or patients used in particular research investigations. Investigators generally can never study all individuals who supposedly manifest a particular form or type of psychopathology. Rather, they must usually settle for a much smaller number of cases that purportedly represent or typify the disorder under investigation. A variety of sampling problems may be encountered in this process, and it is worth examining some of these problems.

Sampling Problems

As indicated, investigators usually can study only small samples of the population they are interested in evaluating. An immediate critical issue is how well the sample selected for study actually represents the population or group it supposedly represents. How typical, for example, is a sample of thirty or fifty patients diagnosed as cases of schizophrenia in a state hospital in New Jersey, of *all* "schizophrenics" or of those in other types of settings? How far can one generalize from the findings obtained with this specific sample? Ostensibly, at least, findings obtained from a particular sample representative of a given category of disorder presumably have relevance for other comparable samples. The problem, therefore, is how does one define both the sample studied and the other samples of the population or diagnostic group to which the results are supposedly applicable?

Unfortunately, there are no true standard reference measures which can be used to define a particular clinical group of subjects, and the terms used for clinical diagnosis leave much to be desired. Consequently, it is exceedingly important to select the sample with great care and to provide as much useful descriptive information as possible concerning the sample. However, some published studies fail to provide adequate descriptive data for their samples. Such items as age, length of hospitalization, frequency of hospitalization, marital status, work history, previous treatments, family resources, education, intelligence, type of psychiatric ward or institutional setting, maintenance on medications, and the like, are all potentially important variables which may influence test performance, treatment outcome, duration of improvement, and similar variables. It should be apparent that significant variation on some or many of these variables between studies limits the

reliability of the results secured and the drawing of conclusions that may have broad applicability.

The problems mentioned are particularly apparent when samples of modest size are drawn from institutional settings that vary widely in a number of dimensions. Patients in university or private hospitals generally are quite different from those in state or VA psychiatric hospitals, and generalizations from one setting do not necessarily fit other settings, even though the patients may all carry an official diagnosis of schizophrenia. For example, in a previous study of prognostic scales used in research on schizophrenic patients, we were unable to obtain an adequate number of "reactive" or good prognosis patients in the state hospital where we were conducting our study and had to secure patients from a city hospital that had fewer chronic patients (Garfield & Sundland, 1966).

Although sample size is of some importance because small-scale studies are more prone to produce findings limited in reliability, size, alone, is not a sufficient criterion. The selection of subjects and sample specifications are clearly of prime importance. If one is studying or comparing selected types of disordered behavior, the criteria used in selecting subjects should be explicit, and the procedures used should be those for which the reliability and validity are known or available and which meet commonly accepted standards. Particularly where studies are conducted of groups based largely on psychiatric diagnosis, it is essential to state clearly how the diagnoses were derived and that other supporting selection criteria be used. One large recent study examined the extent to which diagnostic instruments for assessing axis II personality disorders diverge from clinical diagnostic procedures. "Whereas current instruments rely primarily on direct questions derived from DSM-IV, clinicians of every theoretical persuasion found direct questions useful for assessing axis I disorders but only marginally so for axis II" (Westen, 1997, p. 895). Axis II diagnoses were made by "listening to patients describe interpersonal interactions and observing their behavior with the interviewer. In contrast to findings with current research instruments, most patients with personality disorders in clinical practice receive only one axis II diagnosis" (Westen, 1997, p. 895).

Diagnoses based on old records and provided by different psychiatrists also do not constitute a sound or reliable basis for subject selection. Diagnostic criteria and nomenclature change over the

years, and it is a difficult task to compare and equate diagnoses based on different diagnostic schemes, as several studies have indicated (Fenton, Mosher, & Matthews, 1981; Goldstein & Anthony, 1988; Hill et al., 1996; Klein, 1982; Rutherford, Alterman, Cassiola, & Snider, 1995).

Another problem is the randomization of subject selection. For example, were the subjects selected at random from a previously selected pool of available subjects or were they selected because they were not on drugs, happened to be available to the investigator, were in a special ward, were judged to be cooperative, or in some other manner were really not "typical subjects?" Some studies use moderately complex tasks that necessitate some screening or selection of subjects to comply with the demands of the investigation. Such research compliance leads to a rather selected sample of subjects. The Vigotsky Test of conceptual thinking was at times used as a diagnostic test for schizophrenia, although even non-college-educated normal subjects could not perform satisfactorily on it (Garfield, 1974). Clearly, such selectivity can bias the results and limit the extent to which generalized statements can be made.

Selection of subjects on the basis of a single scale may also not be adequate, particularly if they are then considered to represent a particular diagnostic group. For example, not all subjects who score at 70 or higher on a scale of the MMPI may resemble groups diagnosed on other criteria as schizophrenic, depressed, etc. College students who obtain such scores may or may not be clinically depressed, psychotic, etc., and therefore comparisons with actual clinical populations may not be warranted.

It is clearly desirable to use more than one procedure or method for establishing the diagnosis of the subjects to be used in any research study in which the diagnosis is considered a significant variable. Psychiatric or clinical diagnosis should be supplemented by other criteria such as scores on appropriate tests or standardized rating scales. In depression, for example, scores on the MMPI, the Hamilton Rating Scale (1960), and the Beck Depression Inventory (1972) could be, and should be, used in addition to clinical diagnosis. Other instruments that were developed to aid in obtaining more reliable diagnoses are the Schedule for Affective Disorders and Schizophrenia (SADS) (Endicott & Spitzer, 1978) and the Research Diagnostic Criteria (Spitzer, Endicott, & Robins, 1975).

The former is a structured interview guide with rating scales relevant to the specific diagnostic categories, whereas the latter provides criteria whereby investigators can select relatively homogeneous groups of subjects who meet specified criteria of diagnosis. Although the Research Diagnostic Criteria were used to obtain more precise diagnostic designations, as noted earlier, such diagnostic criteria tended to be quite selective and to leave a significant number of patients undiagnosed. In the NIMH Treatment of Depression Collaborative Research Program, uniform inclusion criteria, including a diagnosis of Major Depressive Disorder based on the Research Diagnostic Criteria and a score of 14 or greater on a modified seventeen-item Hamilton Rating Scale for Depression were used "and uniform exclusion criteria were used across sites" (Elkin, 1994, p. 116). Data were also obtained on a number of patient clinical, demographic, and personality variables that might be related to eventual outcome.

With the advent of DSM-III-R, a new structured interview for use with the new diagnostic system was developed with somewhat separate forms for diagnosing psychiatric inpatients, outpatients, and nonpatients (Spitzer, Williams, & Gibbon, 1987). Although highly structured like most interview schedules of this type, a number of open-ended questions are used. Other more specialized interview schedules have also been developed (McReynolds, 1989).

Various experimental or laboratory tests of thought disorder and communication have also been used in studies of patients with schizophrenia. However, none of these have attained any general recognition as diagnostic measures. On the other hand, investigators do believe that the use of psychometric data along with fixed diagnostic criteria can lead to a more valid definition of schizophrenia (Moldin, Gottesman, & Erlenmeyer-Kimling, 1987).

In addition, clinical diagnoses for research purposes should be based on diagnoses from two or more clinicians with a reasonably high indication of reliability between them. In a study on the use of many raters to increase the validity of judges, groups of one to ten judges rated a patient's mood from speech samples taken at various times during psychotherapy (Horowitz, Inouye, & Siegelman, 1979). These ratings were averaged and then correlated with an objective measure of anxiety. The correlations increased noticeably, up to a theoretic

cal asymptote, as the number of judges increased. Thus, using five or six judges will tend to increase both the reliability and validity of ratings.

If such procedures are followed, there is greater assurance of the reliability of diagnosis, and there are several external or operational reference points in defining the samples used. To be sure, extra effort is required to carry out such procedures and, to a certain extent, such procedures might reduce the size of potential samples and raise new issues of selectivity and limited generalizability. However, the samples would be more clearly defined, and the dangers of relying exclusively on somewhat haphazard means of classification would be lessened. In the long run, the conflicting results obtained with the use of diffuse, unclear, and unreliable diagnostic categorization might lessen.

Another issue involves the possible selectivity of a patient sample to match it with an available control group. For example, if the control group has an average IQ of 98, an average educational attainment of tenth grade, or is composed primarily of ward attendants, a subject sample selected to match them on one or more of these variables may be a highly selective and unrepresentative sample of the patient group they are supposed to represent. They are not patients typical of a particular diagnostic group, and broad generalizations to other more randomly selected groups would not be justified. For example, in my previous study of hospitalized patients diagnosed as schizophrenic, very different patterns of performance on the Wechsler-Bellevue Scale were obtained for patients who differed in education and IQ (Garfield, 1949). The most striking difference was noted on the arithmetic subtest for individuals who differed in educational levels. Schizophrenics from the lowest educational group performed at their lowest level on this subtest, whereas the group with some college education obtained its highest score on this subtest. Furthermore, comparisons of samples of schizophrenic patients studied in different investigations, who differed noticeably in mean IQ, also revealed significant differences on test patterns among these samples (Garfield, 1949). In other words, there were as many significant differences among the various samples of patients as there were between a given sample and a normal group of control subjects.

The selection and specification of subjects used in research on clinical diagnosis is thus a matter of primary importance, and would-be investigators,

as well as those who read the research reports, should give careful attention to the issues discussed in the preceding paragraphs. In the final analysis, the results can be no better than the type and representativeness of the subjects used.

Proper Control Groups

Another problem frequently encountered in research reports involves the appropriateness of the control groups used. Although we are more sophisticated about such matters now than in the past, problems of appropriate controls are still evident. Obviously, a group of patients that has been hospitalized for some time should not usually be compared with a group of apparently normal college students, but comparisons like this have been made.

The problem becomes especially significant when a particular investigation focuses on differential clinical diagnosis or on the specification and appraisal of patterns of test performance or other diagnostic indicators for a specific category of patients. If the results of the study are to have any clinical significance in the practical sense, then the experimental group must be compared to other clinical groups with which they would normally be compared in the actual clinical situation. For example, comparisons of test performance or other measures of a sample of patients with a diagnosis of schizophrenia should be made with other clinical groups normally seen in that type of clinical situation and in approximately the usual proportions. In any clinical or hospital setting where a clinical diagnosis is sought, the problem is rarely one of comparing the given patient to a normal population. Rather, the issue is one of differential diagnosis and appraisal in which a number of specific diagnostic questions, such as the following may be raised: Is there any suggestion of psychotic disturbance or of possible brain damage? How serious is the thought disturbance or depression manifested by the patient? In trying to reach answers to such questions, clinicians must consider and compare the patterns of various types of psychopathology. They do not simply compare or contrast the patient's performance to the performance of nonpathological or normally adjusted individuals.

Thus, in studying a diagnostic pattern for possible use in clinical diagnosis, the investigator should compare the results of the particular clinical

group of interest with those of other diagnostic groups that are usually encountered in practice and from whom the aforementioned group is to be compared or differentiated. For clinical diagnosis, it is efficacious to have a control group made up of the proper mix of the other diagnostic groups that are normally encountered in the particular setting or of several groups representing the types of disorders that are most frequently confused with the group under study.

As emphasized earlier, the investigator should provide adequate information on all groups of subjects, indicating how they were selected and from what subpopulation they were drawn. For example, if a control group of thirty patients was selected for comparison with the group under study, why and how were these particular subjects selected, and from what number of comparable subjects were they drawn? If they were the only ones who had certain data or test scores available, what were the reasons for this particular state of affairs? How selective is the group, and how representative is it of supposedly similar subjects? Selective bias may greatly impair the kinds of conclusions that may be drawn and the extent to which the findings may be generalized.

It should be stressed that whatever control groups are used, they should be comparable in the variables of importance for a particular investigation. Where cognitive tests are used, the groups should show some comparability in level of ability, education, and age, because these may affect performance. Obviously, however, if one's particular focus is the diagnosis of mental retardation, such comparability may not be necessary or meaningful. Length of institutionalization, medications, type of ward, degree of cooperation, and other such attributes may also be important variables.

In essence, therefore, considerable attention should be given to selecting adequate and appropriate control groups in research on clinical diagnosis. Although this is particularly relevant to differential diagnosis and related problems, the issue of appropriate control groups also applies to experimental or theoretical studies of psychopathology. Numerous studies of various psychological functions in schizophrenic subjects have compared the latter quite frequently with normal controls. This may have value at a certain stage of investigation, but it has limited value if one is interested in ascertaining or demonstrating particular patterns of response or thought in patients

with this specific clinical disorder. The investigator is actually trying to discover or demonstrate response patterns that characterize a particular pathological group. Whether the patterns obtained are distinctive of the particular type of pathology in question can be demonstrated only if the performance of the pathological group is compared with other pathological groups of comparable severity. In this particular instance, other psychotic groups would be the most adequate control group.

Although many of the points stressed in this section may appear obvious, they have been overlooked and continue to be disregarded by investigators in psychopathology. For example, a recent study of borderline personality disorder, with several positive features, also exhibited some of the deficiencies previously discussed (Nurnberg, Hurt, Feldman, & Suh, 1988). Patients for this study were selected from consecutive admissions to a twenty-three bed adult inpatient unit of a university teaching hospital. The criteria used specified an age range of 16 to 45, "no evidence or history of organic mental disorder, neurologic disorder, substantial concurrent medical illness, mental retardation, or alcohol or drug addiction as a primary diagnosis; no DSM-III-R diagnosis of schizophrenia, major affective disorder, paranoid disorder, or schizoaffective disorder; and an independent clinical diagnosis of borderline personality disorder by the treatment team" (p. 1280). All patients also were rated independently before discharge by the senior investigator to confirm the diagnosis of borderline personality disorder according to DSM-III, an appropriate score on the Diagnostic Interview for Borderline Patients (Gunderson, Kolb, & Austin, 1981), and the absence of exclusion criteria. In this way seventeen patients (ten women and seven men) ages 17 to 35 years were selected.

Let us now evaluate what has been presented thus far about this study. A number of inclusive and exclusionary criteria have been specified to obtain what might be viewed as clear or "pure" cases of borderline personality disorder. The procedures and age and sex of the subjects have been clearly indicated so that an attempt at replication is possible. However, no data are provided on how many patients were evaluated, how many were rejected for not meeting study criteria, and the educational or socioeconomic status of the sample selected. In other words, is this group highly selective, for example, 17 out 1,000, or is such a group

easily obtained from newly admitted inpatients? There is also no information on the reliability of the diagnosis.

So much for the experimental group. The control group with which it was compared consisted of twenty subjects (twelve women and eight men) selected from the hospital staff. These individuals were subjected to the same exclusion criteria that were used for the patients. In addition, they had to have no previous or present psychiatric treatment and be free from emotional disturbance or an acute major life event change within the past year. They ranged in age from 18 to 40 years. Again there is no information on the size of the group from which this control sample was selected or on educational and social class indexes.

The two groups were compared on the basis of a seventeen-item criteria instrument. By using the five best items, it was found that the presence of any two was a good predictor of borderline personality disorder in the patient group but produced a false negative rate of 30% in the controls. However, the use of four out of the best five predictors reduced diagnostic errors significantly.

As already pointed out, the use of a normal group or in this case, a rather selective normal control group, greatly increases the possibility of obtaining significant differences. Comparisons need to be made with other comparable diagnostic groups and attempts at cross-validation would be required if the criteria are to have diagnostic utility in the clinical situation. This is particularly true because many patients have more than one diagnosis (Wolf, Schubert, Patterson, Grande, et al., 1988) and as pointed out earlier, the rate of comorbidity is especially high for personality disorders.

Clinical Versus Statistical Significance

In a number of articles, significant correlations or differences at the .05 level of significance are reported with little concern shown over the number of significance tests performed. Although it should be apparent that the interpretation of the significant findings obtained is directly related to the number of statistical tests performed, this stricture is not always observed. If thirty-five comparisons or correlations are performed and two are at the .05 level of significance, it seems clear that the results obtained are so close to a chance occurrence that little should be made of them.

Similarly, post hoc analyses are sometimes

treated as if explicit hypotheses were being tested. Obviously, considerations enter into such analyses that differ when a specific hypothesis, stated in advance of the investigation, is being tested. Although these matters are rather basic in experimental design and statistical analysis, the lessons on these topics are either not learned well or are quickly forgotten. When the investigators emphasize significant findings that they have not predicted in advance and that are noted after the investigation has been completed, they essentially are capitalizing on chance occurrences. For the results to be taken seriously, they should be replicated on a new sample of subjects.

A related issue involves the practical or clinical significance of findings that are significant statistically at the .05 or even at the .001 level of significance. It appears from numerous reports that researchers have been led to worship at the shrine of statistical significance. Very likely, this may result from the emphasis individuals place on obtaining "positive" results and the fear of not being able to reject the null hypothesis. Many investigators appear content, and some even euphoric, at obtaining "positive results" at the .05 level of significance, regardless of whether the results appear to have potential diagnostic use. Of all the limitations the present writer has encountered in reviewing journal manuscripts, the emphasis on statistical significance and the disregard of practical psychological significance is probably the most frequent.

Clearly, researchers must examine their data to see if the results obtained are due to chance. A statistical test of the differences obtained between selected clinical groups or of the correlations obtained on certain measures and designated criteria for specific diagnostic categories is a necessary procedure for estimating the influence of chance on the results. No criticism of this procedure is intended here. However, one should recognize that for clinical research this represents only the first of the necessary procedures for appraising the results obtained. Such a statistical test informs us of the probability that our results may be explained by chance occurrences. If our results are significant at the .05 level, the interpretation should be that there are only five chances in a hundred that the results obtained may be attributed to chance. The findings, of course, could be due to chance, but the odds are against it. However, all one can reasonably conclude from such findings is that they do not appear to be due to chance, and that if the study

were repeated, we might expect comparable findings. This, of course, does not guarantee that the new findings will be comparable to those in the original study, for conflicting findings are by no means uncommon in studies of psychopathology. However, whether the results obtained have any potential clinical usefulness cannot be determined by these statistical tests alone. Other appraisals must be made.

Some factors that influence statistical results also need to be considered. Statistical tests are very much influenced by the size of the samples used and by their variability. Large samples are generally less influenced by selective and chance variables than very small samples. Thus, findings that are small may be statistically significant in the former instance, whereas they would fail to attain significance with smaller samples. For example, with samples of around thirty subjects, correlations have to be in the neighborhood of .35 or so to reach significance. In contrast to this, with a sample of several hundred subjects, a much lower correlation, in the neighborhood of .10, may be statistically significant, although the amount of predicted variance in the scores has no practical significance. For example, in a study that I conducted of 855 clinical psychologists, a correlation of .086 was obtained between career satisfaction and satisfaction with the American Psychological Association (Garfield & Kurtz, 1976). This correlation was significant at the .01 level. However, such a correlation is clearly a "low correlation" and has little or no practical significance.

Thus, besides the level of significance, we must also consider the size of the sample and the actual amount of variance accounted for by the correlation coefficient if we are to interpret the findings in terms of their utility. Moderately high correlations that are not statistically significant have little value and are unreliable.

Similarly, low variability within groups of subjects generally increases the probability of securing statistically significant differences. However, though small standard deviations increase the possibility of useful discrimination between different clinical groups, the actual utility of the measures or comparisons used requires further analysis of the actual data obtained.

Although there have been some discussions of the difference between clinical and statistical significance in the published literature, the importance of this topic has received attention only

recently (Jacobson & Revenstorf, 1988; Jacobson & Truax, 1991; Kazdin, 1994; Lambert & Hill, 1994). Many investigators appear content to rest on their statistical laurels and manifest little concern about the practical value of their results. However, there are several aspects of the research data which should be examined for their potential clinical significance. For example, regardless of the mathematical procedures used to test hypotheses within a statistical model, it is also important to know how much of the variance is accounted for by the particular variables studied. For practical as well as theoretical purposes this is an important consideration, but it is frequently omitted in the discussion of results. In the case of correlational data, simply squaring the coefficient of correlation provides an estimate of the amount of variance accounted for by the particular set of correlates. With other methods of analysis, the implications may not be as readily apparent, but it is equally important to provide an estimate of the variance accounted for by the experimental manipulation.

The importance of such analyses can be illustrated briefly here. In the report of the activities and preferences of a sample of 855 clinical psychologists (Garfield & Kurtz, 1976), numerous findings at the .01 level of significance or better were obtained. Some may have been the result of the numerous comparisons made, but the sample size was very likely of some importance. Consequently, correlations of .10 which were highly significant statistically were judged of little practical importance because they accounted for only 1% of the variance. In another study of more than 1000 clients in a number of community mental health centers, several correlations of around .10 were reported as highly significant, even though they were obviously of little significance clinically or socially (Sue, McKinney, Allen, & Hall, 1974). For example, the correlation between diagnosis and premature termination was .10, and this was significant at the .001 level of confidence. However, by itself, such a significant finding accounts for a negligible amount of the variance. Particularly where large samples are used, authors should feel obligated to stress the implications of their findings in terms of the variance accounted for by the variables under study.

In addition to estimating the amount of variance accounted for by the variables studied, other analyses can also be performed. The means and standard deviations for the clinical samples studied are

of potential value to other clinicians and investigators. Consequently, they should be reported, and the extent of overlap of the distributions also should be stated clearly. Also of value for clinical diagnosis are the numbers of subjects who would be correctly diagnosed by the diagnostic procedures evaluated and those who would be misdiagnosed—that is, data on false positives and false negatives. Such data are clearly important in evaluating any diagnostic procedures, but they are not always obtained or provided. It should be apparent that a particular diagnostic technique may differentiate two or more clinical groups at the .05 level of significance but yet produce so many false positives or negatives that it has very limited clinical utility. For such reasons, it is important that investigators analyze their data in terms of clinically relevant diagnostic considerations and present their analyses clearly.

Base Rates

Another related problem in research on clinical diagnosis concerns the old issue of base rates. Although this important matter was raised some years ago and is not an unfamiliar topic in either the areas of diagnostic assessment or psychotherapy (Gathercole, 1968; Meehl & Rosen, 1955; McNair, Lorr, & Callahan, 1963; Milich, Widiger, & Landau, 1987), a number of studies seemingly have disregarded it even when it was clearly relevant. Consequently, base rates are worth some discussion.

I can begin by referring to an earlier experience of mine. Working as a clinical psychologist in a VA Hospital more than 50 years ago, I collected psychological test data on a moderate sized sample of patients who had been referred for psychological evaluation. I compared my diagnostic impressions based on test data with the clinical diagnoses made at the staff conferences on these patients and, among other things, noted that my diagnosis of schizophrenia agreed with the staff diagnosis in 67% of the cases. On the whole, I was not displeased with this degree of agreement. I prepared an article on this study and submitted it to the Branch Chief Psychologist for his evaluation. The Branch Chief, David Shakow, returned it to me with his comments. He particularly raised the issue of how my diagnosis of schizophrenia compared with the rates of such admissions to the hospital, and suggested that I secure the base rates

for diagnoses of schizophrenia in my hospital for comparison. I reluctantly carried out a survey of hospital admissions for a specific period and discovered to my surprise that the number of patients officially diagnosed as cases of schizophrenia was just about 67%. In other words, my diagnostic work did not exceed the base rate for diagnoses of schizophrenia, and automatically diagnosing every admitted patient as a schizophrenic would have been as accurate as the diagnoses derived from my psychological test evaluation. Needless to say, this was a sobering experience which has remained rather vivid in my memory.

The matter of base rates, thus, is a factor that must be considered in evaluating certain kinds of research on clinical diagnosis. To be worthwhile clinically, diagnostic procedures must clearly exceed the base rates for a particular disorder. Otherwise, one may be wasting time and effort. Attention to such matters, along with attention to false positives and negatives indicates the potential difficulties in using diagnostic procedures for disorders where the incidence is very high, or where it is very low, as in the case of suicide. In the latter instance, a diagnostic or predictive measure must be extremely effective in discriminating the cases being evaluated if it is to be clinically useful.

Thus, for specific kinds of problems pertaining to differential diagnosis or prediction, it is essential for the researcher to provide data on the base rates for the disorders of interest and to clearly show the advantages as well as disadvantages for the procedures being evaluated.

Inadequate Data Presentation

In this section, I discuss some of the deficiencies noted in some research reports on clinical diagnosis. These include such problems as not providing basic information on the measures used, necessary information on important variables that might influence results, how diagnoses were secured, how the subjects were selected, and similar aspects. The examples discussed will illustrate the kinds of problems encountered when such information is not included in the report.

At present, when a large number of patients, both inpatients and outpatients, are receiving medication of various kinds, it is extremely important to provide this information in the research report. If the medications used have any potency, they are bound to influence the behavior and mental func-

tioning of the subjects studied. The taking of medication must be clearly mentioned, and also the medication used, the dosages, and in many cases, the duration of medication should also be specified. If part of a group of subjects is on medication and part not on medication, there are clearly problems in mixing the results of these two subgroups and treating them as one relatively homogeneous group. In a related fashion, comparing a clinical group of subjects receiving medication with a control group which is not must obviously limit the kinds of conclusions that can be drawn from such comparisons. If one is attempting to compare the effects of drugs on two groups of comparable patients, then, of course, the previous comparison would be feasible, providing that a placebo was used with the control group. However, if the comparison is done to compare the mental functioning, behavior, or personality characteristics of a given diagnostic group with some other group, then such a comparison would provide results that were contaminated by the influence of the medication.

Another more common problem involves the lack of adequate information presented on the particular techniques or methods of appraisal used in the research study. This is of particular importance when the procedures used are not standardized or have been constructed by the investigators for their specific research without adequate preliminary reliability or validity studies. It is the responsibility of investigators to describe clearly the procedures and techniques they have used in their study so that others may fully understand what has taken place and be able to attempt replications of the study. Readers of such reports should also evaluate the adequacy of the research before attempting to apply it to their own clinical or research work.

With the pressures for publication and the corresponding desire to use journal space efficaciously, it is understandable that editors want manuscripts to be as brief and concise as possible. Nevertheless, this does not mean that significant information about a research project should be omitted. For example, when relatively unknown tests or rating scales are used, the investigator should describe them in sufficient detail so that the reader clearly understands the techniques used and can appraise their suitability for the samples and the problem under investigation. This is not an infrequent occurrence. Lambert and Hill (1994) stated,

“The proliferation of outcome measures (a sizable portion of which were unstandardized scales) is overwhelming if not disheartening” (p. 74). The investigator should also provide pertinent data concerning the reliability and validity of the procedures used in these instances as well. Because the value of the results obtained in any research study depends on the adequacy of the measures used, such information is essential.

A final point concerns inadequate or apparently biased citing of the relevant research literature. I cannot recall seeing any discussion of this topic in presentations of research on either clinical diagnosis or treatment. Perhaps it is assumed that all investigators are aware of the need to review carefully the existing research on the topic under investigation. Nevertheless, this issue is mentioned in critiques of research reports or reviews of research (Garfield, 1977, 1978). The issue is of some importance where there is conflicting literature on a specific topic and investigators refer primarily to those published reports that support their findings or position and omit mention of findings that fail to do so. Such a practice violates accepted standards of scholarship, misleads uninformed readers of the research reports, and may tend to perpetuate the use of fallible diagnostic techniques.

Cross-Validation

One of the concerns about much past research, not limited to clinical diagnosis alone, has been the large number of conflicting findings in the literature and the difficulty in replicating published findings. This has become such a frequent occurrence in research in clinical psychology that many review articles tend to present a summary of the number of positive and negative studies on a given topic (e.g., Garfield, 1994; Luborsky, Singer, & Luborsky, 1975). If more than half of the studies are favorable to a given proposition, then that view may be judged to have some support, even where the studies may vary greatly in quality. This is a rather risky means of drawing conclusions about some technique or finding. If a particular clinical treatment for schizophrenia, for example, is found helpful in eight investigations and harmful in four, should we conclude that overall the treatment is helpful? The fact that we have such conflicting findings should make us suspect some possible limitations in the research reported and to withhold judgment until we are able to explain the discrepant findings.

Most likely, the discrepancies among research reports are due to subject variables, sample size, and variations in diagnostic and treatment procedures, as well as to chance variables. Because of the kinds of problems already mentioned concerning variations in assigning clinical diagnoses, in selecting subject samples, in the kind of settings used, and in the procedures used, the findings from any single investigation are probably best viewed as suggestive. Although attempted replications by other investigators in different settings are essential for appraising the value of any investigation, there is one procedure that most researchers could use to improve the reliability of their findings—and I am surprised that it is not used more frequently. This is simply to secure enough subjects in the experimental and control groups so that all groups can be randomly divided into two subgroups. The study is then conducted so that one set of subgroups serves as the initial group and the second set serves as an attempt at cross-validation. This is a relatively straightforward procedure which has been used in some past studies, but relatively infrequently (Garfield & Wolpin, 1963; Lorr, Katz, & Rubenstein, 1958; Sullivan, Miller, & Smelser, 1958).

In the study by Sullivan et al. (1958), two cross-validations were carried out on MMPI profiles of patients who terminated prematurely from psychotherapy; the results of the cross-validation attempts were clearly very important for the final conclusions drawn. Significant differences between premature terminators and those who continued in therapy were found for several MMPI Scales for *each* of the several groups of subjects investigated. However, *none* of the scales that differentiated the two groups under study in one sample showed a consistent pattern. For each separate appraisal, different scales were found significant in their differentiation. Consequently, the findings secured in the first appraisal were not supported in the subsequent cross-validations, and the final conclusions reached were different from what they would have been if the cross-validations had not been attempted. This old but well-conducted study clearly illustrates the importance and the necessity of cross-validation.

Although attempted replications or cross-validations by other investigators are also required to evaluate fully the significance and utility of findings reported in any single investigation, the procedure suggested above is useful for increasing the potential value of single studies.

Problems in Validating Tests and Scales for Clinical Diagnosis

Traditionally, the clinical diagnosis of a patient was made by a clinician, usually a physician, on the basis of a personal interview, some type of case history, and perhaps also a physical or neurological examination. As medicine developed, a variety of diagnostic procedures were developed such as X rays, blood tests, etc., which greatly facilitated the accuracy of the diagnosis made by the clinician. In psychopathology, similar attempts to increase the accuracy of diagnosis have been made. For psychologists, the main techniques have been psychological tests and rating scales. Essentially, these have been attempts to objectify clinical observation and to provide a more systematic appraisal of the psychological functioning of the patient as an aid to diagnosis.

There are potential advantages in using such instruments compared with clinical judgment alone. The former can be administered in a standard fashion, normative data can be secured, scoring and interpretation are potentially more objective, and comparisons of comparable samples of subjects are facilitated. Nevertheless, despite these potential advantages, psychological tests and rating scales developed for evaluating psychopathology for clinical diagnosis have been seriously limited by problems in the validation process.

Although a number of psychologists and psychopathologists have been critical of the reliability and validity of psychiatric diagnoses and have attempted to develop better diagnostic techniques, nevertheless, they have frequently relied on them as a basis for validating their own diagnostic procedures. Using a fallible criterion for the purpose of validation is bound to produce difficulties. In the present instance, there is also evidence of what appears to be circular or faulty reasoning. The initial premise is that clinical diagnoses have serious limitations. Consequently, more effective techniques need to be developed. To validate these potentially more effective techniques, clinical diagnoses will be used as the criteria of validity. If there is reasonable agreement between the tests and clinical diagnoses, then the tests themselves can be considered valid. If this procedure doesn't make good sense to you, the reader, then you are comprehending it correctly. It should be apparent that it is difficult to improve diagnostic procedures if inadequate criteria of validity are used.

The issue mentioned here has constituted a serious problem in the attempt to develop tests and scales to improve clinical diagnosis. The real issue ultimately goes back to the adequacy of the diagnostic system being followed. Where syndromes or categories of illness can be clearly described, where the focus is on physical factors or observable behavior, and where there is relatively little overlap with competing diagnostic categories, the chances of devising diagnostic techniques that will increase the efficacy of clinical diagnosis is enhanced. If the categories themselves are vague and unreliable, it is difficult to see how tests and scales can be adequately validated unless only very "clear-cut" cases are used. In such instances, of course, the procedures will apply only to selected cases.

The reliability and validity of diagnoses also have implications for treatments developed for specific disorders. To the extent that psychotherapy manuals are currently geared to psychiatric diagnoses, the importance of variability among patients is minimized (Garfield, 1996). "With diagnostic categories being the focus of our outcome research, little concern is given to the unique determinants/dynamics that may be relevant to our interventions (see Clarkin & Kendall, 1992)" (Goldfried & Wolfe, 1998, p. 145).

Clinical Diagnosis: Some Concluding Comments

It is readily apparent that any research on diagnostic groups (e.g., schizophrenia or bipolar disorder) can be no better than the validity or meaningfulness of the diagnoses obtained and used. This problem has plagued research in this area for many years. On the one hand, systematic and reliable classification of subjects facilitates research and the accumulation of potentially meaningful data about types of psychopathology. On the other hand, if the classification scheme used for such research is beset with problems of clarity, reliability, and validity, the results based on such classification are bound to be limited in their usefulness. An unreliable and loose scheme is bound to produce unreliable and variable results. The most highly quantified data and the most exacting statistical analyses cannot provide worthwhile conclusions if the assumptions or foundation upon which they are based are weak.

In line with suggestions discussed earlier, investigators need to specify and describe their research subjects in ways that give more meaning to the diagnostic categories studied. In cases diagnosed as schizophrenia, for example, the patients should also be described in terms of other related measures such as the process-reactive continuum, good or poor premorbid, the MMPI, IQ, factored scales such as those developed by Lorr et al. (1966), and the like. Major symptoms of the subjects should also be described and rated on reliable scales. To treat schizophrenia as a single category or disorder is to court trouble.

Unless we pay attention to the important issues involved and try for as much specification as possible of the disorders we are studying, our research efforts will tend to produce conflicting and disappointing results, and clinical practice will be the loser. We can learn from our past deficiencies and, hopefully, strive to improve the quality of our investigative efforts. I acknowledge that considerable effort and thought have gone into the planning and completion of DSM-IV, and in many ways it represents a considered attempt at improving the diagnostic nomenclature. However, DSM-IV, as indicated previously, has problems deriving from its categorical diagnostic system, and decisions concerning diagnoses have been reached on other than scientific or critical clinical study. As Meehl (1995) has suggested, "Further research of diagnostic systems should be based on taxometric analyses rather than on committed decisions based on clinical impressions and nontaxometric research" (p. 266). I would add, also, that frequent changes in official diagnostic systems create additional problems for research and should be avoided as much as possible and limited to those disorders that clearly need rather immediate revision or removal.

CHAPTER 3

Behavior Genetic Approaches to the Study of Psychopathology

Soo Hyun Rhee, Sarah A. Feigon, Jessica L. Bar, Yukiharu Hadeishi, and Irwin D. Waldman

Introduction

Psychopathologists have long been interested in the etiology of mental disorders. The earliest rudimentary attempts at classifying mental disorders were accompanied by similar efforts at divining their causes. Along with classification, treatment, developmental course, and outcome, etiology forms one of the cornerstones of psychopathological research. There are many approaches for investigating the underlying causes of a disorder. These include examining a broad class of biological variables such as psychophysiological, neurotransmitter, and hormonal activity, as well as social variables such as parental behavior, social class, peer group influences, and the effects of growing up in a particular neighborhood. Behavior genetic methods for investigating the etiology of a disorder represent a useful, complementary alternative to these other approaches. These methods that include family, adoption, and twin designs are particularly useful for disentangling genetic and

environmental influences on a disorder or its symptoms. As such, they have certain advantages over the other approaches mentioned, particularly that the distinction between genetic and environmental influences is typically “cleaner” than that between biological and social influences, for example. Nonetheless, as we will discuss at the end of this chapter, the most powerful inferences regarding etiology may come from combining behavior genetic methods with these other approaches to investigating etiology.

The past 15 years has seen a dramatic increase in the number of behavior genetic studies of psychopathology, the sample size in such studies, and the sophistication of the analytic methods used to infer genetic and environmental influences. It was not that long ago that the evidence for genetic and environmental influences on most psychiatric disorders came from a handful of studies using small, clinically referred samples. The first major shift came with the Scandinavian adoption studies of schizophrenia, affective disorder, alcoholism, and criminality. These studies employed national registries of both adoptions and mental disorders to recruit large samples of nonreferred adoptees and their adoptive (and often times biological) parents. Although the sample sizes in these studies were quite large, the statistical methods used were still fairly rudimentary and relied primarily on the simple comparison of parent–offspring concordances or correlations to infer genetic and environmental causes. Following from these adoption studies in

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

the 1970s and early 1980s came large twin studies of the major mental disorders, using more sophisticated biometric model-fitting methods that allowed statistical contrast of alternative etiological models for their fit to the observed correlations. In some studies, such analyses included correlations from many different familial relationships and combined data from many different samples to infer genetic and environmental influences while examining cross-sample heterogeneity (e.g., McGue, Gottesman, & Rao, 1985). Indeed, behavior genetic studies of psychopathology have increased sufficiently in number, sample size, and methodological sophistication that now a sufficient number of them permit meta-analyses for a number of disorders, including alcoholism (Heath et al., 1996), aggression (Miles & Carey, 1997), and antisocial behavior (Rhee & Waldman, 1998).

In this chapter, we will give a brief presentation of behavior genetic methods, focusing especially on twin designs, because twin studies have certain advantages over family and adoption designs. We will then summarize the results of recent behavior genetic studies for a number of the major mental disorders, including schizophrenia and schizophrenia spectrum disorders, mood and anxiety disorders, including childhood internalizing disorders, and childhood externalizing disorders. For a number of disorders, we will also review multivariate behavior genetic studies that are especially useful for illuminating comorbidity among disorders. We will conclude by highlighting some new approaches and future directions in behavior genetic studies of psychopathology. These will include approaches for examining whether genetic and environmental influences differ throughout the range of symptoms from those at the disordered extreme, the inclusion of specific environmental variables and putative endophenotypic variables within behavior genetic models, and the examination of genotype–environment interactions and correlations. In addition, although the focus of this chapter is on quantitative genetic studies, we will briefly discuss the promise of molecular genetic studies of psychopathology in the final section.

The Use of Twin Data for Drawing Inferences Regarding Genetic and Environmental Influences

Although family and adoption studies are part of the armamentarium of behavior genetic methods,

twin studies have become the design of choice in contemporary behavior genetic studies. Family studies are useful for examining whether and to what extent the causes of disorders are familial or nonfamilial but cannot resolve whether this familiarity is genetic or environmental in origin. Adoption and twin studies are required to disentangle genetic and environmental sources of familial aggregation of disorders. Twin studies have a number of advantages over adoption studies, however. These include greater accessibility and representativeness of samples to the general population, thus yielding greater generalizability of findings; contemporaneous measurement of relatives who are the same versus different ages (i.e., twin pairs versus adoptees and their biological and adoptive parents), which permits using the same rather than different measures; and greater statistical power due to both larger sample sizes and greater genetic similarity between relatives. In addition, it often is difficult if not impossible to assess disorders in the biological parents of adoptees, and the assessment of psychopathology in their adoptive parents frequently is based on retrospective reports. These factors make twin studies the more powerful, less problematic, and hence more popular behavior genetic design.

A brief description of the use of data from twins to estimate genetic and environmental influences on symptoms of a disorder may be helpful before reviewing the results of behavior genetic studies of psychopathology. Behavior geneticists typically are interested in disentangling three sets of influences that may cause individual differences or variation in a given trait. First, heritability, or h^2 , refers to the proportion of variance in the trait that is due to genetic differences among individuals in the population. Second, shared environmental influences, or c^2 , refer to the proportion of variance in the trait that is due to environmental influences that family members experience in common and which increase their similarity for the trait. Third, nonshared environmental influences, or e^2 , refer to the proportion of variance in the trait that is due to environmental influences that are experienced uniquely by family members and which decrease their similarity for the trait.

To estimate these influences, twin studies rely on the fact that monozygotic (MZ) twins are identical genetically, whereas fraternal or dizygotic (DZ) twins, just like non-twin siblings, on average, are only 50% similar genetically. It also is assumed that MZ twins are no more similar than

DZ twins for the *trait-relevant* aspects of the shared environment; that is, that environmental influences on the trait of interest are shared in common between members of fraternal twin pairs to the same extent that they are shared between members of identical twin pairs (this is known as the *equal environments assumption*). Given these assumptions, the correlation between identical twins comprises heritability and shared environmental influences (i.e., $r_{MZ} = h^2 + c^2$), because these are the two sets of influences that can contribute to identical twins' similarity for the trait. In contrast, the correlation between fraternal twins comprises one-half of heritability and shared environmental influences [i.e., $r_{DZ} = (1/2h^2) + c^2$], reflecting the smaller degree of genetic similarity between fraternal twins. Algebraic manipulation of the two equations for twin similarity allows one to estimate h^2 , c^2 , and e^2 [viz., $h^2 = 2(r_{MZ} - r_{DZ})$, $c^2 = 2r_{DZ} - r_{MZ}$, $e^2 = 1 - r_{MZ}$].

Although estimating these influences by using the twin correlations can be done simply by hand, contemporary behavior geneticists use biometric model-fitting analytic methods that can incorporate additional information on familial relationships (e.g., correlations between non-twin siblings or parents and their children), provide statistical tests of the adequacy of these three influences (viz., h^2 , c^2 , and e^2) in accounting for the observed familial correlations, and test alternative models for the causal influences underlying the trait (e.g.,

a model including genetic and nonshared environmental influences versus a model that also includes shared environmental influences). In the path diagram in Figure 1, we present a comprehensive biometric model for the genetic and environmental influences on symptoms of a disorder for two twins. This path diagram shows the basic biometric model (Neale & Cardon, 1992) for estimating additive and dominance genetic influences, shared and nonshared environmental influences, and the direct influence of one twin's behavior problems on the co-twin's behavior problems. Note that there are now two types of genetic influences, dominance and additive genetic influences, which are summed to arrive at an estimate of broad-sense heritability, or h^2 . Although this path model represents the full set of potential causes on twins' behavior problems, there is not enough information in the conventional twin study design to estimate all five of these parameters simultaneously. Consequently, contemporary twin studies present and contrast the results of a series of restricted models (i.e., models that contain a subset of all potential causes) to find the most parsimonious model that fits the data well.

In the path diagram in Figure 1, D represents dominance genetic influences, A represents additive genetic influences, C represents shared environmental influences, E represents nonshared environmental influences, and i represents the direct

Figure 1. Path model for univariate behavior genetic analyses of a disorder. D = dominance genetic influences, A = additive genetic influences, C = shared environmental influences, E = nonshared environmental influences, and i = direct influence of one twin's symptoms on the co-twin's symptoms.

influence of one twin or sibling's behavior problems on the co-twin or co-sibling's behavior problems. The circles that contain these capital letters represent these latent causal genetic and environmental variables, whereas the corresponding lower case letters (viz., d , a , c , e , and i) represent the magnitude of these influences (i.e., the parameter estimates, which are regression coefficients) on each twin or sibling's behavior problems. The squares of these parameter estimates (viz., d^2 , a^2 , c^2 , and e^2) represent the variance components corresponding to dominance and additive genetic influences and shared and nonshared environmental influences. The three correlations in the model— r_d , r_a , and r_c —represent the similarity of particular causal influences between twins. For example, MZ and DZ twins are both correlated 1.0 for shared environmental influences (viz., r_c) consistent with the equal environments assumption. In contrast, MZ twins are correlated 1.0 for both dominance and additive genetic influences (viz., r_d and r_a), whereas DZ twins are correlated .25 and .5 for dominance and additive genetic influences, respectively, consistent with their average level of genetic similarity.

Programs such as LISREL and MX (Jöreskog & Sörbom, 1999; Neale, Boker, Xie, & Maes, 1999) can iteratively fit such models to twin correlations (or variances and covariances) to provide the best estimates of the parameters; that is, parameter estimates that minimize the difference between the twin correlations implied by the model and those observed in the data. The fit of the model to the data is summarized by a χ^2 statistic, that allows statistical testing of both the fit of a given model and the comparative fit of alternative models. This property often results in restricted models—models that contain only a subset of the parameters in the full model (e.g., only a and e)—that provide an adequate fit to the data. In addition, although we presented the biometric model as it applies to data from twins, the model also can include siblings. This model is equally applicable to adoption study data on biologically related and adoptive siblings and can be extended to analyze data from biologically related and adoptive parent-offspring pairs.

These models and analyses also can be extended to examine genetic and environmental influences on the overlap or covariation between different disorders or symptom dimensions. A recent trend in behavior genetic analyses has been to

extend the investigation of genetic and environmental influences on traits considered singly to the case of multiple traits considered conjointly (Neale & Cardon, 1992). Multivariate behavior genetic analyses seek to explain the covariation among different traits by examining the common genetic and environmental influences. As suggested in the following sections that present the results of multivariate behavior genetic analyses, such analyses can shed considerable light on the classification of psychopathology and the nature of comorbidity. Most published multivariate behavior genetic studies of psychopathology have focused on testing whether the overlap among multiple disorders is due to genetic versus environmental influences and on estimating the magnitude of the genetic and environmental contributions to covariation among the symptoms of those disorders. Multivariate behavior genetic analyses can also be used in a more confirmatory manner to test specific hypotheses relevant to the classification and etiology of psychopathology. For example, one could test the alternative hypotheses that all genetic or environmental influences act individually on the anxiety disorders without contributing to their comorbidity, that the only genetic or environmental influences on specific and social phobias are those that also influence generalized anxiety disorder (GAD), or that the only genetic or environmental influences on specific and social phobias are completely independent of GAD. In addition, different specific alternative hypotheses can be tested for the genetic and shared and nonshared environmental influences. Conducting multivariate behavior genetic analyses in this hypothesis-driven fashion should ensure that their results are even more informative for resolving issues in classifying psychopathology.

A few brief examples should illustrate a number of the hypotheses that can be addressed using multivariate behavior genetic analytic methods. Shown in Figure 2 is a particular type of multivariate behavior genetic model, known as a Cholesky decomposition, which has been used most frequently in multivariate behavior genetic analyses of psychopathology. In this model, one first extracts the genetic and shared and nonshared environmental influences that specific and social phobia share in common with GAD (represented by factors A_1 , C_1 , and E_1 , respectively), then the genetic, and shared, and nonshared environmental influences that social phobia shares in common

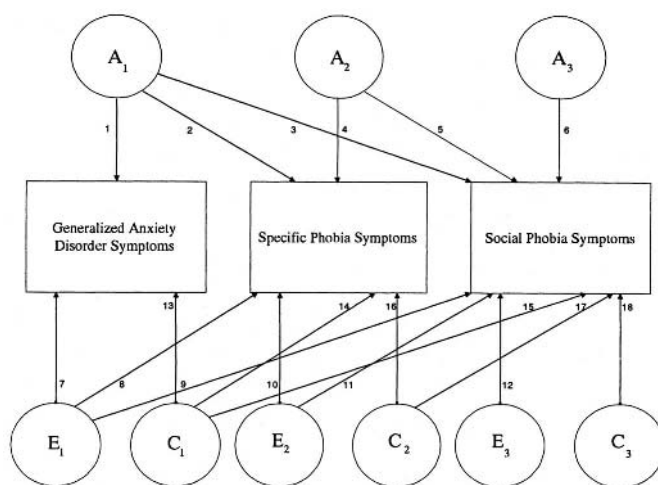

Figure 2. Cholesky decomposition of symptoms of three anxiety disorders.

with specific phobia that are not shared with GAD (represented by factors A_2 , C_2 , and E_2 , respectively), and finally the genetic and nonshared environmental influences that are unique to social phobia (represented by factors A_3 , C_3 , and E_3 , respectively). Although most often used in an exploratory fashion, this model can be used to test a number of substantively driven hypotheses regarding classification and comorbidity among anxiety disorders. As suggested before, one can test whether the only genetic influences on specific and social phobia are those that also influence GAD by testing whether one can drop paths 4–6 from the model without a decrement in fit and do the same for the nonshared environmental and shared environmental influences by dropping paths 10–12 and 16–18, respectively, and testing the change in model fit. One can also test the alternative hypothesis that the only genetic or environmental influences on specific and social phobia are completely independent of GAD by assessing the fit of the model if one drops paths 1–3, 7–9, and 13–15 for the common genetic, nonshared, and shared environmental influence factors, respectively.

Two more restrictive multivariate behavior genetic models, the independent and common pathway models, are shown in Figures 3 and 4. (These models also include symptoms of Panic Disorder to show how they would be extended to reflect four anxiety disorders). The independent pathway

model differs from the Cholesky decomposition in that for each etiological influence (viz., genetic and shared and nonshared environmental influences), there is a single common factor that underlies symptom covariation and a unique factor that is specific to each symptom dimension. The fact that there is only a single common factor for each etiological influence, rather than multiple factors for each etiological influence in the Cholesky decomposition model, means that the independent pathway model places greater constraints on the possible explanations of comorbidity among disorders than the Cholesky decomposition model. For example, the independent pathway model would provide a bad fit to the data if there were common genetic influences on GAD and Panic Disorder, and on specific and social phobia, that did not overlap each other, whereas a Cholesky decomposition model could fit these data quite well. The common pathway model is still more restrictive because it posits that symptoms of all four anxiety disorders reflect a common anxiety disorders factor that has a single set of underlying genetic and shared and nonshared environmental influences and residual genetic and environmental influences that are unique to the symptoms of each of the four disorders. Thus, the common pathway model places very strong constraints on explanations of comorbidity because the comorbidity between two disorders depends solely on their loadings on the latent anxiety disorders factor and the

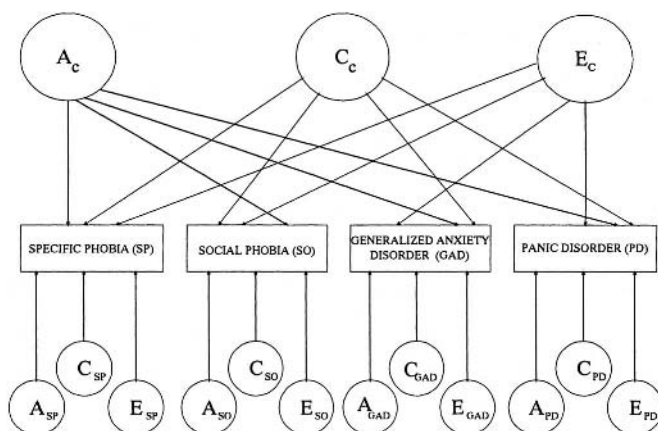

Figure 3. Multivariate genetic analysis of symptoms of four anxiety disorders— independent pathway model.

single set of genetic and shared and nonshared environmental influences that underlie it. Viewed another way, comparisons among these multivariate behavior genetic models provide a strong basis for contrasting competing models for the comorbidity among disorders.

Schizophrenia

Schizophrenia is a relatively common mental disorder that has a life-time prevalence of approximately 1% in the general population (Kleinman,

1988; Thakker & Ward, 1998). The disorder has been defined in various ways since it was first described by Bleuler and Kraepelin in the early 1900s (Kraepelin, 1904; Andreasen & Carpenter, 1993). At present, the most widely used definition of schizophrenia comes from the 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV, 1994). According to the DSM-IV, schizophrenia is defined by the presence of two or more of the following symptoms for a significant portion of time during a 1-month period: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, or neg-

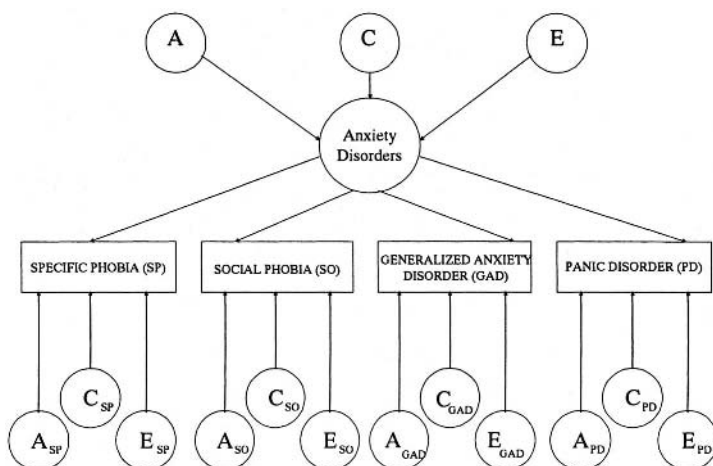

Figure 4. Multivariate genetic analysis of symptoms of four anxiety disorders—common pathway model.

ative symptoms, that is, affective flattening, avolition, or avolition. Research has found that this complex mental disorder is associated with a wide variety of both genetic and environmental risk factors (Cannon, Kaprio, Lonnqvist, Huttunen, & Koskenvuo, 1998; for reviews, see Van Os & Marcelis, 1998; McGuffin & Owen, 1996; Syvalahti, 1994; and Egan & Weinberger, 1997). Several different quantitative genetic models have been proposed to describe the etiology of schizophrenia (e.g., Slater, 1958; Elston, Namboodiri, Spence, & Rainer, 1978; Kidd & Cavalli-Sforza, 1973; Matthyse & Kidd, 1976; Gottesman & Shields, 1967). Behavioral genetic techniques can be used to determine the relative contribution of genetic and environmental influences on the development of schizophrenia.

One of the first things that behavioral geneticists noted in their study of schizophrenia is that the disorder tends to aggregate in families. Indeed, Kraepelin himself emphasized the importance of familial factors in his description of dementia praecox (Kraepelin, 1904). Family studies have indicated that the lifetime prevalence of schizophrenia in close relatives of schizophrenic patients is much higher than the population base rate of 1% noted before. Eight to ten percent of full siblings and 12 to 15% of the offspring of schizophrenic patients will be diagnosed as schizophrenic at some point during their lifetimes (Gottesman, 1993). Although these findings suggest that genetic factors may be involved in the etiology of schizophrenia, it is not possible to differentiate between genetic or environmental influences using data from family studies. These influences can be distinguished by using twin studies, many of which have been conducted over the years.

The twin study of schizophrenia conducted by Franz Kallmann is one of the largest twin studies of schizophrenia. As of 1950, Kallmann had registered a total of 953 schizophrenic index twin cases (Kallmann, 1950; Shields, Gottesman, & Slater, 1967). Four years before this, Kallmann published a more detailed report on 691 twin pairs which has received a great deal of scientific scrutiny over the years (Kallmann, 1946; see Jackson, 1960, and Rosenthal, 1962, for criticisms of Kallmann, 1946). Some of the criticisms that have been leveled against Kallmann's 1946 report have been addressed in subsequent reanalyses of Kallmann's original data (Kety, 1958; Shields et al., 1967). According to Shields et al.'s relatively conserva-

tive reanalysis of Kallmann's data, 50% of his MZ twins had both received definite diagnoses of schizophrenia, whereas only 6% of DZ twins were concordant for schizophrenia. It must be noted that these pairwise concordance rates may be artificially inflated due to the manner in which the schizophrenic co-twins were ascertained (see Shields et al., 1967, for practical reasons and Smith, 1974, for statistical reasons why this may be so). Indeed, the concordance rates reported by other investigators tend to be lower than Kallmann's concordance rates (Farmer, McGuffin, & Gottesman, 1987; Kendler & Robinette, 1983; Moskaleiko & Gindilis, 1981; Onstad, Skre, Torgersen, & Kringlen, 1991; Torrey, 1992; for reviews, see Gottesman, 1996; Portin & Alanen, 1997; Pulver et al., 1996; Tsuang, 1998; Van Os & Marcelis, 1998). Nevertheless, the concordance rates in MZ twins are higher than concordance rates for DZ twins in every twin study of schizophrenia conducted to date, thus providing strong evidence for the contention that genetic factors contribute to the development of this disorder. In addition, the fact that the concordance rate for MZ twins is far less than 100% suggests that nongenetic (i.e., environmental) factors play an important role in the etiology of schizophrenia.

One difficulty with the early twin studies reviewed before is that most of them used pairwise concordances to summarize the similarity between MZ and DZ twins. Probandwise concordances are superior to pairwise concordances in several ways (McGue, 1992). These include (1) characterizing risk for disorder at the level of the individual, rather than at the level of the twin pair, thus facilitating the comparison of risk to a twin with the risks to other types of relatives; (2) the similarity of probandwise concordances to concordances among other relatives (e.g., parents and their offspring) and to the prevalence of the disorder, whereas pairwise concordances have no direct analogue for non-twin relative pairs and are not directly comparable to the prevalence of the disorder. This renders the interpretation of pairwise concordances and the comparison of twin and non-twin resemblance difficult at best; (3) a clear and useful statistical basis for the interpretation of probandwise concordances (viz., the probability that a twin will be affected given that their co-twin is affected), which is lacking for pairwise concordances; and (4) valid estimation of the magnitude of twin resemblance under both complete

and incomplete ascertainment, and hence comparability across studies regardless of the thoroughness of ascertainment. In contrast, sample pairwise concordance rates vary as a function of the thoroughness of ascertainment and thus are not comparable across studies unless the studies have similar levels of ascertainment. In addition, Heath (personal communication, 1994) has pointed out that the analysis of tetrachoric correlations estimated from MZ and DZ concordances and population base rates yield more valid inferences regarding the magnitude of genetic and environmental influences than the concordances themselves, given that the interpretation of concordances and their differences depend heavily on the base rate of the disorder.

Other behavioral genetic studies have provided insight into the question of whether a single gene or multiple genes are responsible for the increased liability to develop schizophrenia. For example, a twin study conducted by Kendler and Robinette (1983) compared the single-locus, two-allele model of the transmission of schizophrenia with the polygenic, multifactorial threshold model (Falconer, 1965; Smith, 1974). The single locus, two-allele model assumes that schizophrenia is due to the effects of a single gene of major effect and that one allele confers a heightened risk for schizophrenia, whereas the other does not (Elston et al., 1978; Kruger, 1973; Slater, 1958). The multifactorial polygenic threshold model, on the other hand, posits that there are multiple genes each of which confers a small degree of risk of developing schizophrenia. According to the multifactorial threshold model, schizophrenia develops when the total liability toward schizophrenia due to the combined genetic and environmental risk factors exceeds a certain threshold. Kendler and Robinette (1983) were able to show that results for schizophrenia in their twin registry were not compatible with a fully penetrant, single-locus, two-allele model of schizophrenia with no phenocopies, nor were they compatible with the more flexible, generalized single-locus model developed by Kidd and Cavalli-Sforza (1973) that allows for incomplete penetrance and the presence of phenocopies. In contrast, their results were consistent with the multifactorial threshold model of the inheritance of schizophrenia. As Kendler and Robinette note, this superiority of the polygenic model to monogenic models is consistent with a more extensive model-fitting study conducted by

O'Rourke, Gottesman, Suarez, Rice, and Reich (1982). Making an assumption of polygenic transmission of schizophrenia allows behavioral geneticists to estimate the broad heritability of schizophrenia (Falconer, 1965). In the Kendler and Robinette study, for example, the estimated $h^2 = .91 \pm 0.16\%$. This value for h^2 is within the range obtained from other twin studies. Values for broad-sense heritability estimated from the concordance rates obtained in six studies cited in Gottesman's review of twin studies of schizophrenia (1991) vary between .52 and .92.

Adoption studies provide another way of disentangling genetic and environmental influences. If the incidence of schizophrenia in the adopted-away offspring of schizophrenic individuals raised by normal parents is higher than that of the adopted-away offspring of nonschizophrenic individuals, this provides strong evidence that genetic influences are involved in the etiology of schizophrenia. Indeed, this has been the case across schizophrenia adoption studies. For example, in the Danish Adoption Study, Kendler, Gruenberg, and Kinney (1994) compared the prevalence of DSM-III diagnoses of schizophrenia in the relatives of schizophrenic and control adoptees. The first-degree biological relatives of schizophrenic adoptees showed an increased risk for schizophrenia compared with the relatives of control adoptees (7.9% vs. 0.9%). This was also true if all interviewed biological relatives were taken into consideration (3.3% vs. 0.3%). The difference in prevalence was larger if the entire schizophrenia spectrum of disorders was considered (23.7% vs. 4.7% in first-degree relatives and 13.0% vs. 3.0% in all interviewed biological relatives).

Another useful method for disentangling genetic and environmental influences on schizophrenia is to compare the rates of schizophrenia in the offspring of MZ twins discordant for schizophrenia. If schizophrenia is primarily due to environmental factors, one would predict that the prevalence of schizophrenia should be considerably higher in the offspring of the schizophrenic twin than in the offspring of the nonschizophrenic co-twin. In contrast, to the extent that schizophrenia is genetically influenced, rates of schizophrenia will be equally high in both sets of offspring. The results of studies using this method are varied. In a follow-up study of Fischer's (1971) Danish twin sample, Gottesman and Bertelsen (1989) found no difference between the prevalence of schizo-

phrenia in the offspring of schizophrenic (16.8%, $N = 47$) and nonschizophrenic co-twins (17.4%, $N = 24$). The rates of schizophrenia in both sets of offspring are well above the prevalence in European populations, which is approximately 1% (Kleinman, 1988; Thakker & Ward, 1998). In a somewhat smaller study using the Norwegian national twin sample, Kringlen and Cramer (1989) found that, whereas 17.9% of the children of schizophrenic twins were later diagnosed with schizophrenia, only 4.4% of the children of nonschizophrenic twins developed schizophrenia. Although this difference does not quite reach statistical significance at the .05 level, the trend for the children of schizophrenic twins who have higher rates of schizophrenia does imply that familial environmental factors may significantly influence the development of schizophrenia in addition to genetic influences.

Considering the results of the disparate behavior genetic designs reviewed before, the overwhelming majority of the evidence indicates that genetic influences play a substantial role in the development of schizophrenia. Indeed, behavioral geneticists have progressed from asking the question of whether genetic factors are important in the etiology of schizophrenia to the question of which model of genetic transmission most accurately describes the inheritance of this disorder (Kendler and Robinette, 1983; McGue, Gottesman, & Rao, 1985; O'Rourke et al., 1982). In general, results of these model-fitting studies favor the multifactorial polygenic threshold model over other models of genetic transmission.

SCHIZOPHRENIA SPECTRUM DISORDERS

As reviewed before, strong evidence exists that schizophrenia is a familial disorder and that genetic influences are involved in the clustering of schizophrenia in families. The liability to schizophrenia seems to be manifested in families not only through the occurrence of the classical disorder, but through other related phenotypes as well. That is, the predisposition to schizophrenia may be expressed in a number of different ways, including schizophrenia-like personality traits and cognitive dysfunctions, personality disorders, and possibly some other nonschizophrenic psychoses. Disorders that occur more frequently in the bio-

logical relatives of schizophrenic individuals than in the biological relatives of nonschizophrenic individuals are called schizophrenia spectrum disorders. Disagreement exists as to the exact composition of this spectrum, however. An accurate description of its boundaries is necessary so that researchers can determine which phenotypes reflect susceptibility to schizophrenia and thus which phenotypes should be included in genetic research on schizophrenia. Examining how the various spectrum disorders aggregate in families can also provide information about the mode of genetic transmission of the liability.

The notion of a *spectrum* of schizophrenic disorders first arose nearly a hundred years ago, when psychiatrists and practitioners began to notice an excess of eccentric personality and character traits among the relatives of their patients with schizophrenia (e.g., Bleuler, 1911/1950; Kraepelin 1909–1913/1971). This less severe, nonpsychotic, familial syndrome was characterized by social anxiety, aloofness, limited emotional response, and odd or disordered thinking. Thus, Bleuler reasoned that schizophrenia might manifest itself in alternate forms and coined the term *latent schizophrenia*, which he applied to individuals who evidenced affective flattening, social withdrawal, and related characteristics, in the absence of psychotic symptoms. He noted that such a dimensional construct might be important for studies of the hereditary basis of schizophrenia.

The first systematic family study involving the schizophrenia spectrum was conducted at Kraepelin's Psychiatric Institute in 1916 (Rudin, 1916). Researchers noticed increased rates of schizophrenia and also of other potentially related psychotic disorders in the siblings of schizophrenic probands. The first behavior genetic study of schizophrenic spectrum disorders was conducted in 1941 in Sweden, when Essen-Moller decided to count twins who had mental disorders with schizophrenic features concordant with their schizophrenic co-twins (Essen-Moller, 1941). Essen-Moller noted the existence of schizophrenia-like personality traits in the schizophrenics' co-twins and found concordance rates of 64% for MZ pairs and 15% for DZ pairs. Early twin studies conducted in England and Japan found similar concordance rates (65% vs. 14% and 59% vs. 15%, respectively; Inouye, 1972; Slater, 1953). In addition, both studies found an excess of traits such as aloofness, lack of feeling, and suspiciousness in

the unaffected MZ co-twins and first-degree relatives of schizophrenic probands.

The study of schizophrenia spectrum disorders gained momentum in 1963 when Kety and his colleagues began the first large-scale adoption study of schizophrenia in Denmark (Kety, Rosenthal, Wender, & Schulsinger, 1968). The Danish Adoption Study was composed of a series of studies designed to gather information about which disorders occurred more frequently among the biological relatives of schizophrenic adoptees than among the biological relatives of control adoptees. In the first, or Copenhagen, sample, Kety looked at hospital records and conducted personal interviews with the biological and adoptive relatives of schizophrenic adoptees (Kety et al., 1968; Kety, Rosenthal, Wender, Schulsinger, & Jacobsen, 1975). Rates of latent schizophrenia—a DSM-II (American Psychiatric Association, 1968) disorder based on Bleuler's construct—were significantly elevated in the biological relatives of schizophrenic probands (14.8%) compared to those of control adoptees (0.9%). Rates were low and equal in the adoptive relatives of both the schizophrenic and nonschizophrenic adoptees. These findings provided empirical support for a schizophrenic-like, nonpsychotic disorder found in the relatives of individuals with schizophrenia. Moreover, the use of an adoption design provided support for Bleuler's idea that latent schizophrenia was related to schizophrenia itself through genetic factors. In 1975, Kety began gathering information for adoptees who lived throughout the rest of Denmark. The findings gathered from this Provincial sample replicated those of the Copenhagen sample (Kety, Rosenthal, Wender, Schulsinger, & Jacobsen, 1978). When both samples were combined to form a National sample, the rates of latent schizophrenia in the biological relatives of schizophrenic probands was 10.8%, whereas the corresponding rates in the biological relatives of control probands was 1.7% (Kety et al., 1994).

The results of Kety's studies were used to develop empirically based diagnostic criteria for DSM-III schizophrenia spectrum disorders (American Psychiatric Association, 1980; Spitzer, Endicott, & Gibbon, 1979). These included the diagnosis of "schizotypal personality disorder" (SPD), an operationalization of the schizophrenic-like, nonpsychotic syndrome of latent schizophrenia. (The term "schizotypal" was chosen because it means "like schizophrenia.") These criteria were later reapplied blindly to the same samples, and

Kety's original results based on global diagnoses were confirmed. For example, DSM-III schizotypal personality disorder was found in 13.6% of the biological relatives of schizophrenic adoptees in the Copenhagen sample, versus 2.0% of the biological relatives of control adoptees (Kendler, Gruenberg, & Strauss, 1981). The application of DSM-III criteria to the relatives of probands in the National sample resulted in rates of schizophrenia spectrum disorders (defined as schizophrenia; schizoaffective disorder, mainly schizophrenic subtype; and schizotypal and paranoid personality disorders) of 23.7% in the first-degree biological relatives of adoptees with DSM-III schizophrenia and 4.7% in the first-degree biological relatives of controls (Kendler et al., 1994). Lowing, Mirsky, and Pereira (1983) found that 15.4% of the adopted-away offspring of schizophrenic mothers in the sample had DSM-III SPD, compared with 7.7% of the adopted-away offspring of controls.

The Danish Adoption Study was the first to provide empirical evidence for the increased prevalence of a less severe, nonpsychotic, genetically related form of schizophrenia. Subsequent family, twin, and adoption studies have confirmed the presence of SPD in the families of schizophrenic individuals (Baron, Gruen, Rainer, et al., 1985; Frangos, Athanassenas, Tsitourides, Katsanou, & Alexandrakou, 1985; Gershon et al., 1988; Kendler, McGuire, Gruenberg, O'Hare, et al., 1993). Kendler & Gardner (1997) found that odds ratios (OR) for SPD in the first-degree biological relatives of schizophrenic probands were homogeneous across three independent family studies and computed a common OR estimate of 5.0 for SPD. Higher rates of schizophrenia were also found among the relatives of probands with SPD, compared with the relatives of psychiatric and normal controls (Baron, Gruen, Anis, & Lord, 1985; Battaglia et al., 1991; Lenzenweger & Loranger, 1989; Schulz et al., 1986; Siever et al., 1990). Researchers now seek to further clarify the nature of SPD by determining its heritable components, that is, which of the components of SPD are seen more frequently in the biological relatives of individuals with schizophrenia and which are affected by genetic influences common to schizophrenia. It appears that SPD may be a heterogeneous category, that is, only part of the disorder defined by DSM-IV (American Psychiatric Association, 1994) may be heritable. In particular, family, twin, and adoption studies suggest that, among schizotypal crite-

ria, only eccentricity, affective constriction, and excessive social anxiety are genetically related to schizophrenia (Torgersen, 1994).

Analyses of interviews of the biological relatives of schizophrenic probands from the Danish Adoption Study found that these relatives were more likely to describe themselves as having been withdrawn or antisocial as children (Ingraham, 1995; Kendler, Gruenberg, & Strauss, 1982). Three traits were observed more frequently among the biological relatives of schizophrenic probands: suspiciousness, flat affect, and withdrawn behavior. Psychotic-like features (e.g., cognitive and perceptual distortions) were not observed. Subsequent twin studies have replicated these findings. In a series of studies conducted with the Norwegian Twin Registry, Torgersen found a higher frequency of SPD among MZ co-twins of probands with SPD compared with DZ co-twins (33% vs. 4%), as well as increased rates of SPD in the MZ co-twins of schizophrenics compared with DZ co-twins (20% vs. 14.8%) (Torgersen, 1984; Torgersen, Onstad, Skre, Edvardsen, & Kringlen, 1993). Personal interviews showed that feelings of isolation, social anxiety, and inadequacy were common among the co-twins of schizophrenic probands and that inappropriate affect and odd speech and behavior also were common among first-degree relatives. Psychotic-like phenomena were absent once again. Torgersen et al. (1993) concluded that schizotypal features were genetically transmitted but that the only heritable aspects of SPD were the affect-constricted and eccentric features. Further evidence that the negative symptom criteria of SPD may be heritable independently of the positive symptom criteria comes from Kendler, Ochs, Gorman, and Hewitt's (1991) factor analysis of schizotypal symptoms in normal MZ twins. The authors' factor analyses revealed two independent dimensions of schizotypy, one related to the social withdrawal and deficit symptoms, the other related to the positive, or psychotic-like, symptoms. Thus findings from behavior genetic studies of SPD seem to consistently point to the negative symptom criteria of SPD as those responsible for its familial association with, and genetic relatedness to, schizophrenia. Negative symptoms may be a more direct reflection, or true manifestation, of the underlying schizophrenic genotype—an interpretation consistent with Bleuler's early descriptions.

Evidence that supports the inclusion of DSM-IV disorders other than SPD in the schizophrenia

spectrum is less consistent. Elevated rates of paranoid personality disorder (PPD) were found in the biological relatives of schizophrenic adoptees, compared to controls in the Copenhagen sample of the Danish Adoption Study (6% vs. 1%; Kendler, Masterson, Ungaro, & Davis, 1984). In contrast, Lowing et al. (1983) did not find a higher frequency of PPD in the adopted-away offspring of schizophrenic, compared to control parents, but did find increased rates of schizoid personality disorder (10% vs. 3%). The relationships between these personality disorders and schizophrenia may be an artifact, however. Both PPD and schizoid personality disorder are defined by a subset of SPD criteria; thus diagnoses of either may be coextensive with a diagnosis of SPD (Parnas et al., 1993). The literature on psychotic disorders is also inconsistent. Several family studies have found higher rates of schizoaffective disorder among the relatives of schizophrenic than among control probands (Gershon et al., 1988; Maier, Hallmayer, Minges, & Lichtermann, 1990; Kendler, McGuire, Gruenberg, Spellman, et al., 1993). Some evidence for a familial relationship between nonaffective psychoses and schizophrenia also exists, and studies found increased rates of schizophreniform disorder, delusional disorder, and/or atypical psychosis in the families of schizophrenic versus control probands (Baron, Gruen, Rainer, et al., 1985; Gershon et al., 1988; Kendler, Gruenberg, & Tsuang, 1985; Kendler, McGuire, Gruenberg, Spellman, et al., 1993; Maier et al., 1990). Kendler and Gardner (1997) computed a common OR estimate of 4.0 for "other non-affective psychoses" across three independent family studies. These included the DSM-III/DSM-III-R (American Psychiatric Association, 1987) categories of schizophreniform disorder, schizoaffective disorder, delusional disorder, and atypical psychosis (psychosis not otherwise specified).

In sum, the boundaries of the schizophrenia spectrum extend from schizophrenia-like personality traits such as poor social functioning, odd thoughts and behavior, and suspiciousness at one end, to the full-blown disorder of classical schizophrenia at the other. Included within these boundaries are the DSM-IV disorders of SPD, possibly PPD, and probably several other nonschizophrenic psychotic disorders (Kendler & Gruenberg, 1984). Many family studies have been conducted to establish that a familial association exists between these disorders and schizophrenia, but fewer twin and adoption studies have been

conducted to investigate the role that genetic influences play in their etiology. As stated earlier, different models exist to explain the genetic transmission of the liability to schizophrenia. For example, some researchers believe that a single major gene specific to schizophrenia exists, and that this liability will be expressed in alternative phenotypes, depending upon the presence or absence of other genetic potentiators and environmental stressors (Meehl, 1962). An influential alternative model is the multifactorial polygenic threshold model (Gottesman & Shields, 1982). According to this view, there is no single gene primarily responsible for the liability to schizophrenia. Rather, a large number of vulnerability genes and environmental influences exist that contribute to an individual's liability, and a liability threshold must be surpassed for an individual to manifest the disorder. Thus, different disorder phenotypes will be expressed by surpassing successively higher severity thresholds. Mixed models combine features of both of them. For example, a single major gene may operate in some families in addition to the polygenic effects that may be primarily responsible for the genetic liability to schizophrenia (Morton & MacLean, 1974). Alternatively, several genes may be necessary but not sufficient to trigger vulnerability (Gottesman, 1991). A better understanding through twin and adoption studies of the way spectrum disorders are genetically related to schizophrenia, combined with knowledge about the way these disorders aggregate in families, will help researchers decide which, if any, of these models may be correct. Knowledge of the genetic model underlying schizophrenia and the schizophrenia spectrum disorders can help significantly in guiding molecular genetic studies of these disorders.

MOOD AND ANXIETY DISORDERS

The results of recent twin studies of mood and anxiety disorder symptoms across the life span suggest some differences in the etiology of these symptoms in childhood versus adulthood. Only a few twin studies have been conducted with children and adolescents, so we will begin with a review of the more extensive adult findings. In the final section of the chapter, we discuss the potential theoretical implications of discrepancies between the child and adult findings concerning mood and

anxiety disorder symptoms in terms of genotype-environment correlation. In this section, we will review univariate findings (concerning the etiology of a single symptom dimension) before discussing multivariate findings (concerning common etiological influences acting on two or more different symptom dimensions) for mood and anxiety disorders.

Univariate Studies of Mood and Anxiety Disorder Symptoms

Adults. Kendler, Heath, Martin, & Eaves (1986) examined the causes of individual differences in anxiety and depressive symptoms in adults recruited from a large, nationwide twin registry in Australia. Symptoms of anxiety and depression were assessed by using a self-report questionnaire, the Delusions-Symptoms-States Inventory (DSSI). The authors found that a model including only genetic and nonshared environmental influences provided a satisfactory fit to the observed data, and the heritability for most symptoms ranged from .33 to .46. Several studies have been based on assessments of DSM-III, DSM-III-R, or DSM-IV affective disorders. In a sample of adult female twins recruited from a large population-based twin registry in Virginia, Kendler and colleagues (1992b) found that liability to major depression was moderately heritable ($h^2 = .20$ to $.45$), and the remainder of the variance in liability was once again attributable to nonshared environmental influences. The authors later conducted analyses on follow-up data from the same sample that allowed them to control for unreliability of measurement and obtained an increased heritability estimate of around 70% for major depression (Kendler et al., 1993b). This suggests that a sizable proportion of the nonshared environmental influences in the earlier study was due to measurement error rather than specific environmental risk factors. Kendler et al. (1994) extended these findings to twins and to non-twin relatives recruited from the American Association of Retired Persons as well as the Virginia Twin Registry and found that additive genetic influences explained 30–37% of the variance in symptoms, with no evidence for shared environmental influences.

Consistent with these results from unselected samples, McGuffin, Katz, Watkins, and Rutherford (1996) obtained moderate estimates of the heritability for unipolar depression by using a va-

riety of diagnostic criteria in a selected sample of hospitalized adult probands and their co-twins, where h^2 ranged from .48 to .75. Once again, the authors found no evidence for shared environmental influences. The higher heritability obtained in the McGuffin et al. study may be due to sampling characteristics because hospitalized probands are more likely to be severely ill than individuals who manifest depressive symptoms in an unselected sample.

Kendler et al. (1996) were interested in determining whether various alternative manifestations of depression would show different etiologies. They performed a latent class analysis of the DSM-III-R symptoms of major depression in a population-based sample of female twins. The analysis yielded three classes of clinically significant depressive symptoms, which were termed "severe typical depression" (distinguished by frequent weight loss and decreased appetite rather than weight gain and increased appetite, insomnia rather than hypersomnia, and frequent co-occurrence of anxiety and panic), "mild typical depression" (characterized by similar but less severe symptoms than "severe typical depression"), and "atypical depression" (characterized by frequent hypersomnia, increased appetite, and weight gain, associated with co-occurring bulimia). They found that among twins concordant for major depression, concordance for the specific subtype was more common than would be predicted by chance. The concordance for specific subtype of depression was also greater in monozygotic than in dizygotic twins, suggesting a genetic basis for the observed patterns of symptoms. They concluded that depression is not etiologically homogeneous but may consist of subtypes that have differing etiologies.

Finally, several studies examined the causes of affective illness defined broadly (including both depressive disorders and bipolar disorders). McGuffin and Katz (1989) reanalyzed twin data previously reported by Bertelsen, Harvald, and Hauge (1977) and obtained a high heritability of .86, with a very modest contribution of environmental influences ($c^2 = .07$; $e^2 = .07$). Kendler, Pedersen, Neale, and Mathé (1995) assessed genetic and environmental influences on affective illness (defined using DSM-III-R diagnostic criteria as either major depression [with or without history of mania] or bipolar illness) in a combined hospital-ascertained and population-based (i.e., unselected) Swedish

sample. The hospital-ascertained sample was combined with the unselected sample to increase the number of participants with rare diagnoses such as bipolar illness without sacrificing the greater generalizability afforded by including nonreferred participants (Kendler et al., 1995). The authors did not find that the estimated heritability of affective illness (either bipolar or unipolar illness) differed between the hospital-ascertained and population-ascertained samples. They found that liability to major depression (with or without mania) was attributable primarily to genetic influences ($h^2 = .60$) and the remaining liability variance was attributable to nonshared environmental influences and measurement error. Potential explanations for the higher heritability found in this study, compared with the results obtained by Kendler et al. (1992b), include the older average age of subjects in the Swedish study, the use of questionnaire versus interview-based assessment, and possible population heterogeneity in the variance component estimates. Liability to bipolar illness was more highly heritable ($h^2 = .79$) than liability to major depression, and liability to affective illness (defined as either bipolar or unipolar illness) was intermediate in heritability ($h^2 = .64$), the remaining liability variance in all cases was attributable solely to nonshared environmental influences and measurement error.

Univariate behavior genetic findings for anxiety disorders suggest a pattern of causal influences similar to those found for depression. Several large-scale behavior genetic studies of anxiety disorders in adults have been conducted using DSM-III or DSM-III-R diagnostic criteria. Kendler, Neale, Kessler, Heath, & Eaves (1992a), using data from the same Virginia-based, adult female sample described before, conducted model-fitting analyses on liability to DSM-III generalized anxiety disorder and reported that the best fitting model included additive genetic and nonshared environmental influences, and about 30% of the variance in liability was attributable to additive genetic influences. The same authors (Kendler et al., 1993a) conducted univariate analyses of liability to DSM-III-R panic disorder in women from the same twin sample. Results were similar to those for generalized anxiety disorder, that is, a model including additive genetic and nonshared environmental influences provided the best fit to the data for most definitions of panic disorder, and genetic influences accounted for about 30% of the

variance in liability. In the case of phobias, Kendler et al. (1992d) reported that liability to any phobia (agoraphobia, social phobia, animal phobia, or situational phobia) in women drawn from the Virginia population-based sample was attributable solely to additive genetic and nonshared environmental influences, and the heritability was .32. The only phobia subtype for which shared environmental influences contributed significantly to liability was situational phobias (e.g., phobias of tunnels, bridges, and airplanes). No significant heritable influences were found for this phobia subtype. Shared environmental influences, it was estimated, accounted for 27% of the variance in liability to situational phobias, and the remaining variance was attributable solely to nonshared environmental influences. Heritabilities were moderate (and similar) for agoraphobia ($h^2 = .39$), social phobia ($h^2 = .32$), and animal phobias ($h^2 = .32$).

Univariate behavior genetic analyses have suggested that both depression and anxiety are moderately heritable in adults. Expressed differently, these findings suggest that nonshared environmental influences account for at least half of the variance in symptoms of anxiety and depression in adults. Bear in mind, however, that part of the nonshared environmental portion of the variance represents measurement errors; therefore, when estimates are corrected for unreliability of measurement, heritability estimates may increase somewhat (e.g., Kendler et al., 1993b). Still, environmental influences almost always account for a significant portion (usually at least a third) of the population variance in symptoms of these disorders, even after correction for measurement error. There is little evidence, however, that shared environmental influences are an important source of variation in adults' symptoms.

Children and Adolescents. There have been several univariate twin studies of depressive symptoms in childhood. Eley and Stevenson (1997; see Eley, 1997) obtained evidence for a small-to-moderate effect of shared environmental influences (accounting for about 20% of the variance) as well as additive genetic influences (accounting for about a third of the variance) in children's self-reported depressive symptoms. Thapar and McGuffin (1994) found that the presence of shared environmental influences on depressive symptoms depended upon the age of the children. In younger children (age 8–11), variation in symptoms

was attributable predominantly to shared environmental influences ($c^2 = .77$), whereas in adolescents (ages 11–16), shared environmental influences could be dropped from the model, and additive genetic influences, it was found, accounted for the majority (70–80%) of the variance in symptoms. Eaves et al. (1997) also found modest shared environmental influences (as well as moderate genetic influences) on depressive symptoms, but only when children's self-report was used ($h^2 = .15$ –.16; $c^2 = .14$ –.26). When parent report was used, depressive symptoms in children were highly heritable, and there was no evidence for shared environmental influences ($h^2 = .54$ –.66). Finally, Rende, Plomin, Reiss, & Hetherington (1993) found shared environmental influences for extreme depression scores in adolescents ($c^2 = .44$) and no significant genetic influence on extreme scores. In contrast, these authors found genetic influences, but not shared environmental influences, for individual differences in the normal range of depressive symptoms ($h^2 = .34$).

With regard to anxiety symptoms, Thapar and McGuffin (1995) reported that variation in parent ratings of children's anxiety symptoms (using the Revised Children's Manifest Anxiety Scale) could be accounted for by additive genetic and nonshared environmental influences, and that the heritability was .59. In contrast, when child report was used, additive genetic influences could be dropped from the model, and shared environmental influences accounted for 55% of the variance. Topolski et al. (1997) reported that shared environmental influences, but not additive genetic influences, substantially influenced liability to DSM-III-R separation anxiety disorder (SAD) in children ages 8–16 using children's self-report ($c^2 = .40$). For overanxious disorder (OAD, a DSM-III-R diagnosis that corresponds to DSM-IV GAD), on the other hand, they found that shared environmental influences could be dropped from the model without a significant reduction in fit, whereas additive genetic influences, it was estimated, contributed moderately to the variance in liability ($h^2 = .37$).

The finding of shared environmental influences on children's anxiety symptoms is not limited to self-report data, however. Slutske et al. (1996) reported that genetic and shared environmental influences each accounted for roughly half of the variance ($h^2 = .52$; $c^2 = .38$) in lifetime DSM-IV SAD symptoms in adolescent girls using mother

report. Similarly, Feigon et al. (1997a) found moderate genetic and shared environmental influences on parent-rated DSM-III-R SAD symptoms among nonreferred Australian twin children ages 4–18 ($h^2 = .46$; $c^2 = .22$). The same authors (Feigon et al., 1997b) also found moderate shared environmental, as well as genetic, influences on DSM-III-R avoidant disorder symptoms ($h^2 = .41$; $c^2 = .52$) and somatic complaints ($h^2 = .45$; $c^2 = .37$) in children. Eley and Stevenson (1997) found that shared environmental influences accounted for about a third of the variance in children's anxiety symptoms using several self-report scales, and about 10% of the variance was due to genetic influences. Feigon and Waldman (1998) obtained similar estimates of genetic and environmental influences on mother reports of SAD symptoms ($h^2 = .58$; $c^2 = .27$) and GAD symptoms ($h^2 = .36$; $c^2 = .35$) but did not find any shared environmental influences on social phobia symptoms ($h^2 = .67$) in twins aged 5–18 recruited from the Georgia Twin Registry. The authors also found significant etiological heterogeneity due to sex in the case of SAD and evidence for shared environmental influences on girls' but not boys' symptoms. Genetic influences on SAD symptoms were greater in boys than girls ($h^2 = .83$ and $.49$, respectively).

In contrast to other findings that support a substantial shared environmental contribution to children's anxiety symptoms, Eaves et al. (1997) did not find evidence for shared environmental influences on symptoms of either DSM-III-R SAD or OAD in children ages 8–16. In their sample, additive genetic influences, it was estimated, accounted for about 75% of the variance in SAD symptoms for girls ages 8–16 when parent report was used, but there was no substantial familial correlation among boys. When child report was used, the heritability estimates were modest in boys ($h^2 = .19$) and girls ($h^2 = .31$), but there was still no evidence for shared environmental influences in either sex. For OAD, they found moderate additive genetic influences in both boys and girls ($h^2 = .30$ – $.66$). Surprisingly, in contrast to the results for SAD and OAD, shared environmental influences were moderate on a self-report, composite measure of global anxiety symptoms in boys ($c^2 = .33$).

In contrast to the failure to find appreciable shared environmental influences on mood and anxiety, disorder symptoms in adults, the results from several twin studies suggest that shared envi-

ronmental influences, as well as additive genetic influences and nonshared environmental influences, contribute moderately to anxiety and mood symptoms in children (collectively termed the childhood internalizing disorders). The finding of shared environmental influences on children's internalizing symptoms is not entirely consistent, however, with heterogeneity across diagnostic categories, parent versus child informant, and variables such as age and sex (see Feigon, Waldman, Levy, & Hay, 1997b; Feigon & Waldman, 1998). An important caveat is also that rater effects, such as the tendency for parents to contrast their DZ twins when rating their characteristics, may lead to biased heritability and shared environmental influence estimates in children and adolescents. In future studies, these methodological issues and discrepant findings will need to be addressed by using models that incorporate information from multiple raters. With respect to the generalizability of the findings reviewed, it is worth noting that few studies of anxiety and mood disorders in children have employed DSM diagnoses based upon strict diagnostic criteria (although most of the studies reported here assessed DSM-III or DSM-III-R symptoms), and most have been based on self- or parent-report questionnaires rather than on diagnostic interviews (exceptions are the studies by Eaves et al., 1997, and Topolski et al., 1997, in which assessments were both interview- and questionnaire-based).

Multivariate Behavior Genetic Studies of Mood and Anxiety Disorder Symptoms

Most multivariate behavior genetic contributions to the classification of mood and anxiety disorders have been based on three general approaches: (1) split an existing diagnostic category into subtypes and examine differences in the causes of the resulting subtypes; (2) look for common causes that cut across the symptoms of several diagnostic categories, using multivariate behavior genetic methods; or (3) combine the first two approaches (i.e., break down a given diagnostic category into clusters of symptoms and then examine their common causes) to determine whether the etiologies of various symptom clusters may be partially overlapping and partially independent.

One example of the splitting approach is the

study by Kendler et al. (1996; see earlier), who reported that genetic and environmental influences on various subtypes of depressive illness appeared to have different etiologies. Research with adults suggests that genes may act in a non-specific way to confer risk for a variety of mood and anxiety syndromes, and the particular syndrome manifested depends either on the degree of genetic risk (e.g., as indexed by number of ill relatives) or on individual-specific, nonshared environmental influences. On the other hand, a few studies (reviewed later) suggest that the mood and anxiety syndromes are etiologically heterogeneous, and different sets of genes and/or environmental risk factors influence different patterns of symptoms within a diagnostic grouping. In this way, behavior genetic research can contribute to the development of an etiologically based classification of psychopathological syndromes. Following, we review multivariate behavior genetic studies that have contributed to our understanding of the boundaries between different mood and anxiety disorders by examining their common and unique causes.

Adults. Kendler et al. (1992c) reported that additive genetic influences largely explained the observed covariation of symptoms of GAD and major depression in women and were entirely shared between the two disorders; nonshared environmental influences accounted for the remaining unique liability variance for these disorders. The finding of a common genetic factor for GAD and major depression (with no unique genetic influences) was replicated by Roy, Neale, Pedersen, Mathé, and Kendler (1995) in an extension to a mixed male and female adult sample. Kendler et al. (1993c) also found that the observed covariation of major depression and phobia symptoms in women was largely attributable to additive genetic influences and that nonshared environmental influences contributed to the unique variance in liability to each of the two disorders. When the same authors investigated sources of overlap among phobias (agoraphobia, social phobia, animal phobia, and situational phobia; Kendler et al., 1992d), they found that the familial aggregation of these phobias in women could be explained by common genetic and nonshared environmental influences and that additional unique genetic and nonshared environmental influences contributed to the variance in liability to each of the specific subtypes of phobia. For most of the phobias (except animal

phobia), however, the common nonshared environmental factor contributed a greater share of the liability variance than the common genetic factor. Using the same Virginia-based twin sample, Kendler et al. (1995) examined the causes of comorbidity among panic disorder, phobias, GAD, major depression, alcoholism, and bulimia nervosa in women. They reported that the genetic influences responsible for the overlap between major depression and GAD in female twins appeared to be distinct from the genetic influences responsible for the overlap between panic disorder and phobias. Based on the finding of more than one shared genetic factor, the authors speculated that the anxiety disorders may be etiologically heterogeneous. Although provocative, this hypothesis seems hard to reconcile with the earlier findings by this group on common genetic influences on depression and phobias (Kendler et al., 1993c).

Additional evidence for a genetic basis to the overlap of anxiety and depressive symptoms comes from studies using the Australian National Health and Medical Research Council twin Registry, a nationwide, volunteer registry. Jardine, Martin, and Henderson (1984) found that genetic influences accounted for about 50–60% of the observed covariance between Neuroticism (a personality dimension associated with risk for mood and anxiety disorders), symptoms of anxiety, and symptoms of depression, and that the remaining covariation was attributable to nonshared environmental influences and/or measurement error. Kendler, Heath, Martin, and Eaves (1987) reanalyzed the same data (focusing on anxiety and depressive symptoms but not Neuroticism), and concluded that common genetic influences largely-explained the covariance between anxiety symptoms and depressive symptoms, and that nonshared environmental influences primarily contributed to the unique variance in anxiety and depressive symptoms.

The relationship between unipolar affective disorder and bipolar affective disorder has also been examined using twin data. Kendler, Pedersen, Neale, and Mathé (1995) reported that their data were consistent with a multiple threshold model in which the two forms of affective disorder are alternative manifestations of a single continuum of liability, rather than separate phenomena with distinct causes, and that bipolar disorder represents a more severe point on the continuum. Karkowski and Kendler (1997) analyzed data from the Virginia-based female twin sample described ear-

lier and reported that the data supported the conceptualization of unipolar and bipolar affective disorder as points of differing severity along the same continuum of illness (i.e., the two disorders have common causes). The application of the multiple threshold model to the bipolar-unipolar distinction is also consistent with two other pieces of data: (1) epidemiological studies showing that bipolar disorder occurs much less frequently in the population than unipolar depressive disorder, and (2) family studies showing a higher rate of affective disorders in the relatives of bipolar versus unipolar probands (Tsuang & Faraone, 1996). Both the greater familial loading of affective disorders in bipolar patients compared to unipolar patients and the lower population prevalence of bipolar compared to unipolar disorder are consistent with a model in which bipolar disorder is only manifest when a higher threshold of liability (resulting from a high degree of genetic and/or environmental risk) is surpassed.

Evidence from multivariate behavior genetic analyses in adult twin samples suggests that familial causes contribute substantially to the diagnostic overlap (or symptom covariation) among the anxiety and depressive disorders. In addition, the results of these studies suggest that the familial causes underlying the covariation among anxiety and depressive symptoms in adults are largely or entirely genetic. Now we review the results of the few multivariate behavior genetic studies of mood and anxiety disorders in children and adolescents to examine the extent to which the causes of comorbidity are similar to those found in adults.

Children and Adolescents. In contrast to the growing body of data on genetic and environmental influences on the covariation between anxiety and depressive symptoms in adults, very few multivariate behavior genetic studies of similar disorders or symptoms have been conducted with children and adolescents. Recently, two multivariate behavior genetic studies examined the causes of covariation among symptoms of various internalizing disorders in children. Eley and Stevenson (1997; see Eley, 1997) found that genetic influences accounted for 80% of the covariation between children's reports of anxiety and depressive symptoms and that shared environmental influences explained the remaining 20% of the covariation. Feigon et al. (1997b) examined the causes of covariation among three different types of anxiety disorder symptoms (separation anxiety symp-

oms, avoidant disorder symptoms, and somatic complaints) and found that the covariation among the three types of symptoms was largely attributable to common environmental influences (primarily common shared environmental influences). There was no evidence for common genetic influences on symptom covariation, that is, genetic influences contributed only to the variance that was unique to each of the three types of symptoms.

Thus, studies obtained evidence for common shared environmental influences on symptom overlap, although the magnitude of these influences differed greatly between the two studies. An obvious difference, of course, is the finding of substantial common genetic influences on symptom overlap in Eley and Stevenson's but not Feigon et al.'s study. Several differences in design may have contributed to the differences in the findings of these two studies. One difference is that Eley and Stevenson (1997) were interested in the causes of covariation between anxiety and depressive symptoms, whereas Feigon et al.'s (1997b) study was concerned with the causes of covariation among various types of anxiety symptoms. A second difference is that Feigon et al. used parent ratings of symptoms and Eley and Stevenson used child self-report measures. Both studies, however, support the notion that familial causes (whether genetic or shared environmental) are likely to be most important in accounting for the overlap among anxiety and depression disorders in children, as well as in adults. Additional data from new twin samples are needed to clarify the causal mechanisms that underlie comorbidity between anxiety and depressive disorders in children and adolescents.

CHILDHOOD DISRUPTIVE BEHAVIOR DISORDERS

In this section, behavior genetic studies that examined childhood externalizing disorders (i.e., the disruptive behavior disorders attention deficit hyperactivity disorder [ADHD], oppositional defiant disorder [ODD], and conduct disorder [CD]) will be reviewed. ADHD is characterized by symptoms of inattention, hyperactivity, and impulsivity. Although the distinction between inattention, hyperactivity, and impulsivity, on the one hand, and aggression and conduct problems, on the other, was at one time controversial (see Bark-

ley, 1982; Rutter, 1983), recent reviews and studies (e.g., Hinshaw, 1987; Loney & Milich, 1982) have provided ample support for their discriminant validity. The essential feature of ODD is defiant, hostile behavior toward authority (e.g., parents and teachers), whereas the essential feature of CD is serious violation of age-appropriate norms and rules. In a review of studies that examined the relationship between ODD and CD, Loeber, Lahey, and Thomas (1991) concluded that ODD and CD are developmentally related but clearly distinct and that there are unique covarying groups of ODD and CD symptoms.

Univariate Behavior Genetic Studies of Childhood Disruptive Behavior Disorders

ADHD. The largest family studies of ADHD were conducted by Biederman and his colleagues (e.g., Biederman et al., 1986; Biederman, Faraone, Keenan, Knee, & Tsuang, 1990; Biederman et al., 1992). In general, they found that the first-degree relatives of ADHD probands are at significantly higher risk of ADHD than the first-degree relatives of controls. The risk of ADHD for the relatives of probands increases further when ADHD in the probands is accompanied by CD (Faraone, Biederman, Keenan, & Tsuang, 1991; Faraone, Biederman, Jetton, & Tsuang, 1997).

Adoption studies of ADHD provide evidence that the familiarity in ADHD can be attributed largely to genetic influences. Biological parents of hyperactive children are more likely to have been hyperactive themselves as children or to show signs of attentional problems (e.g., slower mean reaction times) than the adoptive parents of hyperactive children (Alberts-Corush, Firestone, & Goodman, 1986; Cantwell, 1975; Morrison & Stewart, 1971). A history of psychiatric problems in their biological parents is also related to increased rates of hyperactivity or ADHD in adoptees (Cadoret & Stewart, 1991; Cunningham, Cadoret, Loftus, & Edwards, 1975).

Goodman and Stevenson (1989) conducted the first large twin study (102 MZ and 111 same-sex DZ twin pairs) of ADHD symptoms and reported heritability estimates that ranged from 32 to 42% ($c^2 = 12$ to 28%; $e^2 = 40$ to 46%) for measures of inattention and 42 to 100% ($c^2 = 0$ to 27%; $e^2 = 0$ to 58%) for measures of hyperactivity. Gilger, Pennington, and DeFries (1992) assessed ADHD

in eighty-one MZ and fifty-two DZ twin pairs using the Diagnostic Interview for Children and Adolescents and found that the probandwise concordance rates were significantly different for MZ (81%) and DZ (29%) twin pairs. Waldman, Rhee, Hay, and Levy (1998) examined DSM-III-R ADHD symptoms in a large population-based twin sample (1034 MZ pairs, 1009 DZ pairs, and 345 sibling pairs) and found that ADHD was influenced mostly by genetics ($h^2 = .90$; $e^2 = .10$).

Edelbrock, Rende, Plomin, and Thompson (1995) examined Child Behavior Checklist (CBCL) attentional problems in ninety-nine MZ and eighty-two DZ twin pairs and found evidence of significant genetic influences but no shared environmental influences ($h^2 = .66$; $e^2 = .34$). Schmitz, Fulker, and Mrazek (1995) and Gjone, Stevenson, and Sundet (1996) also examined CBCL attentional problems in larger samples and found similar results (Schmitz et al., 1995: $h^2 = .65$; $e^2 = .35$ in 66 MZ and 137 DZ twin pairs; Gjone et al., 1996: $h^2 = .73$ to $.79$; $e^2 = .21$ to $.27$ in 526 MZ and 389 DZ pairs).

Several studies examined the heritability of extreme levels of activity and inattention (labeled h^2_g , following DeFries & Fulker, 1988). Stevenson (1992) examined several measures of inattention and hyperactivity and reported varying levels of h^2_g for inattention (.25 to .76) and for hyperactivity (.16 to .75). Gillis, Gilger, Pennington, and DeFries (1992) and Rhee, Waldman, Hay, and Levy (1999) reported higher h^2_g levels for ADHD symptoms ($h^2_g = .98$ and $.99$, respectively). Gjone, Stevenson, and Sundet (1996) reported h^2_g for attention problems by symptom severity and found that h^2_g did not increase as severity increased ($h^2_g = .82$ for ≥ 0 SD above the mean, $h^2_g = .88$ for ≥ 0.5 SD above the mean, $h^2_g = .86$ for ≥ 1.0 SD above the mean, and $h^2_g = .77$ for ≥ 1.5 SD above the mean).

If the MZ correlation is more than twice the DZ correlation, the presence of nonadditive genetic influences and of contrast effects is a possibility. In some twin studies of ADHD, the DZ correlation was very low or even negative (e.g., Nadder, Silberg, Eaves, Maes, & Meyer, 1998; Silberg et al., 1996; Thapar, Hervas, & McGuffin, 1995). One explanation for extremely low DZ correlations (viz., near-zero or slightly negative) is a contrast effect, that is, raters exaggerating the difference between DZ twin pairs. Another explanation is sibling interaction, where one twin's ADHD level

has a direct opposite effect on the other twin's ADHD level. When data from only one rater is used, it is not possible to distinguish between a contrast effect and sibling interaction. Several researchers have examined alternative models testing for the presence of sibling interaction/contrast effects.

Thapar et al. (1995) compared a model positing that hyperactivity is caused by additive genetic influences and nonshared environmental influences (an AE model) to a model which also included a sibling interaction/contrast effect (an AE-B model). The AE-B model ($h^2 = .88$; $b = -.24$) fit significantly better than the AE model, and Thapar et al. interpreted these results as evidence for sibling interaction. Silberg et al. (1996) examined hyperactivity in four groups of children (older boys, older girls, younger boys, younger girls), and also found that an AE-B model was the best fitting model in all four groups ($h^2 = .67$ to $.70$; $e^2 = .25$ to $.32$; $b = -.22$ to $-.08$). Nadder et al. (1998) compared models including and excluding the sibling interaction/contrast effect for ADHD symptoms. The AE-B model was the best fitting model, the heritability estimate was 58 to 61%, the nonshared environment estimate was 39 to 42%, and a sibling interaction/contrast effect was $-.13$ to $-.18$, but this model did not fit significantly better than an ADE-B model.

Eaves et al. (1997) examined the issue of possible rater bias by testing for the presence of sibling interaction/contrast effects and by comparing the results of parent and teacher reports of ADHD symptoms. For parent reports, the AE-B model fit better than a model including dominance genetic influences (the ADE model); the heritability estimates after removing contrast effects ranged from $.55$ to $.82$, and the magnitude of nonshared environmental influences ranged from $.18$ to $.45$ (the magnitude of rater contrast effects ranged from $-.09$ to $-.24$). For teacher reports, the AE model was the best fitting model ($h^2 = .54$ to $.62$; $e^2 = .38$ to $.46$), and there was no evidence of significant contrast effects. Because contrast effects were present in parent reports but not in teacher reports, Eaves et al.'s results suggest that the very low DZ correlations are caused by contrast effects rather than sibling interaction. In another recent paper that examined hyperactivity in this sample, Simonoff et al. (1998) were also able to show that such findings are due to rater contrast effects rather than direct sibling interaction because

mother ratings show a contrast effect, whereas teacher ratings show a different form of bias that can be due to either twin confusion (difficulty attributing behavior to the correct child) or to correlated errors.

In the most recent version of the DSM (DSM-IV; American Psychiatric Association, 1994), there are three subtypes of ADHD: predominantly inattentive type, predominantly hyperactive-impulsive type, and the combined type. These three subtypes are based on surpassing the diagnostic thresholds on one or both of the inattention and hyperactivity-impulsivity symptom dimensions underlying DSM-IV ADHD. This is a significant change from the DSM-III-R (American Psychiatric Association, 1987), where ADHD symptoms were viewed as one dimension and a diagnosis of ADHD was given if ≥ 8 out of 14 symptoms (of inattention, hyperactivity, or impulsivity) were present. This change was based in part on factor analytic evidence that the symptoms of ADHD load on two separate dimensions (inattention-disorganization and hyperactivity-impulsivity; e.g., Lahey et al., 1988; Pelham, Gnagy, Green-slade, & Milich, 1992), as well as on evidence that there are significant differences between children with symptoms of inattention only (e.g., greater academic difficulty; Edelbrock, Costello, & Kessler, 1984) and children with symptoms of both inattention and hyperactivity (e.g., poor peer relationships; Lahey, Schaughency, Strauss, & Frame, 1984).

Given the evidence supporting the distinctiveness of two separate ADHD symptoms dimensions, it is important to examine potential heterogeneity in the etiology of inattention and hyperactivity-impulsivity symptoms. Goodman & Stevenson (1989) calculated separate heritability estimates for inattention and hyperactivity and found lower heritabilities for inattention (32 to 42%) than for hyperactivity (42 to 100%). Unfortunately, inattention and hyperactivity were assessed by using different methods (laboratory measures for inattention and parent or teacher ratings for hyperactivity) and make these results difficult to interpret.

More recently, Sherman, Iacono, and McGue (1997) conducted a behavior genetic study that examined inattention and hyperactivity-impulsivity symptoms separately. A different pattern of results was found for teacher and mother reports. For teachers, the best fitting model for inattention was the ACE model ($h^2 = .39$, $c^2 = .39$, and $e^2 = .22$),

whereas for hyperactivity-impulsivity, the AE model provided the best fit ($h^2 = .69$; $e^2 = .31$). For mother reports, the AE model was the best fitting for both inattention ($h^2 = .69$; $e^2 = .31$) and for hyperactivity-impulsivity ($h^2 = .91$; $e^2 = .09$). Sherman et al. also conducted bivariate genetic analyses to examine the magnitude of genetic influences on the covariation between inattention and hyperactivity-impulsivity symptoms. The covariation between inattention and hyperactivity-impulsivity symptoms was due to genetic influences, shared environmental influences, and nonshared environmental influences ($h^2 = .33$; $c^2 = .45$; $e^2 = .22$) for teacher reports, but there was no evidence of shared environmental influences for mother reports ($h^2 = .86$; $e^2 = .14$). Heath et al. (1996) also examined inattention and hyperactivity separately but reported similar heritability estimates for inattention ($h^2 = .88$; $e^2 = .12$) and for hyperactivity ($h^2 = .89$; $e^2 = .11$) and found a moderate genetic correlation ($r_g = .52$) between inattention and hyperactivity. Waldman, Elder, Levy, and Hay (1996) reported slightly higher heritability levels for hyperactivity-impulsivity ($h^2 = .88$ to $.92$; $e^2 = .08$ to $.12$) than for inattention ($h^2 = .81$ to $.83$; $e^2 = .17$ to $.19$), and a higher genetic correlation ($r_g = .8$) between inattention and hyperactivity-impulsivity.

ODD and CD. Compared to the number of studies that examined ADHD and the symptoms of inattention, hyperactivity, and impulsivity, there are fewer behavior genetic studies that have examined ODD or CD symptoms. Many studies have examined related antisocial behavior constructs in children and adolescents such as delinquency (e.g., Rowe, 1983) or aggression (e.g., van den Oord, Verhulst, & Boomsma, 1996), but given the evidence that behavior genetic studies examining different operationalizations of antisocial behavior (e.g., DSM CD diagnostic criteria versus aggression) result in significantly different results (Rhee & Waldman, 1998), the present review will be limited to studies that examined ODD or CD symptoms assessed via DSM criteria.

Several studies examined ODD and CD symptoms as a composite variable, and their results vary. Simonoff et al. (1995) found little evidence of shared environmental influences on ODD/CD ($h^2 = .40$ to $.73$; $c^2 = .00$ to $.03$, $e^2 = .27$ to $.60$). Similarly, Nadder et al. (1998) found that an AE model with no contrast effects was the best fitting model for ODD/CD symptoms ($h^2 = .53$ to $.65$; $e^2 = .35$ to $.47$). In contrast, Silberg et al. (1996)

examined a composite variable of ODD and CD symptoms in four groups of children (i.e., older and younger boys and girls) and found that the ACE model was the best fitting ($h^2 = .25$ to $.66$; $c^2 = .04$ to $.42$; $e^2 = .29$ to $.33$) because it fit significantly better than a model, including sibling interaction/contrast effects.

Several studies conducted behavior genetic studies that examined ODD symptoms without confounding CD symptoms. Eaves et al. (1997) examined mother, father, and child interview data and found that the AE model was the best fitting across informants but that heritability was higher for parent reports ($h^2 = .49$ to $.65$; $e^2 = .36$ to $.51$) than for child reports ($h^2 = .21$ to $.23$; $e^2 = .77$ to $.79$). They found no evidence of sibling interaction/contrast effects. Willcutt, Shyu, Green, and Pennington (1995) found that ODD symptoms were moderately heritable ($h^2 = .55$; $e^2 = .45$), and Waldman, Rhee, Levy, and Hay (1998) found evidence of substantial additive genetic influences ($h^2 = .85$) and minimal shared environmental influences ($c^2 = .01$; $e^2 = .14$) on ODD symptoms.

Studies that examined CD symptoms separately also reported varying results. Willcutt et al. (1995) and Waldman et al. (1998) found similar results for the etiology of CD symptoms, including moderate genetic, shared, and nonshared environmental influences (Willcutt et al., 1995: $h^2 = .34$ to $.38$; $c^2 = .29$ to $.38$; $e^2 = .24$ to $.37$; Waldman et al., 1998: $h^2 = .51$; $c^2 = .34$; $e^2 = .14$), whereas Lyons et al. (1995) reported a lower magnitude of genetic influences ($h^2 = .07$; $c^2 = .31$; $e^2 = .62$). In contrast, Slutske et al. (1997) found no evidence for shared environmental influences on retrospective reports of CD symptoms during childhood or adolescence ($h^2 = .71$; $c^2 = .00$; $e^2 = .29$). Eaves et al. (1997) found different results for mother and father reports of CD symptoms. For mothers' interview data, there was evidence of substantial additive genetic influences ($h^2 = .69$; $e^2 = .31$) and no shared environmental influences for both sexes, whereas for fathers' interview data, the ACE model fit best for both sexes ($h^2 = .27$ to $.58$; $c^2 = .09$ to $.37$; $e^2 = .33$ to $.36$). Eaves et al. found no evidence of sibling interaction/contrast effects across informant and sex.

Several adoption studies (Cadoret, Cain, & Crowe, 1983; Cloninger, Sigvardsson, Bohman, & von Knorring, 1982; Mednick, Gabrielli, & Hutchings, 1983) showed evidence of genotype-environment interaction in criminality. These studies

found that adoptees with criminality in both their biological and adoptive parents are more likely to be criminal themselves than those with criminality in either their biological or adoptive parents. Unfortunately, similar studies examining ODD and CD are not available. Future adoption studies should examine genotype–environment interaction in ODD and CD given the evidence suggesting that childhood externalizing behavior and adulthood criminality are substantially related (e.g., Pulkkinen & Pitkänen, 1993; Robins, 1966).

Multivariate Behavior Genetic Studies of Childhood Disruptive Behavior Disorders

Numerous studies have documented a significant overlap between ADHD, ODD, and CD in both clinical and nonreferred samples. Biederman, Newcorn, and Sprich's (1991) review found that ADHD and CD co-occur in 30 to 50% of children and ADHD and ODD co-occur in at least 35% of children and that this result is consistent across both clinical and epidemiological samples. The considerable phenotypic overlap among these disorders suggests that the disorders share common etiological influences. Several behavior genetic studies have examined the etiology of the overlap among ADHD, ODD, and CD by using multivariate behavior genetic analytic methods.

Nadder et al. (1998) conducted bivariate behavior genetic analyses to examine the covariation between ADHD and ODD/CD symptoms. The best fitting model was an AE-B model that included common additive genetic, nonshared environmental, and contrast effects explaining the covariation between ADHD and ODD/CD symptoms. The genetic correlation between ADHD and ODD/CD symptoms was .50, and the correlation for nonshared environmental influences was .39.

Silberg et al. (1996) also used bivariate behavior genetic analyses to study to covariation between hyperactivity and ODD/CD symptoms. For both younger (8 to 11 years old) and older (12 to 16-year-old) children, the covariation between hyperactivity and ODD/CD symptoms was due predominantly to common genetic influences and small to moderate common nonshared environmental influences. A model that posited a single genetic factor for conduct problems and hyperactivity fit best for the younger children ($r_g = 1.00$; $r_e = .07$ to $.08$), whereas a model that included common

and specific genetic influences for hyperactivity and ODD/CD fit best for the older children ($r_g = .46$ to $.58$; $r_e = .23$ to $.32$).

Willcutt et al. (1995) conducted bivariate behavior genetic analyses for the pairwise combinations of ADHD, ODD, and CD symptoms. They found substantial common genetic influences on the covariation between ADD and ODD symptoms (bivariate $h_g^2 = .56$ to $.87$), but statistically nonsignificant common genetic influences on the covariation between ADD and CD (bivariate $h_g^2 = .16$ to $.26$) and the covariation between ODD and CD (bivariate $h_g^2 = .21$ to $.22$).

Waldman et al. (1998) took a different approach to examine the etiology of the covariation among ADHD, ODD, and CD symptoms simultaneously and conducted a Cholesky decomposition to test whether there are specific genetic and environmental influences on childhood antisocial behavior (i.e., ODD and CD symptoms) that are unique compared to those on ADHD. Waldman et al. found evidence for common additive genetic influences on ADHD, ODD, and CD, a distinct set of common additive genetic influences that affect only ODD and CD, and additive genetic influences on specific only to CD. The only shared environmental influences were common to ODD and CD. The correlations for the additive genetic influences among ADHD, ODD, and CD symptoms were all high ($r_{ADHD,ODD} = .73$; $r_{ADHD,CD} = .82$; $r_{ODD,CD} = .79$), and the correlation for the common shared environmental influences between ODD and CD was 1. The covariance between ADHD and ODD and between ADHD and CD was mostly due to additive genetic influences (93% of the covariance was due to additive genetic influences and 7% to nonshared environmental influences). In contrast, the covariance between ODD and CD was due to additive genetic influences (79%), shared environmental influences (9%), and nonshared environmental influences (12%).

Conclusions Regarding Behavior Genetic Studies of Childhood Disruptive Behavior Disorders

Despite heterogeneity in the results of the behavior genetic studies of childhood externalizing disorders, several general conclusions can be drawn. First, both ADHD symptoms in the general population and extreme levels of ADHD in selected populations are highly heritable, and there

is little evidence of shared environmental influences. Several researchers have found near-zero or slightly negative DZ correlations that suggest the presence of sibling interaction (siblings influencing each other's traits in an opposite direction) or contrast effects (raters exaggerating the difference between twins), rather than nonadditive genetic influences (Thapar et al., 1995; Silberg et al., 1996; Eaves et al., 1997; Nadder et al., 1998; Simonoff et al., 1988). In their comparison of results across multiple informants, Eaves et al. (1997) and Simonoff et al. (1998) provided evidence that the very low DZ correlations for ADHD are most likely the result of rater contrast effects rather than sibling interaction. Most researchers who have conducted behavior genetic studies of ADHD have examined ADHD symptoms as a single dimension rather than examining inattention and hyperactive-impulsive symptoms separately. Given the evidence regarding the classification of ADHD symptoms, more behavior genetic studies examining the etiology of inattention and hyperactivity-impulsivity as two separate dimensions need to be conducted.

The results of behavior genetic studies that examined ODD symptoms separately resemble those for ADHD, and there is substantial additive genetic influences and little evidence of shared environmental influences (Willcutt et al., 1995; Eaves et al., 1997; Waldman et al., 1998). The results for CD symptoms are less consistent, but unlike the results of studies that examined ADHD or ODD symptoms, most researchers found significant shared environmental influences on CD (Willcutt et al., 1995; Eaves et al., 1997; Waldman et al., 1998). All researchers who tested for the presence of contrast effects on ODD or CD symptoms did not find evidence of them (Silberg et al., 1996; Eaves et al., 1997; Nadder et al., 1998). The differing results for genetic and environmental influences on ODD and CD symptoms emphasize the distinctiveness of their etiologies and the importance of examining ODD and CD symptoms separately in future behavior genetic studies.

Several researchers conducted multivariate behavior genetic analyses to examine the etiology of the overlap among ADHD, ODD, and CD (Nadder et al., 1998; Silberg et al., 1996; Waldman et al., 1998; Willcutt et al., 1995). In general, these studies found substantial overlap between the genetic influences on ADHD and the genetic influences on ODD and CD. Given that these genetic

correlations are not equal to 1, however, there is also evidence of genetic influences that act specifically on ADHD, ODD, and CD symptoms.

FUTURE DIRECTIONS

Genetic and Environmental Influences on Normal Range Variation and on the Disordered Extreme

An emerging topic in behavior genetic studies of psychopathology is whether genetic and environmental influences are similar across the range of symptoms as for the disordered extreme, or whether the etiology of normal range variation in the trait(s) relevant to a disorder is the same as the etiology of the disorder itself. Behavior genetic methods are beginning to be used to test contrasting models of psychopathology that regard disorders as merely the extreme of normal functioning, as opposed to categorically distinct entities. Several behavior genetic techniques have been developed to address this issue, and each of those techniques does so slightly differently. For example, one can use a multiple regression approach to test whether the genetic and environmental influences on symptoms of a disorder increase or decrease with increasing symptom levels. One can also use model fitting techniques to test whether the magnitude of genetic and environmental influences—and the best fitting etiological model—for symptoms of a disorder are the same as those on the diagnosis. The most commonly used method to address such questions is a regression-based method (DeFries & Fulker, 1988) which tests whether the heritability of the extreme condition (i.e., h^2_g), often a diagnosis, differs from the heritability of normal range variation of symptoms in the population (i.e., h^2). Unfortunately, the test of $h^2_g - h^2$ tends to be very low in statistical power, as pointed out by the authors (DeFries & Fulker, 1988), and thus may suggest that the etiology of normal range variation in symptoms is the same as that of the disordered extreme, even in the presence of sizable differences in the two heritabilities. Hopefully, researchers will begin to use a diversity of behavior genetic methods to address the differential etiology issue. Thus, although there is considerable interest in the use of behavior genetic methods to address such questions, a number of technical problems and conceptual issues in

these analyses need to be resolved before they yield clear answers to the classificatory issues raised before.

Inclusion of Specific Environmental and Endophenotypic Variables in Behavior Genetic Models

Standard behavior genetic analyses represent genetic and environmental influences as unspecified, anonymous, or “black box” variables (Kendler, 1993). Kendler (1993) notes that the statistical power to detect shared environmental influences is low in such standard models, whereas incorporating specified environmental variables within a behavior genetic model increases the power to detect such influences if they are present. Accordingly, behavior genetic research has begun to incorporate specific environmental measures to detect the effects of these variables against a background of multiple genetic and environmental influences. Perhaps the most widely cited example of this approach is one that is relevant to the etiology of depression and anxiety disorders in adults. The results of standard behavior genetic analyses of twin data, reviewed earlier, typically have not suggested any significant role for shared environmental influences in the etiology of adults’ mood and anxiety disorder symptoms. Kendler, Neale, Kessler, Heath, and Eaves (1992e) demonstrated a statistically significant effect of childhood parental loss (i.e., separation or death) on liability to DSM-III-R major depression, GAD, phobias, and panic disorder in adult females, against a background of other (anonymous) genetic and environmental risk factors. Nonetheless, the estimated relative magnitude of this influence in explaining variation in liability to mood and anxiety disorders in adulthood was small (accounting for 4.9% of the variance in liability to panic disorder, 2.9% of the variance in liability to phobias, 2.5% of the variance in liability to GAD, and 1.6% of the variance in liability to major depression in the population of women studied).

Thus, this study represents a specific example of a more general research design, namely, including specific, putative causal mechanisms within multivariate behavior genetic models. This extended behavior genetic design is appropriate for including many different types of putative causal variables (e.g., perinatal birth complications, measures of executive functions, psychopathological

measures, specific family and/or neighborhood environmental variables) within behavior genetic models. Findings from these studies can establish whether the relationship of such putative causal variables to the disorder is due primarily to common genetic or common environmental influences. These analyses can be useful for testing whether these putative causal variables represent *endophenotypes* that may be closer to the underlying genetic and environmental influences than the disorders themselves. Thus, another way to view such analyses is that they can help elaborate the specific causal mechanisms for a disorder that are captured by the broad and abstract genetic and environmental variance components that emerge from behavior genetic analyses. Another putative causal mechanism that may be included in behavior genetic models is specific candidate genes that are hypothesized to play some causal role in a disorder. With this in mind, we briefly discuss burgeoning molecular genetic studies of psychopathology in the next section.

Molecular Genetic Studies of Psychopathology

Molecular genetic studies of most major forms of psychopathology have become a major area of contemporary etiological research. Approaches to finding genes that underlie psychiatric disorders have included both association studies of the role of specific candidate genes, as well as genome scans of anonymous DNA markers by using linkage analysis. Generally speaking, such studies have produced mixed findings for almost all psychiatric disorders; some studies report exciting positive findings, and others report failures to replicate. There are many reasons for these mixed findings and failures to replicate, but one of these deserves special attention, in our opinion. Molecular genetic analyses of psychiatric disorders might be more successful if continuous symptom dimensions or related traits are analyzed either along with, or instead of, the categorical disorder phenotype (viz., the diagnosis).

Consider the case of the genetics of schizophrenia as a specific example. Recent results suggest that linkage analyses based on more specific phenotypic indicators than the schizophrenia diagnosis alone may be more successful than a search for linkage among individuals diagnosed with schizophrenia but with disparate syndromes and

symptoms. For example, Brzustowicz et al. (1997) hypothesized that different aspects of the schizophrenic phenotype may be influenced by different genes. Their evaluation of genetic markers on the short arm of chromosome 6 revealed no evidence for linkage by using categorical schizophrenia diagnostic definitions (i.e., narrow, broad, and very broad). Examining linkage for positive symptom, negative symptom, and general psychopathology symptom scales, however, yielded significant evidence for linkage for the positive symptom scale only (empirical $p < .05$). The specificity of these results suggests that the positive and negative dimensions of schizophrenia may have different susceptibility loci, in which case schizotypy may be genetically related to schizophrenia through a common diathesis pertaining to negative symptoms. Similarly, Serretti, Macciardi, and Smeraldi (1998) hypothesized that the influence of dopamine D2 receptor gene (DRD2) variants should be analyzed at the symptom dimension, rather than syndrome, level. They based their reasoning on the results of a previous study that found a stronger association between DRD2 and schizophrenia in those subjects without negative symptoms (Arinami et al., 1996). Serretti et al. (1998) identified four factors of psychotic symptoms. Subjects with the S311C variant of DRD2 presented with higher scores on the Disorganization factor than those without this particular variant. Moreover, none of the other factors (Excitement, Depression, Delusion) was associated with the S311C variant. These results also suggest that different aspects of the schizophrenic phenotype may be influenced by different underlying genetic vulnerabilities.

The results of multivariate behavior genetic studies of disorders also have important implications for molecular genetic studies of those disorders. It is important to know, for example, whether candidate genes that influence one disorder (e.g., ADHD) also influence other related disorders (e.g., ODD and CD). Multivariate behavior genetic analyses of such disorders can help guide molecular genetic research by determining to what extent the substantial phenotypic overlap among them is due to common genetic influences compared with common environmental influences. Multivariate behavior genetic analyses also can suggest whether all of the genetic influences on these disorders are shared in common or whether each of the disorders exhibits genetic influences that are unique compared to those on the others. If

the latter is true, a search for candidate genes that influence ODD and CD uniquely would be fruitful, whereas if the former is true, one would need merely to search for candidate genes for ADHD to find those that also influence childhood antisocial behavior.

Examination of Genotype–Environment Interactions and Correlations

Genotype–Environment Interaction—The Contingent Contributions of Genes and Environments to Disorder. Despite the importance of genotype–environment interactions to many theories of the development and etiology of psychopathology, genotype–environment interaction has received relatively little attention in recent behavior genetic studies of psychopathology. There are a number of reasons for investigating genotype–environment interactions for psychopathology. First, although the vast majority of behavior genetic studies of psychopathology implicitly assume that genetic and environmental influences on the liability to a disorder act additively and independently, this is not necessarily the case. Individuals' genetic predispositions for a disorder may be actualized to a greater or lesser extent in different environments, and certain environmental risk factors may contribute to vulnerability to disorder only in individuals who are genetically predisposed. Second, many developmental psychopathologists have emphasized the point that, at least in theory, genetic and environmental influences on a trait are population-specific. This suggests that the heritability of a disorder may be high in one population and low in another or that shared environmental influences may be important in some populations or environments (e.g., in extreme circumstances of poverty or abuse) but not in others (e.g., in the majority of rearing environments.).

We used the term “at least in theory” above because most advocates of the population-specificity of genetic and environmental influences have proposed this in the absence of any research to support it. Indeed, the consistency of heritability estimates across studies varies considerably for different disorders. In the area of childhood disruptive behavior disorders, for example, the heritability of ADHD is estimated consistently in the .6–.9 range, whereas estimates of the heritability of CD are much more variable. Although this may simply reflect methodological differ-

ences in behavior genetic studies of ADHD and CD (e.g., more similar operationalizations, measures, and informants across studies for ADHD than for CD), it also may indicate that CD is a more sensitive phenotype than ADHD, in the sense that the causes of CD may differ appreciably, depending on the characteristics of the population and environment in which it is being studied. Needless to say, this is a highly speculative notion that awaits targeted investigations of genotype–environment interaction for support or refutation.

One final point regarding genotype–environment interaction concerns the behavior genetic designs in which it has traditionally been examined. Most investigations of genotype–environment interaction have been conducted within the context of adoption study designs rather than twin study designs. Adoption studies have provided intriguing findings regarding genotype–environment interaction for a number of disorders, such as the findings for criminality and antisocial behavior mentioned before. Nonetheless, adoption studies have a number of limitations, such as relatively small and unrepresentative samples that are not characteristic of large, contemporary twin studies. Consequently, it would be beneficial for behavior geneticists to examine different types of genotype–environment interactions for a variety of disorders within the context of large twin studies. Twin researchers could expand on their examination of differences in genetic and environmental influences as a function of sex and age to include a multitude of environmental moderator variables. These variables could include perinatal complications, family environmental variables such as socioeconomic status and parental supervision and monitoring, and neighborhood characteristics such as income disparity and crime rates. The inclusion of such variables in twin studies of psychopathology will paint a more complete picture of the degree to which genetic and environmental influences vary across populations and environmental contexts, rather than treating this merely as a theoretical possibility. Such studies also will increase our understanding of the specific ways in which genetic and environmental influences combine in determining individuals' liability to psychopathology.

Genotype–Environment Correlation—Possible Theoretical Implications of the Decline of Shared Environmental Influences with Age. The finding of a decreasing impact of shared environmental influences or an increasing

impact of genetic influences on symptoms of psychopathology (e.g., anxiety and depression) during development may support Scarr and McCartney's (1983) hypothesis that maturation is associated with an increase in *active genotype–environment correlation* and a corresponding decrease in *passive genotype–environment correlation*. *Genotype–environment correlation* refers to the tendency for individuals' genetic propensities for a trait or disorder to be associated with their environmental exposures or experiences that also influence the trait or disorder. There are three types of genotype–environment correlation: *passive*, *reactive*, and *active*. *Passive* genotype–environment correlation refers to the tendency for children in intact biological families to experience a rearing environment that is correlated with their genetically influenced characteristics, because they are genetically related to their parents and siblings who provide that environment. *Reactive* genotype–environment correlation refers to the tendency for individuals to elicit certain responses from others in their environment based (in part) on their genetically influenced characteristics. *Active* genotype–environment correlation refers to the tendency of individuals to choose or construct (Plomin, 1994) environments that are consistent with their genetically influenced characteristics. Note that genotype–environment correlations are not necessarily positive; they can also be negative. For example, individuals may elicit or choose environments that help to *counteract* their genetic propensities (Plomin, 1994). Note also that genotype–environment correlation refers to the tendency to experience or seek out certain characteristics based partly on one's genetic predispositions and also to the fact that both the genetic predispositions and the environments *influence* the trait or disorder being studied.

The notion of genotype–environment correlation also suggests that the environment does not act entirely independently from heritable influences (Plomin, 1994). Social supports and life events (both known to be associated with the level of depressive symptoms in adults) are examples of environmental variables that may be differentially experienced by adults based in part on their genetically predisposed characteristics and result in genetic “mediation” of an environmental influence on symptoms of depression. Multivariate studies have been conducted to test for genetic mediation of the relationships of both social supports and life events to depression. Neiderhiser, Plomin, Lich-

tenstein, Pedersen, and McClearn (1992) found evidence for partial genetic mediation of the relationship between life events and depressive symptoms. Similarly, in the case of social supports, Bergeman, Plomin, Pedersen, and McClearn (1991) found that the relationship of social support to depressed mood and life satisfaction was mediated in part genetically. Kessler et al. (1992) replicated this finding for the relationship between social support and depression (see Plomin, 1994, for a thorough review of this topic).

To the degree that genotype–environment correlation is involved in the etiology of a particular trait, it is expected that measures of the trait-relevant environment experienced by an individual will show genetic influences. Scarr and McCartney's (1983) hypothesis concerning "genotype \rightarrow environment effects" sought to address several puzzling findings for a variety of traits: (1) over the course of childhood and adolescence, the similarity of MZ twins increases, whereas that of DZ twins decreases; (2) a similar divergence in similarity occurs between biological and adopted siblings, and there is a greater decrease in similarity among adopted siblings; (3) MZ twins reared apart are unexpectedly similar to one another and show a level of similarity for most traits that is greater than that of DZ twins reared together and that is often almost as high as that of MZ twins reared together. Scarr and McCartney proposed that all of these findings could be explained by an age-graded increase in the magnitude of active genotype–environment correlation and a concomitant decrease in the magnitude of passive genotype–environment correlation. This would explain the relative decline in similarity between DZ twins and adoptive siblings because an increase in active genotype–environment correlation would lead DZ twins (whose genetic relatedness is less than that of MZ twins) and adoptive siblings (who are unrelated genetically) to select increasingly disparate environmental experiences than MZ twins (who are genetically identical).

Based on the prediction of a divergence with age between the MZ and DZ twin correlations, the Scarr–McCartney hypothesis posits that heritability should increase with age, whereas the magnitude of shared environmental influences should decrease with age, a prediction that receives some support from findings for childhood and adolescent anxiety and depression. Feigon et al. (1997) were interested in directly testing the

expected age-related changes in heritability and shared environmental influences in analyses of data on DSM-III-R separation anxiety disorder (SAD) symptoms in children. This hypothesis was tested by modeling age moderation of the genetic and environmental estimates using multiple regression methods. Indeed, Feigon et al. (1997) found that the magnitude of genetic influences on DSM-III-R SAD symptoms in children increased with age. This finding was consistent with the results reported before by Thapar and McGuffin (1994; see also Thapar & McGuffin, 1996), who found that age moderated the heritability for depressive symptoms in children and adolescents, such that the magnitude of genetic influences was greater in older than in younger children, but the magnitude of shared environmental influences was lower in older than in younger children. An increase in the relative magnitude of genetic influences with age also has been observed for childhood fears (Rose & Ditto, 1983). It has been hypothesized that this increase is due in part to the increasing role of active genotype–environment correlation across development proposed by Scarr and McCartney (1983). For the case of fears, Stevenson et al. (1992) proposed that active genotype–environment correlation may take the form of avoidance of fear-provoking situations. Such avoidance would be expected to increase as the child ages because of a decrease in forced exposures to feared situations which were previously imposed by parents. The increased ability of the child to avoid fear-provoking situations might thus result in the loss of opportunities for habituation, thus allowing greater expression of the genetic liability to be fearful.

Although the increase in active genotype–environment correlation is a compelling explanation for these findings, it is important to consider that changes in the magnitude of heritability with age is also consistent with other hypotheses. These include an increase in genetic variance due to the age-specific activation of genes that influence risk for the disorder, as well as a decrease in the experience of disorder-relevant environmental risk factors.

Summary

In this chapter, we have reviewed the behavior genetic literature for a number of the major forms of child and adult psychopathology, including

schizophrenia, schizophrenia spectrum disorders, and schizotypal personality; affective and anxiety disorders in both children and adults; and the childhood disruptive disorders ADHD, ODD, and CD. Unfortunately, space limitations precluded our review of behavior genetic research on other important disorders, such as autism, substance abuse and dependence, and personality disorders. We also provided background material on the statistical methods used in contemporary twin studies to conduct univariate and multivariate behavior genetic analyses, as well as a brief discussion of some exciting new and future directions in behavior genetic studies of psychopathology. The latter included genetic and environmental influences on normal range variation and on the disordered extreme, the inclusion of specific environmental and endophenotypic variables in behavior genetic models, molecular genetic studies of psychopathology, and the examination of genotype-environment interaction and correlation. These future directions will facilitate the progression of behavior genetic studies of psychopathology beyond the simple estimation of broad, abstract genetic and environmental variance components for a single disorder to the examination of more complex models for the specific etiological mechanisms that underlie disorders and their overlap.

CHAPTER 4

Biological Variables in Psychopathology: A Psychobiological Perspective

Don C. Fowles

Introduction

The purpose of this chapter is to advocate a psychobiological approach to theories of psychopathology—appealing especially to psychologists to adopt a more biological perspective. Even though, happily, in recent years acceptance of biological influences on psychopathology has increased considerably among psychologists, many still give little more than lip service, and training in neuroscience is seldom part of a clinical curriculum. As a result, clinical psychologists tend to be cut off from various biopsychological disciplines that have obvious relevance to understanding behavior and psychopathology.

Foremost among these, the field of behavior genetics provides ample demonstrations of the influence of genetic differences on behavior. Additionally, behavior genetics provides perhaps the greatest justification for the study of personality differences that are so important in the clinic. A second, and more clinical, area that cannot be ignored is psychopharmacology and the related

discipline of behavioral pharmacology. Even though the situation is not as simple as one drug, one diagnosis, undeniably there is some specificity involved in the use of drugs to treat psychopathological disorders: the different classes of drugs have different effects, and there is some specificity of the efficacy of the pharmacological treatment as a function of patient diagnosis. This drug-to-diagnosis matching is not well understood, and drug effects often cut across diagnostic boundaries. Nevertheless, the effects of these drugs must be understood if we are to have a comprehensive and adequate theory of psychopathology. Indeed, one of the most important potential advantages of adopting a psychobiological perspective is to develop a theoretical bridge between the effects of pharmacological treatment on neuroregulators, on the one hand, and the behavioral phenomena that constitute the disorder, on the other hand.

This theoretical bridge is an appropriate contribution for psychologists to make to the understanding of psychopathology because they are in a position to develop expertise in both behavioral theories and theories of brain–behavior relationships. Doing so will require mastery of such areas of study as behavioral neuroscience, behavioral pharmacology, and behavioral endocrinology. The rapid growth of knowledge in these fields is increasing our knowledge of neuroregulators and

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

providing a better understanding of brain–behavior relationships. Although now it is difficult to span the theoretical gulf seamlessly between clinical phenomena and the concepts of these fields, attempts can be made and such an integration ultimately will contribute to our understanding of psychopathology.

Just as many psychologists have tended to minimize biology, many psychiatrists have tended to minimize psychological influences. The zeitgeist in psychiatry has so emphasized biological, especially genetic, factors—and this view has so pervaded the mass media—that the importance of environmental influences also needs to be stressed. Both clinical psychology and psychiatry can benefit from a psychobiological approach.

In part, the gulf between psychology and psychiatry is enhanced by uncritical use of the disease model. For example, some members of both professions tend to conclude that biological variables are important in psychopathology as support for the so-called medical or disease model. That conclusion is fundamentally flawed: biology is not a disease. Within-species genetic variation is entirely natural and affects virtually every aspect, at least to some degree, of brain structure and function (Rutter & Plomin, 1997). Whatever merit there may be to a disease model, it must rest on more than the demonstration of a genetic influence on behavior or on the finding that behavior has a biological substrate. In fact, there have been recent challenges to the uncritical application of the disease model that may help to move the two disciplines closer together. These will be discussed here.

Compatibility of Biology and Psychology

Several important trends have served to underscore the need for more complex theories of psychopathology and to blur the distinction between biological and environmental influences. These trends include (1) clear demonstrations of environmental effects on brain structure and even gene manifestation, (2) the documentation of pervasive comorbidity in psychiatric disorders, and (3) evidence that both pharmacological treatments and genetic influences on psychopathology may be better understood as affecting temperament rather than discrete diseases.

Environmental Effects on Brain Structure

In the traditional biological approach to psychopathology, genes determine brain structure, which, in turn, creates a vulnerability or predisposition to psychopathology. In recent years, however, a burgeoning literature points to experience-dependent changes in brain structure even in adults (e.g., Garraghty, Churchill, & Banks, 1998), dramatically blurring the distinction between biological-genetic and environmental influences. Kolb & Whishaw (1998) describe the evolution of this literature from the early reports of increased cortical mass for animals raised in “enriched” environments to current documentation that numerous types of experience produce major increases in the number of synaptic connections in species ranging from fruit flies to humans. The increased synaptic connections are promoted especially through the growth of dendrites (representing up to 95% of the receptor surface on which synaptic connections are formed) and of surrounding tissue that provides support for the increased metabolic demands of the enlarged neurons. These changes reflect an increase in the functional capacity of neural systems that have been stimulated by environmental conditions.

Along the same lines, Depue, Collins, and Luciana (1996) apply evidence for experiential effects on brain structure to the development of what Depue calls the Behavioral Facilitation System or BFS (described in more detail later), which responds to reward incentive stimuli. These authors argue that during sensitive periods in brain development, characterized by widespread overproduction of cortical synapses, the presence or absence of environmental stimulation greatly influences a process of “pruning back” these synaptic connections, that is, these transient synaptic connections are preserved on a long-term basis with relevant environmental experiences but otherwise are lost (pruned back). Further, two assumptions underscore a self-maintaining property of these environmental effects: an individual who has a strong BFS is said to have a lower threshold for responding to incentive cues and also will engage in greater exploration of the environment in search of rewarding stimulation. Both processes increase the environmental stimulation of the BFS, tending to maintain or strengthen synaptic connections in the Dopamine (DA) pathways. This focus on experi-

ential effects on the strength of the BFS is important because, as will be seen later, the BFS is a motivational system that has clear relevance to theories of temperament and psychopathology.

Kandel (1998) addresses the implications of these environmental influences on brain structure for psychiatry. Although the basic genetic material is fixed (except mutations) and is passed on from generation to generation, the *expression* of a gene is highly subject to regulation. Hormones, stress, learning, and social interaction all produce changes in patterns of neuronal connections by influencing gene expression. Thus, all functions of the brain are susceptible to social influences. Consistent with this perspective, Kandel suggests that successful psychotherapy (or behavior therapy) produces alterations in gene expression and brain structure that may be similar to or synergistic with those produced by pharmacotherapy. Evidence in support of this expectation was provided in an imaging study of obsessive-compulsive disorder (OCD) in which both types of treatment produced changes in brain structure.

It should be clear from these examples that dichotomies between psychological and biological influences are inappropriate. Experience and behavior affect gene expression and brain structure, and reciprocally genes and brain structure affect behavior and experience. There should be no conflict between these perspectives but rather an effort to sort out the processes involved and their complex interactions.

Comorbidity

Mineka, Watson, and Clark (1998) note that DSM-III (American Psychiatric Association, 1980) that embraces a neo-Kraepelinian belief in discrete mental disorders incorporated extensive exclusionary criteria to minimize diagnoses of more than one disorder. In response to criticism of that approach, DSM-III-R (American Psychiatric Association, 1987) greatly reduced these exclusionary criteria. On the basis of research conducted both before and after DSM-III-R, the pervasiveness of comorbidity has been well-documented (e.g., Clark, Watson, and Reynolds, 1995; Hinshaw, 1987; Maser & Cloninger, 1990; Meltzer, 1984; Mineka et al., 1998; Procci, 1989).

This comorbidity challenges the discrete disease model, inasmuch as the rates of comorbidity are too high to be assimilated by the chance occur-

rence of two independent diseases. Rather, comorbidity is more easily compatible with etiological models that hypothesize multiple biological and environmental influences that may involve some common elements of different disorders as we currently conceptualize them. As the discrete disease model becomes less and less tenable, the gap between psychologists and psychiatrists should narrow.

Genetic Vulnerability, Pharmacological Treatment, and Temperament

Kendler, Neale, Kessler, Heath, & Eaves (1992) found that the data from a large twin study fit a model in which Generalized Anxiety Disorder (GAD) and Major Depression shared a common genetic vulnerability, and environmental factors determined whether anxiety or depression dominated the clinical picture. Also of interest, the authors suggest that the genes act largely by predisposing to *general distress*—a concept entirely consistent with concepts of temperament and the notion that dimensions of temperament contribute to the risk of psychopathology. Thus, a genetic study has challenged the older notion that these two common disorders are discrete diseases that have different underlying genetic etiologies, suggesting instead that more temperament-like processes are involved and that environmental influences determine which disorder develops. Along the same lines, Ely (1997) found a substantial common genetic influence for the Aggression and Delinquency scales of the Child Behavior Checklist (Achenbach, 1991) in Swedish twins aged 8–9 and, more surprisingly, cited other data for a major common genetic influence on aggression and depression among adolescents.

In a major paper championing the integration of genetic and environmental influences on psychopathology, Rutter (1997) notes that even large heritability estimates do not preclude large changes as a result of environmental effects. For example, both height and antisocial-criminal behavior show high heritabilities, yet the height of London schoolboys increased 12 cm during the first 50 years of the twentieth century, and crime rates increased fivefold during the last 50 years in most industrialized countries—both changes are attributable to environmental influences. Rutter (1997; Rutter & Plomin, 1997) concludes that the literature suggests a shift from a focus on genetic causes

of a discrete categorical disorder to a focus on polygenetic contributions to the various dimensional risk factors (among which are temperament) involved in the multifactorial origins of psychopathology. Further, the behavior genetics literature has documented the ubiquity of environmental influences, leading to the conclusion that it is nature *and* nurture, not nature *or* nurture (Owen & McGuffin, 1997; Rutter & Plomin, 1997). There is no incompatibility between genetic and environmental approaches.

A similar emphasis on the fundamental relevance of temperament to psychopathology can be seen in the popular book *Listening to Prozac* (Kramer, 1993). (Prozac is a selective serotonin reuptake inhibitor, thereby increasing the activity of the neurotransmitter serotonin.) Kramer, a psychiatrist, discusses the implications of the drug's apparent success in altering personality and temperament in ways that patients find desirable. In contrast to earlier antidepressants, Prozac produced fewer unwanted negative effects (so-called "side effects"), allowing it to become very popular with his patients because of its effects on their *personalities*.

Kramer struggles with the realization that he was practicing "cosmetic psychopharmacology" (pp. 15, 184). Further, Prozac, along with many other psychotropic medications, is useful in a wide range of disorders (p. 45)—thereby undermining the simple one drug, one diagnosis disease model. Kramer concludes that medications do not treat specific illnesses but rather alter neurochemical systems (p. 45) and that Prozac's effects point to the importance of biological temperament (p. 182). Finally, Kramer embraces a "functional theory of psychopathology." He suggests that neurotransmitters (and medication) relate to such behavioral dimensions/functions as anxiety, aggression, and the ability to anticipate future pleasure in activities (p. 183), not to complex entities such as personality or mental illness. Consequently, progress in treating mental illness cannot be separated from progress in altering temperament (p. 184).

Thus, results from the two cornerstones of biological psychiatry—genetics and psychopharmacology—point to the importance of personality, temperament, and such behavioral dimensions as anxiety-proneness, aggressiveness, and sensitivity to reward incentive stimuli. These concepts could hardly be more compatible with psychology, suggesting that a rapprochement between psychologi-

cal and biological approaches to psychopathology is in sight. With this conclusion, it is now time to turn to examples of the use of a motivational theory to understand psychopathology.

Appetitive and Aversive Motivation

A comprehensive review of biological approaches to psychopathology is beyond the scope of a single chapter. Consequently, selected topics are reviewed to illustrate various points of articulation between biology and psychopathology. Specifically, the constructs of appetitive and aversive motivation are employed to illustrate a theoretical framework in which biological and psychological approaches to understanding psychopathology may be integrated (Fowles, 1988, 1992b, 1994).

In the attempt to formulate a psychobiological theory of psychopathology, motivational constructs borrowed from animal learning literature prove particularly useful for several reasons. First, their origin in research with nonhumans makes it possible to examine the contribution of neurotransmitter systems, which then relate directly to pharmacological and other biological theories of psychopathology. Second, the overlap between the concepts of motivation and emotion is sufficiently great that it is plausible to apply motivational constructs to what have traditionally been viewed as emotional disorders. Third, because these motivational constructs derive from the animal learning tradition, they necessarily emphasize environmental influences and have clear implications for behavior. Fourth, in the particular theoretical approach employed here, cognitive/information processing plays a large role, making this approach not at all incompatible with cognitive approaches to psychopathology. Thus, motivational constructs provide a theoretical bridge between biological concepts and the emotional and behavioral features that define psychopathology.

The constructs in question are hypothesized antagonistic appetitive and aversive motivational systems (e.g., Gray, 1975, 1987; Mackintosh, 1974). The primary function of these systems is to influence the probability of a behavioral response. The appetitive system activates behavior in response to cues indicating response-contingent positive outcomes, whereas the aversive system inhibits behavior in response to cues indicating

response-contingent negative outcomes. In conflict situations, in which cues indicate both positive and negative outcomes, the appetitive and aversive systems oppose each other, and the probability of the response is determined by the relative strengths of the output from these reciprocally antagonistic systems. In addition to the behavioral consequences of activity in these motivational systems, both systems have affective components, as well: positively hedonic for the appetitive system and negatively hedonic for the aversive system.

For the present purposes, it is convenient to focus on Gray's (e.g., 1976, 1979, 1982, 1987; McNaughton & Gray, 1999) portrayal of the appetitive and aversive motivational systems, in part because Gray has also dealt with topics that are relevant to a biological approach to psychopathology. Gray calls the aversive motivational system the Behavioral Inhibition System or BIS, underscoring its effect on behavior. This author (Fowles, 1980) suggested *Behavioral Activation System* or BAS as a parallel name for the appetitive system, and Gray prefers to call it the *Behavioral Approach System* (also BAS); both names similarly call attention to the behavioral effect of this system. To understand the functions of the BAS and BIS and their interaction, it is necessary to consider four basic paradigms.

The first paradigm is a simple reward paradigm with 100% reinforcement, in which the organism learns to respond to obtain a reward. In this situation, conditioned stimuli associated with reward (Rew-CSs) exert their control over behavior via the BAS, that is, the BAS activates reward-seeking behavior in response to Rew-CSs.

This simple reward-learning situation can be transformed into an approach-avoidance conflict by introducing response-contingent punishment, once the rewarded response has been established. The introduction of punishment (in addition to the reward) results in reducing the rate or probability of responding (passive avoidance). Passive avoidance in the conflict situation is attributed to the inhibition of the approach response by the BIS in response to conditioned stimuli for punishment (Pun-CSs). Thus, it can be seen that, in this conflict situation, the BAS and the BIS act in opposition to each other: the BAS tends to activate approach behavior in response to Rew-CSs, and the BIS tends to inhibit these responses in the face of Pun-CSs. Whether an approach response will occur depends on which of these mutually antagonistic

systems is dominant—an outcome that, in turn, is influenced by the relative strength of the Rew-CS and Pun-CS inputs.

A similar mutual antagonism between the two systems is found in extinction: the nonoccurrence of an expected reward produces frustration, the functional equivalent of punishment. Stimuli in extinction become conditioned stimuli for frustrative nonreward, which activate the BIS and subsequently inhibit the approach response. As the non-reward CSs (nonRew-CSs) increase in strength over extinction trials, BIS activity increases and eventually becomes strong enough to inhibit the approach response. This brief description shows that the approach-avoidance conflict and the extinction paradigms are similar in many respects; the major difference is in the source of the aversive unconditioned stimulus (UCS)—whether it is an externally applied punishment or the nonoccurrence of an expected reward.

The fourth paradigm is the one-way, active-avoidance task, in which a conditioned stimulus is presented for several seconds before the onset of a shock. The animal receives the shock if it does nothing, but if it makes a response during the CS that takes it out of the compartment, it can avoid the shock altogether. The avoidance response is maintained by the nonoccurrence of an expected punishment, the functional equivalent of a reward. Consequently, the avoidance response is activated by the BAS in response to conditioned stimuli for relieving nonpunishment (nonPun-CSs), that is, the active-avoidance response is comparable to responses in a reward-learning situation. A paradigm traditionally viewed as involving anxiety in response to the threat of shock is viewed, in this model, as primarily involving the activation of behavior under the control of positive incentive motivation. Note that this conclusion implicates the appetitive motivational system in the response to stressful events. When faced with a threat of punishment, activation of the BAS may lead one to *actively cope*—that is, attempt to find a successful active-avoidance response. Alternatively, dominance of the BIS will inhibit responding (passive coping or inactivity).

Several aspects of the analysis of the four paradigms in terms of the two motivational systems require comment. First, the crucial variable is what happens to behavior. If behavior is activated, the BAS is involved; if behavior is inhibited, the BIS is involved. Second, Gray offered four terms

to refer to the emotional or motivational state induced by each of these CSs. The two aversive motivational states are called "frustration" (for nonRew-CSs) and "fear or anxiety" (for Pun-CSs). The two appetitive motivational states are called "hope" (for Rew-CSs) and "relief" (for nonPun-CSs). Frustration and anxiety involve the same underlying motivational state; the difference between them is a matter of labeling based on the external stimulus conditions. Similarly, hope and relief involve a single motivational state; the differences again are attributable to the circumstances that induced that state. Third, in contrast to earlier S-R learning theories, this model incorporates an *expectancy* concept that allows the theory to account for the effects of the *nonoccurrence* of rewards and punishments.

Gray (1987, pp. 294–313) summarized his view of the neurophysiological substrate of the BIS that has been the focus of much of his own work. The BIS centers on the septohippocampal system (SHS), especially the control of hippocampal theta activity (5–12 Hz in the rat) by a pacemaker in the medial septal area, but includes the closely related Papez loop, noradrenergic pathways that ascend from the locus coeruleus to the SHS, serotonergic pathways that ascend from the raphe nuclei to the SHS, and neocortical structures (entorhinal, prefrontal, and cingulate cortex) that have two-way communication with the SHS. The SHS functions as a comparator, comparing actual with expected stimuli. When there is a mismatch (i.e., novelty) or when signals of punishment or nonreward are encountered, the SHS shifts to the control mode, in which it activates the (behaviorally inhibiting) outputs of the BIS. To fulfill this comparator function, the SHS must have access to information about current sensory events, past environmental regularities that allow predicting events, the next intended motor programs or plans, and information about the past consequences of such motor programs (Gray, 1987, pp. 293–294). Thus, the operation of the BIS involves extensive *information processing* that requires input from many higher level functions.

Gray has not been as concerned with the neural basis of the BAS, but he does suggest (e.g., Gray, 1987, pp. 308–309) that DA pathways are involved. Specifically, there is consistent evidence that the mesolimbic DA pathway that ascends from the A10 nucleus in the ventral tegmental area to the nucleus accumbens and the ventral striatum

plays a key role in incentive motivation. Consequently, it is likely that this pathway plays a central role in the BAS. As will be seen later, the mesolimbic DA system has been implicated in theories of both drug abuse and of the affective disorders. In both instances, the mesolimbic DA system is presumed to activate behavior in response to (reward) incentive cues—a function quite consistent with serving as the neurophysiological substrate for Gray's BAS. Thus, there is consistent support for the hypothesis that the mesolimbic DA system is involved in activating behavior in response to cues for reward. It should also be noted that Gray's BAS overlaps substantially with Depue's BFS (mentioned before and described more fully later), in both behavioral functions and underlying neurochemical pathways (Fowles, 1994).

Gray includes a third major system in his theoretical framework—the *fight/flight system*. This system is said to mediate the behavioral effects of *unconditioned* punishment and nonreward that result in escape and defensive aggression. The major pathways in the fight/flight system are the amygdala, the ventromedial nucleus of the hypothalamus, and the central gray of the midbrain (Gray, 1987, pp. 324). The ventromedial nucleus exerts tonic inhibitory control over the central gray, which is the "ultimate executive organ for either flight or defensive attack" (p. 324). In response to unconditioned punishment and unconditioned frustrative nonreward stimuli, the amygdala sends inhibitory signals to the ventromedial nucleus, thereby disinhibiting the central gray and the fight/flight response. Interestingly, the SHS sends excitatory signals to the ventromedial nucleus that intensify inhibition of the central gray in response to novel or threatening stimuli. Whether passive avoidance or fight/flight occurs in response to these stimuli depends on the relative strength of the inputs from the SHS and the amygdala.

To the extent that the material just presented identifies major motivational systems that play a central role in both emotional response and the regulation of behavior, it should be possible to identify their contribution to most major forms of psychopathology, as attempted by Fowles (1992b, 1994). This contribution may be direct or indirect. Direct effects include either *quantitative* individual differences in the strength of one of these systems inherently relevant to psychopathology (e.g., a weak but functioning BIS tends to produce BAS

dominant or impulsive behavior) or a *qualitative* breakdown of function (e.g., an absence of BIS control over the BAS will lead to the unrestrained appetitive behavior seen in mania). Indirect effects occur when the primary source of the psychopathology is not found in one of the motivational systems—for example, schizophrenia—but where individual differences in the activity of the BAS and BIS affect the symptom pattern.

Anxiety Disorders

Competing Conceptualizations of Anxiety

In a number of papers published in the 1970s, Gray (e.g., 1976, 1978, 1979) proposed a “neuropsychological theory of anxiety” that draws on the motivational constructs described before. This early work can best be viewed as an attempt to understand, in terms of the constructs of learning theory, the common behavioral effects of those pharmacological agents that clinically reduce anxiety. Among these are alcohol, barbiturates, and minor tranquilizers.

Gray (1977) reviewed the extensive literature on the behavioral effects of antianxiety drugs, and he (1979) summarized the conclusions from that review. The studies reviewed pointed to reduced effectiveness of the BIS in inhibiting behavior in response to PUN-CSs and nonREW-CSs. With respect to the paradigms described before, the antianxiety drugs disinhibit behavior in the passive-avoidance situation, and they increase resistance to extinction following continuous reinforcement. Rates of response are also reliably increased under fixed-interval, fixed-ratio, and differential reinforcement of low-rate (DRL) schedules. The common feature of these three schedules is that an event signals that the animal's responses will not be rewarded for a period of time, thereby serving as a nonREW-CS. On the other hand, the antianxiety drugs do not affect responses that are viewed as primarily mediated by the BAS (e.g., simple reward learning and one-way active avoidance) or the fight/flight system. This specific effect of antianxiety drugs on the BIS, combined with the aversive quality of the stimuli that activate the BIS (i.e., cues for punishment and frustrative non-reward) make a strong case for Gray's conclusion that the BIS represents an anxiety system. Thus,

Gray's work provides a behavioral construct (the BIS) that is centrally involved in anxiety and that provides a link to biological treatments.

In recent years, however, a burgeoning literature has emphasized the importance of the *amygdala* for developing conditioned fear (e.g., LeDoux, 1995, 1996, pp. 157–174). More specifically, the lateral nucleus of the amygdala receives input (CSs from fear conditioning), and the central nucleus of the amygdala generates output for the fear response (e.g., freezing, autonomic nervous system responses, stress hormone release, etc.). The work of Davis (e.g., 1992) on the ability of CSs from fear conditioning to potentiate the startle response inspired Lang and his colleagues (e.g., Lang, Bradley, & Cuthbert, 1990) to develop the fear-potentiated startle paradigm with human subjects. This paradigm stimulated hundreds of studies and underscored the importance of the amygdala in fear and anxiety.

Noting the popularity of this work on the amygdala and the view of many that the amygdala rather than the SHS is centrally involved in anxiety, Gray and McNaughton (1998) attributed the differences between the SHS/BIS theory and the amygdala/startle theory to different starting points. Gray begins with the assumption that anxiolytic drugs affect anxiety and this path leads to the SHS. LeDoux and Davis begin with the assumption that responses to the CS in a classical aversive conditioning paradigm define anxiety and follow a path to the amygdala.

In a summary and revision of Gray's theory, McNaughton and Gray (2000) include the amygdala in an expanded and somewhat more complex BIS that provides, to some degree, an integration of the two approaches to understanding anxiety. McNaughton and Gray employ Blanchard's (e.g. Blanchard & Blanchard, 1990; Blanchard, Griebel, Henrie, & Blanchard, 1997) distinction between fear-related versus anxiety-related behaviors. *Fear-related* behaviors are those associated with the *fight/flight* response when a predator or an impending punishment is *present*. In contrast, *anxiety-related* behaviors are associated with *exploration or approach* in an approach-avoidance conflict, when a predator/punishment may or may not be present, that is, *fear* involves simple avoidance without conflict, whereas *anxiety* involves approach and goal conflict.

In this view, the SHS codes anxiety, whereas the amygdala mediates the fear that underlies both

active and passive avoidance tendencies, controls behavioral avoidance consequent on anxiety, and increases arousal and autonomic responding. The SHS and its control of theta in the hippocampus is still the most important neural component of the BIS/anxiety system, and the amygdala is more obviously related to fear and fight/flight. However, the two structures are viewed as interacting in many situations as part of the BIS, and the amygdala contributes especially to passive avoidance in response to output from the SHS.

To summarize, the different perspectives offered by the septohippocampal and the amygdala literatures have not been fully reconciled, but some suggestions can be made. First, the cornerstone of Gray's theory of anxiety is the effects of anxiolytic drugs, whereas the amygdala/startle literature is tied strongly to immediate fear stimuli such as the CS in classical conditioning paradigms. Second, in the revised theory, the BIS is tied to approach-avoidance (goal) conflict. Anxiety derived from activity of the BIS involves *approach* to a source of danger, whereas the fight/flight system and *fear* involve *avoidance* of a source of danger. The amygdala is centrally involved in fear and fight/flight. Third, activity in the central nucleus of the amygdala produces an increase in autonomic and central nervous system *arousal*, whereas activity in the SHS involves more *information processing* and is more cognitive.

Application to Anxiety Disorders

In an interesting extrapolation to psychopathology, McNaughton and Gray attribute GAD to excessive output from the SHS. Underscoring the information processing aspects of the SHS, they describe GAD as primarily a *cognitive disorder* that involves an excessive perception of threat and a subsequent suppression of approach and excessive avoidance of threat. In contrast, the fight/flight system (which has a greater involvement of the amygdala/fear system) mediates panic attacks (Gray, 1987, p. 366).

Gray's BIS theory readily accounts for the association between anxiety, on the one hand, and such characteristics as shyness, social withdrawal, sensitivity to punishments, a tendency to be easily discouraged, and a failure to develop active means of coping with situations, on the other hand—a dimension of internalizing disorders identified in

multivariate studies of children (Achenbach & McConaughy, 1997; Quay, 1986). These are the characteristics to be expected in an individual in whom the balance between the BIS and the BAS has shifted heavily toward dominance of the BIS. The more reactive BIS would generate anxiety in situations that are only moderately threatening. On the assumption that other people dispense both rewards and punishments, much social interaction can be seen as involving an approach-avoidance conflict. The dominance of the BIS over the BAS would, in this case, result in passive avoidance (shyness and social withdrawal). Similarly, the dominance of passive avoidance in conflict situations would impede the development of active coping skills. Finally, the dominance of the BIS in extinction situations would produce more rapid extinction that is manifested as a tendency to become easily discouraged and to give up when pursuing goals. Therefore, this cluster of characteristics can be seen as a consequence of a temperament in which the BIS is strongly dominant.

To more clearly assess application to anxiety disorders, it is useful to consider Barlow's (1988) theoretical analysis. Barlow distinguishes between two types of anxiety, which he calls anxiety and fear. More completely, anxiety is termed *anxious apprehension*, whereas fear is an *alarm reaction*. Anxious apprehension refers to a process of anticipatory anxiety that helps to prepare the organism to cope with the challenges and stresses of everyday life, and this process (in extreme form) underlies GAD. At pathological levels, anxious apprehension is said to consist of a diffuse cognitive-affective structure that has the following components: (1) negative affect, (2) high arousal, (3) perceptions of helplessness or uncontrollability of future events, and (4) "worry" or the allocation of attention to negatively valenced self-evaluative concerns and/or the autonomic correlates of the arousal itself.

Although Barlow's (1988) "anxiety" and Gray's BIS are not identical, there is enough overlap to argue that similar constructs are involved (Fowles, 1992a). Barlow's emphasis on preparation for stresses and challenges is entirely consistent with the role of the BIS in approach-avoidance conflict situations and situations involving frustration (failure) and with Gray's (1987, p. 263) comment that it prepares the organism for vigorous activity. Both anxiety systems, it is assumed, produce an increase in arousal. Barlow's emphasis on "worry"

can be seen in Gray's (1982, p. 13) comment that the BIS allocates attention to "the maximum possible analysis of current environmental stimuli, especially novel ones" and his (1987, p. 263) description of the BIS as the "stop, look, and listen" system. Further, the conclusion, cited before from McNaughton and Gray (1999), that excessive output from the SHS is involved in the etiology of GAD underscores the similarity of Barlow's anxiety systems and Gray's BIS. Because the BIS is responding to potential threats (including uncertain threats in the form of novelty), it is reasonable to see that this vigilant anticipation and appraisal of threats involve worry. More recently, Barlow and Durand (1995, p. 157) comment that the BIS "seems heavily involved in anxiety" and agree that "Gray's thinking is very close to" Barlow's (1988) theory of anxiety and anxiety disorders. Overall, then, the two theoretical constructs share enough features that it can be proposed that Gray's behavioral inhibition system is involved in the etiology of GAD.

Returning to Barlow's (1988) theory, fear is modeled on Cannon's fight or flight response and is seen as a massive alarm reaction to potentially life-threatening situations. Panic attacks are viewed as alarm reactions, albeit *false alarms* in the sense that they are not based on objectively life-threatening situations. Panic attacks seen in the clinic include a fear of dying or losing control, as well as acute anxiety accompanied by somatic symptoms.

Citing evidence that false alarm panics are common in the population, Barlow suggests that they may serve as *unconditioned* stimuli for classical conditioning, leading to further conditioned panic attacks, which Barlow calls *learned alarms*. Because patients with Panic Disorder focus strongly on their internal physiological cues, both Barlow (1988) and Mineka (1985) suggest that interoceptive conditioning is involved, in which internal physiological cues become conditioned stimuli for panic attacks. What brings patients with Panic Disorder to the clinic, however, is not just the occurrence of panic attacks, but rather their anxiety over possible future uncued panic attacks. Whereas many individuals are not disabled by learned and/or unlearned panic attacks, Barlow suggests that those who become *anxiously apprehensive* about future attacks are disabled and seek treatment, that is, the same process of anxiety seen in GAD is proposed as a core feature of Panic Disorder. This line of reasoning is supported by

the finding that patients with Panic Disorder almost always also meet the criteria for GAD.

Both Barlow's alarm reaction and Gray's fight/flight system are modeled after Cannon's fight or flight response. Further, Barlow (Barlow and Durand, 1995, p. 157) cites Gray's fight/flight system as the basis for panic attacks and, as noted above, Gray (1987) relates the fight/flight system to panic attacks. Consequently, panic disorder can be seen as a strong response in Gray's fight/flight system combined with higher levels of activation of the BIS (producing worry and anxious apprehension). That is, Gray's motivational theory describes neurobehavioral systems that are involved in the major anxiety disorders.

Finally, the perception that alarm reactions and/or negative events are neither predictable nor controllable is a risk factor for anxious apprehension in Barlow's theory (see also Mineka, 1985). This perception can be seen as related to the expectancies of response-contingent reward or relieving nonpunishment associated with activation of the BAS. Positive expectancies reduce the perceived threats of frustrative nonreward (failure) and punishment and, thereby, reduce input to the BIS, whereas activation of the BAS has a direct inhibitory effect on the BIS. In contrast, negative expectations will have the opposite effects.

Substance Abuse

Major aspects of the literature on substance abuse fit particularly well with the motivational model. Although at one time it was argued that drug abuse could be attributed to physiological dependence *per se* (Jaffe, 1980; Leshner, 1997), there has been a substantial move toward the view that "abuse of reinforcers" conveys the essence of drug abuse, either through the termination of distress or dysphoria (negative reinforcement) or through the induction of pleasure or euphoria (positive reinforcement) (Baker, 1988; Wise, 1988).

The present discussion focuses on positive reinforcement as a mechanism underlying substance abuse. Such a mechanism suggests the involvement of Gray's BAS. It will be recalled that the BAS responds to cues for rewards, activates behavior, generates a positive emotional state, and is associated with the DA pathways that project from the ventral tegmental area to the limbic system (the mesolimbic DA system).

The contribution of appetitive motivation is particularly clear in the case of stimulant drugs (e.g., cocaine, amphetamines) and opioids (e.g., heroin, morphine). Conditioned incentive stimuli (environmental stimuli previously associated with the consumption of these drugs) generate appetitive motivational states and energize drug-seeking behavior (Stewart, de Witt, & Eikelboom, 1984). These conditioned incentive stimuli, it is also believed, contribute to relapse (Stewart et al., 1984)—that is, former addicts often relapse in the presence of cues previously associated with drug consumption.

Wise (1988) adopts a similar position but emphasizes that positive reinforcers elicit forward locomotion. Additionally, the ability to induce “psychomotor activation” is a common mechanism that underlies almost all drugs of abuse—not only stimulants and opioids, but also alcohol, barbiturates, benzodiazepines, cannabis, and others. This description of the common mechanism in Wise’s theory of drug abuse as response to rewards and activating behavior is quite similar to the behavioral functions of Gray’s BAS (and Depue’s BFS).

A consensus has emerged concerning the neurochemical mechanisms that mediate the addicting effects of many drugs of abuse: these mechanisms involve the mesolimbic and mesocortical DA pathways (Koob & Le Moal, 1997; Leshner, 1997; Stewart et al., 1984; Wise, 1988; Wise & Rompre, 1989; Wise & Bozarth, 1987). Leshner (1997, p. 46) asserts that “Virtually all drugs of abuse have common effects, either directly or indirectly, on ... the mesolimbic *reward* system.... Activation of this system appears to be a common element in what keeps drug users taking drugs ... all addictive substances affect this circuit.” Thus, the construct of appetitive motivation occupies a central position in the current literature on substance abuse, and the neurochemical substrate for these drug effects is the DA pathways associated with the BAS.

It is reasonable to further suggest that drug-seeking and drug-consuming behavior reflect the outcome of an approach–avoidance conflict, in which the BAS responds to the immediate positive reinforcing properties of the drugs, whereas the BIS responds to the much delayed negative consequences of drug consumption (e.g., loss of job and friends, legal problems, withdrawal distress, social disapproval, etc.). This conflict model explains

why a temperament of impulsivity/disinhibition is a strong risk factor for substance abuse (Sher & Trull, 1994). A dominance of the BAS over the BIS would produce both an impulsive temperament and a bias toward the positively reinforcing effects of drugs of abuse over the delayed negative consequences. Therefore, to the extent that this approach–avoidance conflict model applies, appetitive and aversive motivational constructs are particularly useful to understanding substance abuse.

Affective Disorders

Much theorizing about affective disorders implicates concepts similar or identical to Gray’s BAS. Almost all theories of depression implicate a loss of appetitive motivation, and Depue’s theory of bipolar affective disorder parallels the BAS at both the behavioral and neurochemical levels.

Appetitive and Aversive Motivation in Depression

The constructs of appetitive and aversive motivation are central to behavioral theories of depression. Depression is viewed as associated with the activation of aversive motivation and/or a disruption of appetitive motivation, and the greater emphasis is on the disruption of appetitive motivation. Indeed, disruption of appetitive motivation is a common feature of almost all behavioral theories of depression (e.g., Eastman, 1976). Similarly, in the cognitive theories of Beck (e.g., 1974, 1983, 1984) and Abramson and her colleagues (Abramson, Seligman, and Teasdale, 1978; Abramson, Metalsky, & Alloy, 1989), the depressed patient is seen as having developed expectations that reward-seeking will be ineffective (hopelessness). Bereavement, the prototype for reactive depressions, causes a reduction in, or absence of, both rewards and cues for rewards. A primary anhedonia—an inability to experience pleasure or to respond to rewards—is postulated by the more biological approaches (Davidson, 1994; Henriques, Glowacki, & Davidson, 1994; Klein, 1974). In still other theories, activation of aversive motivation is said to disrupt or inhibit appetitive motivation (e.g., Eastman, 1976; Ferster, 1973).

Note that in many of these theories aversive motivation is relevant to depression primarily in-

sofar as it inhibits or disrupts appetitive motivation, because the loss of appetitive motivation is what distinguishes depression from anxiety. This view is supported by findings based on self-report inventories, in which high negative affect is associated with both anxiety and depression, but only depression is associated with the absence of positive affect (Mineka et al., 1998). Taking a more cognitive approach, Clark, Beck, & Stewart (1990) found that anxious patients expressed more fear of punishment in the form of thoughts of anticipated harm and danger, whereas depressed patients showed more concern about an inability to obtain rewards as indicated by hopelessness and more negative thoughts involving loss and past failure. The depressed patients expressed certainty (a "knowing" mode) about these events, whereas the anxious patients were apprehensive about what might happen (a "questioning" mode).

The application of Gray's theory organizes these theoretical approaches along the following lines. In the *extinction model*, any event that interferes with reward-seeking behavior (e.g., loss events, failures, or disabilities) places the person on extinction, initially creating negative affect (frustrative nonreward) as a result of disconfirmed positive expectations. To the extent that this interference is perceived as enduring—either by an evaluation of the initial event or resulting from experience with continued trials—expectancies change in the direction of seeing one's behavior as ineffective (hopelessness as proposed by the cognitive theories). As these expectancies change in a negative direction from helplessness (uncertainty) to hopelessness (certainty), the aversive motivational reaction diminishes (there are no longer positive expectations to be frustrated) and is replaced by the failure to activate appetitive motivation. In the *approach-avoidance conflict model*, reward motivation is blocked by aversive motivation in the form of fears of response-contingent punishment for making the appetitive response itself or for failure to perform successfully. If the person is strongly tempted to make the appetitive response, the aversive state of fear or anxiety will predominate. However, if the person comes to feel that the cost of such responding is unacceptably high and gives up, then hopelessness will prevail, appetitive behavior will be abandoned (a dominance of passive avoidance), and the anxiety will diminish (there is no threat in the absence of a response). In one well-documented phenomenon,

anxiety disorders precede major depression rather than the reverse (Mineka et al., 1998); this is interpreted in this context as an anxiety-induced shift from approach-avoidance conflict to a dominance of passive avoidance and the accompanying hopelessness. In the *uncontrollable punishment model* (e.g., an abused child, a battered wife, or a humiliated employee), avoidance responses are unsuccessful, leading to a state of hopelessness. In this case, however, aversive motivation will continue to be strong because of the continuing threat of punishment. Not infrequently, uncontrollable punishment will be mixed with one of the other models. For example, a young widow with several children, little education, and few financial resources may be exposed to numerous threats of punishment, as well as with the loss of rewards previously associated with her husband.

It is also important to note that the reciprocal antagonism between the appetitive and aversive motivational systems means that they are not completely independent. Activation of either system will tend to inhibit the other to some extent, and inactivation of either system will tend to disinhibit the other. Thus, even with a depression whose primary etiology involves inactivating appetitive motivation, there may be an increase in aversive motivation as well (e.g., Klein, 1974). Consequently, aversive motivation may increase as a primary etiological factor and also as a secondary consequence of the disruption of appetitive motivation that contributes to the common finding that anxiety is frequently seen in depression (Mineka et al., 1998). The amount of aversive motivation will depend on the strength of the person's aversive motivational system (disinhibiting a weak system will not result in much anxiety) and on the strength of the environmental cues for punishment and frustrative nonreward.

Mania

The genetic contribution to mania is strong (e.g., Gershon, 1990; Katz and McGuffin, 1993; Owen & McGuffin, 1997; Rutter & Plomin, 1997), underscoring the need to consider biological factors. Mania appears to fit nicely into the theoretical framework that employs appetitive and aversive motivational systems, as seen in Depue's attempt to specify a biological substrate for mania within a neurobehavioral framework.

With respect to motivational systems, the symp-

toms of mania suggest that appetitive motivation is activated noncontingently, unrestrained by the BIS. These symptoms include an elevated, expansive mood, an increase in motor activity, engaging in activities with a high potential for painful consequences that is not recognized, and inflated self-esteem and overconfidence. The manic strongly seeks rewards (i.e., behavioral activation) in an unrestrained manner, confidently expects to achieve them due to insensitivity to the risks of punishment and frustrative nonreward, and enjoys a positive mood and high self-esteem in anticipation of attaining those rewards. Activation of the BAS in Gray's model should produce this covariation of behavioral activation, reward-seeking behavior, and positive mood. The breakdown of restraint of the BAS by the BIS would result in lack of awareness of potential risks and a minimal impact of actual failures. The strength of the activation of the BAS seen in mania suggests that the primary problem is excessive activation of the BAS, as opposed to simple lack of restraint by the BIS, but it is difficult to be certain. This author has suggested elsewhere (Fowles, 1988) that the irritability that arises when the manic is thwarted (Tyrer & Shopsin, 1982) could represent a response to frustration that violates social norms as a result of the lack of control by the BIS.

Depue and his colleagues (Depue, Arbisi, Spont, Leon, & Ainsworth, 1989; Depue & Iacono, 1989; Depue, Krauss, & Spont, 1987) proposed a neurobiological theory of bipolar affective disorder that bears many similarities to the perspective adopted here. Also consistent with the theme of this chapter, Depue and Iacono emphasize the importance of placing neurobiological hypotheses within a *neurobehavioral* framework that allows relating neurochemical deficits to the behaviors critical for diagnosis. At the level of a behavioral theory, the behavioral facilitation system (BFS) described by these authors is strikingly similar to the BAS. The BFS facilitates behavior via activation of locomotor activity and reward-incentive motivation, just as the BAS does. Similarly, Depue and Iacono conclude that the mesolimbic DA system is critically involved in the BFS, especially the projections of the A10 DA cell group in the ventral tegmental area to the nucleus accumbens (mesolimbic DA pathway) and the prefrontal cortex (mesocortical DA pathway).

Depue (Depue et al., 1987; Depue & Iacono, 1989) describe mania as exhibiting high levels of

the multiple manifestations of activity in the BFS: high motor activity (hyperactivity, rapid and pressured speech, and expressive facies), high incentive reward activation (excessive interest and pleasure, desire for excitement), a positive mood (elation, euphoria), high nonspecific arousal (manifested in changes in appetite, energy level, need for sleep, thought, attention, and sensory vividness), and cognitive changes (increased optimism and feelings of self-worth). Bipolar depression represents the opposite of mania, an absence of activity in the BFS (e.g., retardation—an absence of motor activity, anhedonia—no interest or pleasure, etc.). (See also Healy, 1989; Silverstone, 1985; and Wilner 1985, pp. 147–192, for dopamine involvement in mania.)

Depue et al. (1987) propose that the fundamental deficit in bipolar disorder is a failure to regulate the BFS (trait *variability*), which is different from the trait *level* of the strength of the BFS. Individual differences in the strength of the BFS (trait level) will affect the severity of manic episodes when regulation fails. A strong unregulated BFS will more often reach clinical severity for mania, and the manic component will be prominent. In contrast, a weak unregulated BFS is much less likely to result in a clear manic syndrome—producing a clinical picture of unipolar depression, even though the underlying etiology is the same as for bipolar disorder. This model is one of the few that can account for the appearance of unipolar depression among the relatives of bipolar probands, as is found in the genetics literature (e.g., Nurnberger & Gershon, 1992). This account explains the partial effectiveness of the traditional antipsychotic medications in treating mania because these drugs block dopaminergic activity in the mesolimbic and mesocortical pathways (see later). In this theory, the drugs would not address the problem of dysregulation, but they would weaken the BAS and thereby reduce manic behavior.

To summarize, Depue's theory of the etiology of bipolar disorder invokes an appetitive motivational system almost identical to the BAS. A failure of regulation of this system is the primary etiological factor that allows it to swing from excessive activation in mania and an absence of activation in bipolar depression (and some unipolar depressions). Implicating the mesolimbic and mesocortical dopamine pathways as central to this motivational system parallels Wise's concept of psychomotor activation in response to reward in

substance abuse, as well as Gray's own suggestion for the BAS. Thus, the role of dopamine pathways for this appetitive motivational system is strongly documented. The dopamine projections from the ventral tegmental area to the nucleus accumbens are cited by all authors, whereas those to the prefrontal cortex are not always mentioned.

Psychopathy

The modern usage of the term psychopathy dates from Cleckley's (e.g., 1964) clinical descriptions. Two of the features, impulsivity and an absence of anxiety, have been the object of motivational hypotheses. Lykken (1957) demonstrated poor electrodermal conditioning and/or rapid extinction using electric shock as the unconditioned stimulus and proposed that the electrodermal hyporeactivity reflected low fear in anticipation of punishment. Further, he showed that, in a "mental maze" task, psychopaths failed to avoid a punished incorrect alternative as well as controls. Poor performance on this passive avoidance task (an analog impulsivity task) was also attributed to poor fear conditioning.

Both findings have been conceptually replicated many times. After replicating the poor conditioning, Hare introduced a "countdown" to punishment task that also reliably shows electrodermal hyporeactivity in psychopaths in the few seconds before the delivery of punishment. All reviewers have found that electrodermal hyporeactivity in anticipation of punishment is a reliable finding (e.g., Fowles, 1993; Hare, 1978, 1998; Siddle & Trasler, 1981; Zahn, 1986). Similarly, the passive avoidance deficit has been demonstrated many times in psychopaths (e.g., Newman & Kosson, 1986; Newman, Patterson, & Kosson, 1987; Newman, Patterson, Howland, & Nichols, 1991; Newman, Widom, & Nathan, 1985; Schachter & Latane, 1964; Schmauk, 1970; Siegel, 1978) and in conduct disordered children who are low in anxiety (Frick, 1998).

Recent interpretations of Lykken's low fear hypothesis have employed Gray's model to propose that psychopaths have a weak BIS and a normal (or strong) BAS (e.g., Fowles, 1980, 1993; Frick, 1998; Gray, 1970, 1976; Lykken, 1995; Trasler, 1978). This hypothesis accounts for the disinhibitory psychopathology and lack of anxiety seen in psychopaths clinically—both central components

of the BIS. Normal reward learning and active avoidance of punishment is consistent with a normal (or strong) BAS.

In contrast to the electrodermal data, heart rate responses in paradigms that involve punishment do not show hyporeactivity in psychopaths and may even be larger than in controls (Hare, 1978, 1998). To account for this directional fractionation of electrodermal and cardiovascular reactivity, Fowles (1980, 1993) proposed that electrodermal activity in response to threats of punishment may reflect BIS activity, whereas heart rate more strongly reflects somatic activity and activation of the BAS.

Alternative biological hypotheses are also prominent in the literature. For example, Hare (1998) reviews an extensive literature that suggests a broader range of neurobiological anomalies than can be subsumed under the low fear hypothesis. In a similar vein, Patrick and Lang (1999) propose that, in addition to a primary fear deficit, psychopaths show a deficit in higher information processing systems that interact with motivational systems. Resolving these issues is beyond the scope of this chapter, but it is clear that (1) Gray's motivational concepts have been prominent in theories of the deficit associated with psychopathy and (2) alternative theories also refer to neurobiological processes.

Schizophrenia

Two lines of research on schizophrenia provide much of the impetus for biological approaches to psychopathology: the importance of genetic influences in schizophrenia and the efficacy of neuroleptic drugs in ameliorating symptoms. Positive evidence on both counts supports the view that biology must be incorporated into theories of schizophrenia. Thus, schizophrenia provides clear support for the thesis that biological variables are important in psychopathology.

The case for applying motivational constructs to schizophrenia is less clear than in most other disorders because the central features of schizophrenia do not reflect too much or too little of the motivational systems discussed here. Nevertheless, it is reasonable to expect that such fundamental motivational systems might play an important role in modifying the clinical picture in schizophrenia and, for that reason, might account for

some of the considerable heterogeneity in schizophrenia. Adopting this perspective, Fowles (1992b, 1994) proposed that individual differences in the strength of motivational systems constitute part of the genetic contribution to schizophrenia. The following is a brief summary of that effort.

Genetic Contributions

The massive literature on the genetics of schizophrenia can be assimilated into a multifactorial polygenic model but cannot be made to fit a single-major-locus model with high penetrance (Faraone & Tsuang 1985; Gottesman, 1991; Moldin & Gottesman, 1997; Risch, 1990). There is no clear evidence against a simple multifactorial polygenic model, but Gottesman (e.g., 1991) notes the possibility of a mixed model. This model includes a small number of mostly genetic cases (a few single rare genes with high penetrance), a small number of cases due primarily to environmental factors, and a large number of cases falling within one of two polygenic models (one simply polygenic, the other a specific major gene of small effect embedded in a polygenic etiology). Thus, the vast majority of cases involve a polygenic etiology.

Heterogeneity in schizophrenia in the form of a chronic versus an episodic course is, at least as a first approximation, easy to conceptualize in a polygenic model. In the polygenic model with a threshold at which total liability produces symptoms of schizophrenia, a chronic course will (on average) be associated with greater genetic liability because there is an inverse relationship between the amount of genetic liability and the amount of environmental liability needed to reach threshold (Gottesman & Shields, 1982, pp. 63–69, 220–221). At high genetic loading, most environments will bring total liability above the threshold, making a chronic course likely. As the genetic loading decreases and more stressful environments are required to reach the threshold for symptom onset, the probability of encountering such environments diminishes, and an episodic course is more likely.

The polygenic model articulated by Gottesman includes environmental influences in the multifactorial etiology of schizophrenia (*general* environmental liability) and thus falls within the diathesis-stress model in which genetic vulnerability and environmental stress combine to produce an episode of schizophrenia. Additionally, the polygenic model includes both *specific* and *general* genetic

liability. Specific genetic liability increases the risk of schizophrenia *per se*. The sources of general genetic liability have not been specified other than to indicate that they have nothing to do with schizophrenia *per se*. Presumably, they represent *modifiers* or *potentiators* of the specific liability—that is, they are *nonspecific* contributors to etiology. As such, they are not part of the schizophrenia spectrum and will segregate independently of schizophrenia in family studies.

Fowles (1992b) proposed that the general genetic liability includes factors relevant to the stress component in the diathesis-stress model. Two broad categories of such factors are obvious. First, some genetically influenced characteristics may increase stress indirectly by making the environment objectively more stressful. For example, low IQ contributes to educational and occupational disadvantages, and temperament factors may interfere with one's ability to reach an adequate social and occupational adjustment (e.g., such behavioral deficit traits as anhedonia, shyness, social withdrawal, etc.). Second, any factor that increases stress reactivity will directly increase sensitivity to stressful environments (see Gottesman & Moldin, 1998). This second group of influences is especially relevant to motivational theories.

Because the BIS is an anxiety system and it has been suggested that it contributes to GAD, a genetic contribution to the BIS is an obvious potential contributor to general genetic liability. The BAS, with its accompanying positive affect, is less obvious but nonetheless also relevant. First, as noted before, the BAS is involved in many aspects of actively coping with threats. Consequently, it is likely to be activated strongly in stressful situations. Additionally, the finding that dopaminergic activity is increased during stressful events (Brier, Wolkowitz, & Pickar, 1991; Gray, 1987, p. 337; Healey, 1989) implicates the BAS in stress responses. This train of thought suggests that there might be two dimensions of arousal associated with heterogeneity in schizophrenia: (1) BAS activation involving *behavioral activation*, dopaminergic activity, and (sometimes) positive affect; and (2) BIS activation involving *behavioral inhibition* and aversive arousal (anxiety).

The Dopamine Hypothesis

The second major development in biological approaches to schizophrenia was the demonstration of at least some therapeutic benefit from neu-

roleptics or antipsychotic drugs in treating schizophrenia and the determination that it is positive rather than negative symptoms (see later for this distinction) that respond to these drugs (e.g., Buckley & Meltzer, 1995; Crow, 1980; Weinberger & Lipska, 1995; Wirshing, Marder, Van Putten, & Ames, 1995). The therapeutic efficacy of antipsychotic drugs can be attributed to their ability to block DA receptors (e.g., Grace & Moore, 1998; Haracz, 1982; Losonczy, Davidson, & Davis, 1987; Snyder, 1978; Weinberger & Lipska, 1995). This suggests that DA pathways are important in schizophrenia and leads to the dopamine hypothesis of schizophrenia (Snyder, 1978). Much debate has centered on whether an increased sensitivity to dopamine might be a *primary* etiological factor in schizophrenia. At present, it appears more likely that dopamine makes a *secondary* contribution by interacting with some other primary deficit that makes the person sensitive to dopaminergic activity (e.g., Healy, 1989; Liddle, Carpenter, & Crow, 1993; Weinberger & Lipska, 1995).

Regardless of the eventual explanation, these findings concerning DA must be incorporated into a theory of schizophrenia. To bridge the theoretical gulf between neuroregulator effects and behavior, two questions must be answered: What are the behavioral implications of activity in the DA pathways? What do DA-related behaviors have to do with the behavioral phenomena of schizophrenia? If it is true that the mesolimbic (and mesocortical) DA pathways are involved in the BAS (activation of behavior in response to cues for reward and relieving nonpunishment with an accompanying positive hedonic tone), it is likely that antipsychotic drugs reduce activity in this system. From this perspective, one of the major behavioral effects of these drugs would be to reduce the responsiveness of the BAS. As expected from this hypothesis, patients treated with antipsychotic drugs show reduced positive affect and reduced sensitivity to rewards—that is, pharmacologically induced anhedonia (Harrow, Yonan, Sands, & Marengo, 1994; Healy, 1989; Sommers, 1985) that involves a range of negative symptoms (e.g., lack of emotional reactivity, lack of goal-directedness, reduced or retarded speech, diminished social and vocational initiative, etc.).

Positive and Negative Symptoms

Strauss, Carpenter, & Bartko (1974) introduced the distinction between positive and negative

symptoms, promoting awareness of an important aspect of heterogeneity in schizophrenia. Carpenter (1992; Liddle, Carpenter, & Crow, 1993) emphasized the challenge of this distinction to the conceptualization of schizophrenia. Positive symptoms are the presence of abnormal functioning, such as hallucinations and delusions, whereas negative symptoms reflect an inadequacy of normal functioning, such as affective flattening, poverty of speech, and social withdrawal (Sommers, 1985). Crow (1980, 1985) proposed a Type I dimension of schizophrenia characterized by prominent positive symptoms, responsiveness to antipsychotics, an acute onset, an episodic course, and good premorbid adjustment. Because of the role of DA in positive symptoms, Crow suggested that the Type I dimension is due to a neurochemical imbalance that involves dopamine. In contrast, Crow's Type II dimension involves prominent negative symptoms, a chronic course, an insidious onset, poor premorbid adjustment, intellectual deterioration, and a poor response to antipsychotics (Crow, 1985).

Early studies of the activity-withdrawal dimension in schizophrenia (based on ratings of ward behavior among hospitalized schizophrenics) are relevant to understanding negative symptoms. Active schizophrenics are characterized as restless, loud, overtalkative, overactive, and as having many friends and interests; withdrawn patients showed an absence of these features. Withdrawal has been related to chronicity, poor premorbid adjustment, negative symptoms, anhedonia, and high levels of (purportedly cortical) arousal as measured by skin potential and two perceptual measures (Depue, 1976; Venables, 1963a,b, 1967; Venables & Wing, 1962).

The activity-withdrawal dimension is important in this context because the balance between the BAS and BIS should influence the degree of activity versus withdrawal. This perspective suggests that negative-symptom, withdrawn patients show a dominance of passive avoidance due to high BIS activity and, quite likely, a deficiency in BAS activity. The low BAS activity could be due to a temperament-based weak BAS or to depression from a variety of sources (genetic factors, life events, demoralization, institutionalism, etc.).

Assuming that negative-symptom patients are BIS-dominant, the high arousal is presumably aversive arousal and mediates the stress response in the diathesis-stress model. If so, one would expect that anxiolytic drugs would be of some

benefit in treating a subset of schizophrenic patients. In a review of pharmacological treatment, Wolkowitz and Pickar (1991) found that 30–50% of schizophrenic patients show favorable response to benzodiazepines and that this response is predicted by a range of symptoms including negative symptoms, core psychotic symptoms, and negative affect symptoms (see Fowles, 1994, for a more complete description). These findings are consistent with the notion that BIS activation may contribute to a wide range of symptoms.

At the other end of the activity-withdrawal dimension, the active behavior, interest in rewarding activities, and dominance of positive rather than negative symptoms among active schizophrenics all point to a contribution to liability from activation of the BAS. These patients have features of mania (Klein, 1982), further indicating BAS activation. Similarly, the good premorbid adjustment (extraverted behavior) and the contribution of dopamine to positive symptoms in Crow's Type I dimension suggest a BAS contribution to liability.

The Schizoaffective Continuum

Although our diagnostic system treats schizophrenia and the affective disorders as unrelated diseases, there is a continuum from schizophrenia to affective disorders, patients with schizoaffective symptoms outnumber those with purely schizophrenic or purely affective symptoms (Kendell, 1982). Crow (1998, p. 502) concludes that "no objective genetic boundaries can be drawn" between predominantly affective and predominantly schizophrenic patients. The theoretical challenge of the schizoaffective disorders is well recognized (e.g., Baron & Gruen, 1991; Crow, 1986, 1991; Kendell, 1982; Meltzer, 1984; Taylor, 1992; Taylor, Berenbaum, Jampala, & Cloninger, 1993).

In schizoaffective disorder with manic symptoms, the DA theory of schizophrenia combined with Depue's DA theory of mania points to the obvious possibility that some vulnerability to schizophrenia (a primary schizophrenia deficit) combines with the high level of BAS-based DA activity in mania to produce schizophrenic symptoms. The continuum from schizophrenia to mania reflects the relative contributions of specific genetic liability for schizophrenia and the BAS-based general liability. A relatively large liability for schizophrenia requires only a modest amount

of BAS-DA activation and thus frequently would present as schizoaffective mania, mainly the schizophrenic subtype. In contrast, a more moderate liability for schizophrenia requires a strong BAS activation (more clearly a manic episode) to reach the threshold for symptom production, thereby presenting as the schizoaffective manic, mainly the manic subtype. Intermediate cases would show a more or less equal manifestation of schizophrenic and manic symptoms. Thus, the dopamine theories of schizophrenia and mania offer an explanation for the fusion of the boundaries of schizophrenia and the affective disorders. It should be noted that Braden (1984) proposed a very similar model.

In schizoaffective disorder with depressive symptoms, a similar suggestion can be made for a nonspecific contribution of depression to general liability for schizophrenia. Assuming that depression usually involves aversive arousal (from BIS activation), depression can be seen to fit the proposal cited before that aversive arousal contributes to the appearance of schizophrenic symptoms and a negative symptom pattern. Moreover, the hopelessness associated with depression will depress reward-seeking behavior and especially promote the anhedonic features of the negative symptoms. In support of this perspective, the symptoms of depression so overlap with the negative symptom pattern in schizophrenia that it is difficult to distinguish between the two (Sommers, 1985).

Summary

Application of the motivational concepts of appetitive and aversive motivational systems to schizophrenia offers a theoretical framework for potentially understanding aspects of heterogeneity in schizophrenia. Both the BAS and BIS are involved in contributions to general liability to schizophrenia—both through responses to stressful environments and through adding to genetic liability. In this view, the BIS contributes passive avoidance and aversive arousal in the negative symptom syndrome in response to aversive environments and is involved in the schizoaffective continuum with depression. The BAS is involved in DA activity (and positive symptoms) during attempts to cope with stress, with the effects of antipsychotic medications on DA and the subsequent anhedonia, with the schizoaffective continuum with mania, and (when inactive during de-

pression) with the anhedonia in the negative symptom syndrome.

Final Comment

There are many biological theories of psychopathology, but motivational approaches have the advantages of being embedded in an overall theory of behavior, of inherently involving systems that respond to environmental influences, and of articulating with underlying neurobiological systems. The purpose of this chapter is to advocate a psychobiological approach. A motivational approach was used to illustrate how such an approach can integrate clinical features of disorders with genetic hypotheses, pharmacological treatments, and neurobiological systems. Whether or not the specifics of the suggestions offered here withstand the test of time and further research, it is hoped that the general approach illustrates the importance and attractiveness of adopting a psychobiological perspective.

CHAPTER 5

Culture, Ethnicity, and Psychopathology

Jeanne L. Tsai, James N. Butcher, Ricardo F. Muñoz, and Kelly Vitousek

For decades, transcultural psychiatrists, cross-cultural psychologists, clinical psychologists, medical anthropologists, and others have been interested in answering the following questions: Are mental disorders that are observed in Western cultural contexts also seen in other cultural contexts? Does culture influence the expression and meaning of symptoms? Are there disorders that exist only in specific cultural contexts? Does the social and psychological impact of mental illness vary across cultural contexts? And how should clinicians treat individuals of cultural backgrounds different from their own?

Scientists and clinicians have been very interested in answering these questions for several reasons. Cultural studies of psychopathology distinguish among aspects of mental illness that generalize across cultures, that are culture-specific, and that

are unique to the individual. These studies advance our knowledge about human disease and dysfunction. Most studies in psychology and psychiatry have focused primarily on White populations of European descent and assume that what is true for White European samples is true for other cultural groups. However, cross-cultural studies have demonstrated that this is not the case. For instance, cross-cultural studies of depression have revealed that feelings of guilt and self-reproach are more frequently associated with depression in Western than in non-Western cultural contexts (Sartorius, Jablensky, Gulbinat, & Ernberg, 1980). Thus, these symptoms may not be universal aspects of depression.

Cultural studies of psychopathology are also important because they elucidate the subjective experience or meaning of mental illness. For example, Estroff (1989) argues that the disorganizing symptoms of schizophrenia may be experienced more negatively in cultures that view the self as stable than in cultures that view the self as dynamic. Understanding cultural influences on psychopathological processes and the meanings of mental illness is critical for accurately diagnosing and effectively treating culturally diverse clinical populations. This becomes increasingly urgent as our society becomes more global and multicultural.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

Defining “Culture,” “Ethnicity,” and “Psychopathology”

Culture has been defined in a variety of ways. Anthony Marsella, a leading expert in cross-cultural psychology, provides one of the most comprehensive definitions:

At an external level, culture is represented in various artifacts, architectural and expressive forms, institutions, and role and behavioral patterns. But culture is also represented internally, in the values, attitudes, beliefs, cognitive styles, and patterns of consciousness of an individual. As such, it is the primary mediator or filter for interacting with the world; it is the lens by which we experience and define reality and orient ourselves to others, the unknown, and to our subjective experience. (Marsella, 1987, p. 381)

Ethnicity is the “culture” of a specific ethnic group or the segment of a larger society that views itself and is viewed by others as different from the majority culture in language, religion, customs, beliefs, values, physical characteristics, and/or ancestral homeland. Members of an ethnic group “participate in shared activities built around their (real or mythical) common origin and culture” (Yinger, 1986, p. 22). In this chapter, the term “culture” subsumes “ethnicity.”

In general, cross-cultural studies of psychopathology have operationalized “culture” poorly. Most studies use national status as a proxy for culture and race as a proxy for ethnicity. As a result, these studies overlook the tremendous variation within national and racial groups and the similarity among national and racial groups in values, beliefs, and other cultural variables that may influence aspects of psychopathology. Few investigators explicitly identify or measure the cultural variables that presumably explain differences between cultural groups.

Psychopathology is the study of abnormal behavior (Davison & Neale, 1994). However, even in Western clinical psychology and psychiatry, it is difficult to define what constitutes “abnormal” behavior. Davison & Neale (1994) propose that “abnormal behavior” is statistically infrequent, violates cultural or societal norms, creates personal distress and suffering, impairs the individual functionally, and is an unexpected response to environmental cues. In general, cross-cultural studies of psychopathology have relied on Western classification systems such as the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) (American Psychiatric Association, 1994) or the International Classification of

Diseases (ICD-10) (World Health Organization, 1992) to define abnormal behavior. The problems with this approach will be discussed later in the chapter.

Theoretical Perspectives

Scholars differ in the degree to which they believe that abnormal behavior is similar across cultural contexts. Traditionally, theoretical perspectives were cast as either “culture-specific” or “universal.” Culture-specific perspectives maintain that because cultures define what is “normal” and “abnormal” and because cultures change over time, what constitutes “abnormal behavior” can be defined only by members of a particular cultural group at a particular time in history (Draguns, 1977). Thus, abnormal behavior is culturally relative. Most proponents of culture-specific approaches endorse the use of “emic” methods, or tools and instruments that are specific to the culture of interest, to study the cultural aspects of psychopathology.

Universal perspectives, however, view particular behaviors as “abnormal,” regardless of cultural context and historical time. According to this perspective, Western conceptions of abnormal behavior are applicable to other cultural contexts. Proponents of universal perspectives use “etic” methods, or tools and instruments that presumably can be applied in different cultural contexts and, therefore, allow cross-cultural comparisons. The tools and instruments used in “etic” studies are typically developed in Western cultural contexts and translated into the language of the culture of study (Segall, Lonner, & Berry, 1998).

Most current views of psychopathology rarely assume either the “culture-specific” or the “universal” stances in their extreme forms. Instead, current perspectives acknowledge that both cultural similarities and cultural differences exist. However, they vary in what they consider the defining aspect of mental illness, which influences the degree to which they hypothesize cultural variation in mental illness.

Cultural Idioms of Distress

One prevailing viewpoint, the *cultural idioms of distress* perspective, posited by Arthur Kleinman, Byron Good, Janis Jenkins (1991) and other medical anthropologists, suggests that mental ill-

ness cannot be separated from its sociocultural context. As stated by Draguns (1982), a particular symptom only becomes an indicator of distress in its “transaction with the environment.” From this standpoint, what matters is not whether specific symptoms exist across cultures, but whether the *meaning* and *subjective experience* of and the *social response* to these symptoms are similar across cultures (Jenkins, Kleinman, & Good, 1991; Krause, 1989).

Biomedical Approach

In contrast, the *biomedical* perspective, shared primarily by mainstream psychiatrists and psychologists, views the cause of mental disorders as physical dysfunction, such as biochemical or anatomical defects (Rosenhan & Seligman, 1989, p. 47). From this standpoint, internal *symptoms* are the defining aspects of mental illness. Culture may influence the content of specific symptoms (e.g., the religious content of hallucinations) and patients’ beliefs about the origins of mental illness (e.g., spiritual vs. biological causes), but the core symptoms of a specific disorder and their impact on psychological functioning are assumed to be similar across cultures.

Variation Across Different Types of Mental Disorders

Marsella (1987) offers a slightly different perspective that accounts for variation among mental disorders. He proposes that the least cultural variation occurs in mental disorders that are the most biologically based, such as severe neurological disease, and the most cultural variation occurs in mental disorders that most closely resemble “normal” behavior (and therefore, are presumably the least biologically based). Thus, he classifies disorders in the following way (from the least to the most culturally variable): severe neurological disease, minor neurological disease, functional psychotic disorders, neurotic disorders, and minor transient states. According to Marsella (1987), disorders such as schizophrenia would vary less across cultures than unipolar depression or general anxiety disorder. Although this perspective appears to explain much of the current empirical findings, it is limited by our incomplete knowledge of the “biological” aspects of various mental

disorders. Thus, it is unclear whether specific neurotic disorders such as depression are indeed less biological than psychotic disorders such as schizophrenia.

Findings from the empirical literature do not entirely confirm or disconfirm any of these theoretical perspectives. Instead, empirical findings support different aspects of each theoretical perspective. Before turning to the empirical literature on culture and psychopathology, we discuss one of the most challenging issues in the cross-cultural study of psychopathology—assessment.

Assessing Psychopathology Across Cultures

To study mental illness across cultures, one must first be able to identify and then classify mental illness in different cultural contexts (see later section for assessment in clinical treatment). This is one of the most challenging aspects of studying psychopathology across cultures. The most widely used nosological systems were developed in Europe (ICD-9) and North America (DSM-IV) and have been criticized for their Western cultural assumptions (Fabrega, 1989). These systems are fraught with shortcomings, even when applied in Western settings. Low reliability, poor validity, and high rates of comorbidity (i.e., the co-occurrence of presumably distinct disorders) are of highest concern (Butcher, 1982; Clark, Watson, & Reynolds, 1995; Krueger, Caspi, Moffitt, & Silva, 1998).

Additional challenges arise when these systems are used with non-Western cultural and ethnic groups. First, because these systems rely primarily on clinical diagnosis, they may obscure cultural differences and/or similarities in specific symptoms. Thus, cultural differences in prevalence rates of clinical depression, for example, may belie cultural differences in the specific symptoms of depression, such as depressed mood, loss of energy, and sleep problems. Second, behavior that is defined as “abnormal” by these Western classification systems may fall well within the realm of normal behavior in other cultural contexts. In Puerto Rico, for instance, dissociative states are considered normal aspects of religious and spiritual practices, whereas in many Western contexts, they are considered symptoms of mental illness (Lewis-Fernandez, 1998). Third, abnormal behaviors in non-Western cultural contexts may be excluded in

these classification systems. In an attempt to address this last issue, DSM-IV (American Psychiatric Association, 1994) includes an appendix that lists "culture-bound syndromes," or disorders that occur in specific cultural settings only. For example, "koro" is a disorder primarily found in parts of Southern Asia (Taiwan, Indonesia, Malaysia, Borneo, and Southern China) in which males harbor an "obsessive fear that their penises will withdraw into their abdomens." More recently, specific disorders found primarily in Western cultures have also been considered "culturally bound." They include "anorexia nervosa," in which individuals (typically females) have an obsessive concern with their weight, and "multiple personality disorder," in which one person is thought to have multiple personalities that assume control over that person's behavior (Takahashi, 1990).

Although the inclusion of "culturally bound syndromes" into the DSM-IV has been hailed as a major step toward acknowledging the influence of culture on psychopathology, it has also encountered much criticism (Hughes, 1998). This debate will be discussed at greater length later in the chapter. Despite these problems, Western classification systems are widely used in cultural studies of psychopathology due to the lack of alternative non-Western classification systems.

Researchers have employed different methods for assessing psychopathology across cultures. These include self-report inventories (e.g., rating scales, personality instruments) and interview schedules (e.g, structured vs. open-ended).

Self-Report Inventories

Most self-report inventories of psychopathology were developed in Western cultural contexts. These are often translated into another language and adapted in ways that increase their cultural relevance for use in non-Western cultural contexts. These instruments include the Beck Depression Inventory, which has been translated for use with Chinese, Vietnamese, Latino, Hmong and other cultural groups and the Minnesota Multiphasic Personality Inventory (MMPI), which has been translated more than 150 times, validated in numerous cross-cultural settings, and used in more than 46 countries. Recently, the MMPI was revised to assess a broader range of problems, to

contain more contemporary items, and to include norms that are more appropriate for cross-cultural comparisons (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989). This version of the MMPI, the MMPI-2 (for adults), has already been translated into more than 26 languages. The MMPI-A (for adolescents) has also been translated into more than a dozen languages.

The Issue of Equivalence. The main problem with using Western instruments to assess psychopathology in other cultural contexts is their *equivalence* (i.e., the extent to which a word, concept, scale, or norm structure can be considered relevant and applicable to cultural groups other than those for which the instrument was developed) (Marsella, 1987). For example, *linguistic equivalence* is achieved when a specific term is the same across languages. Tanaka-Matusmi and Marsella (1976) demonstrated the lack of linguistic equivalence between the words "depression" and "yuutsu" (the Japanese translation of "depression") by having Americans and Japanese list words that they associated with the terms. Whereas Americans associated depression with being "blue," "sad," "down," in "despair," and "dejected," Japanese associated depression with the "mountains," "rain," "storms," and the "dark." *Conceptual equivalence* is achieved when constructs assume the same meaning across cultures. An example of the lack of conceptual equivalence also comes from American-Japanese comparisons: "dependency" in American culture is considered a negative attribute; in Japan, it is the cultural ideal for interpersonal relationships (Doi, 1973). Other forms of equivalence are *psychometric* and *psychological equivalence*, which demonstrate that the psychometric properties of translated instruments are similar and that the items assume the same significance and meaning across languages respectively (Butcher, Coelho, & Tsai, in press).

Various techniques have been proposed to establish instrument equivalence. Extensive research on the MMPI-2 has shown that equivalence can be achieved by following specific procedures (Butcher, 1996). These include (1) having independent investigators translate English versions of an instrument into the language of interest; (2) combining these independent translations into one version, based on decisions by a committee of cultural and linguistic experts; (3) conducting a series of translations and back-translations until all item

wordings are accurate; (4) administering the original and translated versions of the instrument to bilinguals to ensure that their responses are captured similarly by both versions; and (5) using methods such as item response theory, factor analysis, and norm development to assess the conceptual equivalence of the scale.

For some investigators, however, these techniques for ensuring equivalence are not at all sufficient. They argue that regardless of the lengths taken to establish equivalence, instruments developed in Western culture are replete with Western cultural assumptions and exclude non-Western processes and phenomena. These investigators prefer emically derived instruments. Unfortunately, truly emic instruments are rare. The Hispanic Stress Inventory (Cervantes, Salgado de Snyder, & Padilla, 1991) and a number of African-American instruments (Jones, 1996) are among the few that exist.

Interviews

Interviews have also been used to assess psychopathology across cultural contexts. Structured clinical interviews such as the Diagnostic Interview Schedule (Robins, Helzer, Croughan, & Ratcliff, 1981) and the Present State Examination (Wing, Cooper, & Sartorius, 1974) have been used widely in cross-cultural studies of mental illness. For example, the latter was used in the World Health Organization's study of schizophrenia across cultures (Jablensky, 1989). Issues of equivalence apply here because these interview schedules were developed in Western cultural contexts. Ethnographic interviews are more open-ended and presumably allow respondents to reveal their cultural conceptions of mental illness. Therefore, they are considered more emic in nature. For example, Krause (1989) conducted ethnographic interviews with ten Punjabi men and women of diverse ages to examine "sinking heart," a syndrome of heart distress that has been compared to Western conceptions of depression, Type A behavior, and stress. Krause asked her respondents questions about the causality, symptomatology, treatment, and consequences of "sinking heart," but also encouraged them to talk about what they considered the important aspects of this illness. Based on her interviews, Krause concluded that although Western conceptions of depression, Type

A behavior, and stress overlap with "sinking heart," they do not capture its more subtle physical, cultural, and emotional aspects. For example, "sinking heart" experiences are related to problems in individuals' emotional, sexual, and marital relationships and to conflicts in honor and morality (Krause, 1989).

The primary criticism of ethnographic interviews is that, compared to self-report questionnaires, they are more time- and labor-intensive. As a result, they can be conducted only with small samples. In addition, they are more idiographic (specific to each individual) and do not lend themselves to nomothetic (group) comparisons. Often the lack of standardization in interview format also makes comparisons across ethnographic studies extremely challenging. Thus, critics often question the generalizability of findings from ethnographic interviews.

Multimethod Approaches

The most convincing studies of psychopathology across cultures are those that employ multiple methods and therefore incorporate the strengths of each method. For example, Guarnaccia studied "ataques de nervios" using both ethnographic (Guarnaccia, DeLaCanela, & Carrillo, 1989) and epidemiological methods (Guarnaccia, 1993). From his comprehensive study of four cases of "ataques de nervios," Guarnaccia was able to identify the most meaningful aspect of "ataques de nervios," i.e., their relationship to upsetting or frightening events in the family sphere. In his larger scale epidemiological study, Guarnaccia was able to assess whether these findings generalized to a larger population. He also administered the Diagnostic Interview Schedule/Disaster Supplement (Robins & Smith, 1983) to this population to examine how "ataques de nervios" related to Western psychiatric disorders. Guarnaccia (1993) found that the descriptions of "ataques de nervios" revealed in his case studies generalized to a larger Puerto Rican population. In addition, he found that although the majority of Puerto Ricans who reported an "ataque" also suffered from symptoms of depression and anxiety, "ataque de nervios" could not be easily mapped onto either of these psychiatric disorders. Thus, by using multiple methods, Guarnaccia was able to examine the meaning of "ataque de nervios," its general-

izability across cultural subgroups, and its relationship to Western psychiatric disorders.

Central Questions Regarding Culture and Psychopathology

Researchers have used the methods described previously to answer some of the central questions about culture and psychopathology: Are mental disorders observed in Western contexts seen in other cultural contexts? Does culture influence the expression and meaning of symptoms? Do “culturally bound” syndromes exist? Does the social and psychological impact of mental illness vary across cultural contexts? And how should clinicians treat individuals of cultural backgrounds different from their own? Significantly more empirical research has been conducted on the occurrence and presentation of mental illness (the first four questions) than on the impact and treatment of mental illness (the last two questions). In the next section, we review some of this research.

Are Mental Disorders Observed in Western Contexts Seen in Other Cultural Contexts?

Emil Kraepelin, the principal founder of psychiatric nosology, was one of the first scholars interested in the occurrence and expression of mental illness across cultures. He hypothesized that cultural differences in incidence and prevalence rates of mental disorders across cultures existed and were related to differences in social conditions and ethnocultural characteristics (e.g., values). Furthermore, he believed that examining such differences would advance our understanding of pathological processes (Jilek, 1995):

If the characteristics of a people are manifested in its religion and its customs, in its intellectual and artistic achievements, in its political acts and its historical development, then they will also find expression in the frequency and clinical formation of its mental disorders, especially those that emerge from internal conditions. (“Voelkerpsychologie,” Kraepelin, 1904, p. 437, as cited in Jilek, 1995)

Kraepelin journeyed to Java to collect data to support his hypothesis. He concluded that several disorders that were prevalent in Europe were absent in Java and that the expressions of affective and schizophrenic disorders were somewhat different in Java from those in the United States.

Although he was unable to test this hypothesis directly or in other cultures, investigators since his time have (Jilek, 1995). Most of the existing research on psychopathology across cultures has focused on schizophrenia (and related psychotic disorders), depression (and related affective disorders), anxiety, and substance abuse and dependence.

Investigations of the occurrence of specific mental disorders across cultures are epidemiological. Typically, they use Western classification systems to diagnose mental disorders and then compare the total number of cases of a particular disorder within a specific period (i.e., prevalence) across cultures. A few studies examine the number of *new* cases of a particular disorder within a specific period (i.e., incidence) across cultures, but these studies are relatively rare.

Schizophrenia. The term “schizophrenia” has been used to describe a cluster of symptoms that include delusions; hallucinations; disorganized thought, speech, and/or behavior; restrictions in emotional experience and expression; and lack of goal-directed behavior (American Psychiatric Association, 1994). There is strong evidence of a genetic and biological component in schizophrenia. However, this genetic vulnerability is expressed only under stressful environmental conditions (Gottesman & Moldin, 1997; Gottesman & Bertelsen, 1989). Most of the empirical findings suggest that schizophrenia occurs across cultural contexts at similar annual incidence and lifetime prevalence rates.

The WHO Program of Cross-Cultural Research on Schizophrenia is the most comprehensive of cross-cultural studies of schizophrenia. Conducted from 1967–1986, this research program was comprised of three studies that sampled more than eighteen psychiatric centers in Africa, Asia, Europe, and Latin and North America. More than 3,000 patients were assessed using a standard clinical interview (Present State Examination) and then were reassessed 1, 2, and/or 5 years after the initial screening (Jablensky, 1989). The psychiatric centers included were divided into those that represented “developing” (e.g., Nigeria, India, Taiwan) and those that represented “developed” (e.g., United States, United Kingdom) countries. Across cultural contexts, the lifetime prevalence rate of schizophrenia was a little more than 1% of the population (Jablensky, 1989). Moreover, when schizophrenia was conservatively defined, its an-

nual incidence rates did not statistically differ among the cultures sampled and ranged from 0.7 to 1.4 per 10,000 persons across cultures (Jablensky, 1989). The external correlates of schizophrenia were also similar across cultural groups. Males showed an earlier onset of symptoms than females across the cultural groups; Cetingok, Chu, & Park (1990) found similar sex differences in their study of schizophrenia in Turkish and European-American samples. Schizophrenia was also associated with other cerebral and physical diseases across cultures (Jablensky, 1989). These findings suggest that the core aspects of schizophrenia are minimally shaped by culture.

Exceptions to the WHO findings, however, have been observed. For example, higher incidence rates of schizophrenia were found among British Afro-Caribbean immigrant groups (for review, see Jarvis, 1998). Schizophrenia occurs six to eight times more frequently among British Afro-Caribbean immigrant groups than in the native White British population. Several studies suggest that these differences are not due to misdiagnosis (Jarvis, 1998). Therefore, Jarvis (1998) argues that schizophrenia is not biologically based and, instead, results from environmental stresses such as migration, broken family structure, socioeconomic disadvantage, and racism. Future research must assess whether this is the case.

Affective Disorders. There are several types of affective disorders, but unipolar and bipolar depression are the most distinct. Unipolar depression refers to a constellation of affective and vegetative symptoms that include depressed mood, loss of interest and pleasure in activities, fatigue, agitated movement, sleep problems, and changes in appetite and weight. Other symptoms associated with unipolar depression in Western contexts include feelings of worthlessness and thoughts of death. Bipolar depression describes manic symptoms such as grandiosity, flight of ideas, pressured speech, and irritability; often these manic states are interrupted by episodes of unipolar depression. Unlike unipolar depression, there is evidence that bipolar disorder has a strong genetic component (Egeland, 1994). The bulk of the research findings suggest that unipolar and bipolar depression occur across cultures, but at varying prevalence rates.

Bipolar Depression. Epidemiological studies conducted in the United States did not find ethnic differences in lifetime prevalence rates of bipolar depression. For example, in the Epidemiological

Catchment Area Study (ECA) of 18,000+ adults in five U.S. communities, lifetime prevalence rates of one type of bipolar disorder for White American, African-American, and Hispanic groups were 0.8, 1.0, and 0.7%, respectively (Weissman et al., 1991). Moreover, there were no significant sex differences in lifetime prevalence rates of bipolar depression across the three ethnic groups. More recently, findings from the National Comorbidity Survey (NCS) (Kessler et al., 1994), a study of psychiatric disorders in a national probability sample of 8,090 respondents including African-American, White American, and Hispanic groups, also suggest that prevalence rates of bipolar depression do not differ by ethnicity or sex.

Unipolar Depression. Lifetime prevalence rates of unipolar depression, however, differ among ethnic and cultural groups. For example, in the ECA study, lifetime prevalence rates of unipolar depression were higher for White Americans (5.1%) than for African-Americans (3.1%) and Hispanics (4.4%). Moreover, prevalence rates were higher for women than for men (Weissman et al., 1991) across the three ethnic groups. Findings from the NCS also suggest that African-Americans have significantly lower prevalence rates of depressive disorders than White Americans, even after controlling for differences in income and education. Contrary to the ECA findings, Hispanic groups in the NCS study had significantly higher rates of unipolar depression than non-Hispanic White Americans and African-Americans (Kessler et al., 1994). There are a variety of possible explanations for the discrepancy in findings between the ECA and NCS studies. For instance, the stresses and life circumstances encountered by Hispanic groups may have increased during the two periods. It is also possible that the studies included Hispanic samples that varied in their generational status, acculturation levels, and specific Hispanic heritage (e.g., Cuban vs. Puerto Rican).

In fact, differences in prevalence rates have been found among specific Hispanic groups. For instance, Moscicki et al. (1987) analyzed the Hispanic Health and Nutrition Examination Survey (H-HANES) data and found that the prevalence rates for unipolar depression (in parentheses) varied for Cuban males (1.4%), Cuban females (2.9%), Mexican males (1.0%), Mexican females (3.6%), Puerto Rican males (3.4%), and Puerto Rican females (7.4%). Within the same subgroup, differ-

ences were reported based on the length of the stay in the United States and the generational level. In a study of Mexican immigrants and Mexican-Americans in California, Vega and colleagues (1998) found that unipolar depression levels were lowest for recent immigrants (3.2%), were higher for those who had been in the United States thirteen years or more (7.9%), and were highest for those born in the United States (14.4%). The rates of the last group did not differ significantly from those reported for the entire NCS sample (17.2%).

Although the NCS and ECA studies did not include a significant number of Asian-Americans to allow for statistically powerful analyses, findings from other studies demonstrate differences between White and Asian-American prevalence rates of depression. In a study of 1,747 Chinese-Americans in Los Angeles, Takeuchi and colleagues (1998) found that the lifetime prevalence of depression was 6.9%, which was higher than that for White Americans in the ECA study. Other studies also found higher levels of depressive symptomatology among Asian-Americans compared to White Americans. In a San Francisco community sample, Ying (1988) found that Chinese-Americans had higher levels of depressive symptoms as measured by the Center for Epidemiological Studies-Depression Scale (CES-D) than White American community samples. Asian-American college students also reported *higher* levels of depressive symptoms than their White American counterparts (as measured by the Zung Self-Rating Depression Scale [Fugita & Crittenden, 1990] and the Beck Depression Inventory [Okazaki, 1997]). However, because these studies examined reported levels of depressive symptomatology as measured by rating scales, it is unclear whether the groups would have differed in rates of diagnosable clinical depression.

Prevalence rates of unipolar depression also differ across cultures (Jenkins, 1991). For instance, lifetime prevalence rates of unipolar depression are lower in Asian countries than in Western countries. The Taiwan Psychiatric Epidemiological Project found that prevalence rates of depression in Taiwanese samples were significantly lower than those of White Americans in the ECA study (1.14% in Taiwan, compared with 4.9% in ECA) (Hwu et al., 1986). Recent evidence, however, suggests that the magnitude of this Western-Asian cultural difference may be decreasing (Nakane et al., 1991). A variety of explanations have been

proposed to explain these cultural differences in prevalence rates of depression. For instance, some propose that because Asian cultures place a greater emphasis on family and other social relationships than Western cultures, the occurrence of depression is rare. Others, however, argue that depressive symptoms occur at similar rates in Asian and Western cultures, but because mental illness is severely stigmatized in Asian cultures, depressive symptoms are rarely diagnosed as such (Kleinman, 1986).

Anxiety Disorders. Anxiety disorders are generally characterized by excessive worry and apprehension about the future (Castillo, 1998). Specific anxiety disorders include obsessive-compulsive disorder, panic disorder, simple phobias, and post-traumatic stress disorder. Compared to schizophrenia and depression, we know little about the way culture influences anxiety disorders (Draguns, 1994; Guarnaccia, 1997). This may be due to the rare occurrence of "pure" anxiety disorders. Because anxiety often co-occurs with other disorders such as depression (Sartorius et al., 1996), it may be obscured by these other disorders.

In general, findings from epidemiological studies suggest that groups that are under significant stress have higher prevalence rates of anxiety disorders. The ECA study (Robins & Regier, 1991) found that generalized anxiety disorder was more common among females than males, among individuals of lower income than of higher income, and among African-Americans than White Americans when panic and depression were excluded (Blazer et al., 1991). In a separate analysis of the Los Angeles ECA data, however, Karno and colleagues (1989) found that Mexican-Americans had *lower* rates of generalized anxiety disorder than White Americans. The Mexican American Prevalence and Services Survey (MAPSS) (Vega et al., 1998) found further differences in prevalence rates for anxiety disorder among specific Mexican-American groups. The lowest rates of "any anxiety disorder" were found for recent Mexican immigrants (7.6%); a higher rate was found for immigrants who lived in the United States for 13 years or more (17.1%), and the highest rate was found for U.S.-born Mexicans (24.1%), which was similar to the rate for the entire NCS sample (25.0%). Vega and colleagues (1998) propose that traditional aspects of Mexican culture may protect individuals from these disorders.

Although the NCS study also found sex differ-

ences in rates of generalized anxiety disorder, none of the ethnic differences found in the ECA study emerged. Although there are many possible explanations for the discrepancy in findings between the ECA and NCS studies, it is possible that levels of stress among ethnic groups were less similar during the ECA study than during the NCS study. This possibility is consistent with findings that prevalence rates of depression and related disorders are increasing across the world (Klerman, 1993).

Ethnic differences were also found in prevalence rates of specific anxiety disorders. In the ECA study, African-Americans demonstrated nearly twice the rate of simple phobia and agoraphobia than White Americans (Eaton, Dryman, & Weissman, 1991). In a separate analysis of the Los Angeles ECA data, American-born Mexicans had higher rates of simple phobia and agoraphobia than White Americans or immigrant Mexican-Americans (Karno and colleagues, 1989). These findings were not replicated in the NCS study. In both the ECA and NCS studies, ethnic differences were not found for panic disorder; however, across ethnic groups, females demonstrated higher rates of panic disorder than males. Differences in rates of obsessive-compulsive disorder were also found among ethnic American populations in the ECA study. Specifically, rates of obsessive-compulsive disorder were highest among White American females and lowest among Hispanic males (Karno & Golding, 1991).

Although Asian-Americans were not included in either the ECA or NCS studies, other studies (Okazaki, 1997; Uba, 1994; Ying, 1988) suggest that they have higher levels of anxiety symptoms than White Americans, especially those related to social concerns. Because these findings were based on levels of symptomatology, it is unclear whether White and Asian-American groups would differ in prevalence rates of diagnosable anxiety disorders. Regardless, these differences have been attributed to higher levels of acculturative stress and language difficulties among Asian-American populations, although no studies have assessed whether this is in fact the case (Al-Issa & Oudji, 1998).

Very little is known across cultures about prevalence and incidence rates of most types of anxiety, except obsessive-compulsive disorder. Lifetime prevalence rates of obsessive-compulsive disorder are similar across a number of Western and non-

Western countries, including Taiwan, Uganda, Puerto Rico, Greece, Italy, New Zealand, Korea, and Hong Kong, and range from 1 to 3% (Weissman et al., 1994; Staley & Wand, 1995).

In summary, cultural and ethnic variation have been found in prevalence rates of general anxiety disorder and specific phobias. These differences have been attributed to cultural and ethnic differences in life circumstances and stress. Prevalence rates for disorders such as panic disorder and obsessive-compulsive disorder, however, demonstrate few cultural and ethnic differences. Because relatively few studies have examined the prevalence rates of anxiety disorders across cultural and ethnic groups, more studies are needed before more definitive statements can be made.

Substance Abuse and Dependence. Substance abuse refers to the overuse of alcohol and/or drugs that results in harmful physical, social, legal, or interpersonal consequences; substance dependence is marked by continued use of alcohol or other drugs, despite these consequences. The WHO has argued that an individual's cultural context must be considered when diagnosing an alcohol problem. For a drinking problem to exist, individuals must drink more than is considered acceptable by their culture, must drink during times that are not culturally acceptable, and must drink to the extent that their health and social relationships are harmed (WHO, 1975). Obviously, these criteria can be applied to other substances as well. Like anxiety, there is relatively little cross-cultural work on substance abuse and dependence. In part, this may be because alcoholism and other forms of substance abuse have been considered actual diseases only in the past few decades (Bennett, Janca, Grant, & Sartorius, 1993; Caetano, 1989). Therefore, we expect to see more cross-cultural work on alcoholism and substance abuse and dependence in the near future.

Ethnic differences in rates of alcohol consumption have been found. However, these studies received much criticism (Trimble, 1991). Within the United States, Native Americans have the highest alcohol consumption rate, followed by White Americans, African-Americans, and Hispanic-Americans (Baxter, Hinson, Wall & McKee, 1998). Among Native American tribes, there is considerable variation in alcohol consumption: May (1982) found that whereas a minority of Navajo (30%) reported drinking during the last year, a majority of Ojibwa (84%) reported drinking during the last

year. White Americans tend to use more non-alcoholic recreational drugs than other ethnic groups, except inhalants and cocaine (Baxter, Hinson, Wall & McKee, 1998). Weatherspoon, Danko, and Johnson (1994) found that Koreans living in Korea drink more than Chinese living in Taiwan; however, these differences did not carry over to Korean-Americans and Chinese-Americans living in Hawaii. Across cultural groups, men engage in greater substance use than women (Baxter, Hinson, Wall & McKee, 1998).

It is unclear whether cultural and ethnic differences in consumption rates of alcohol and other substances translate into different prevalence rates for substance abuse and dependence (Trimble, 1991). Evidence from cross-cultural studies of alcohol consumption suggests they do not. Cultures that have the most severe alcohol-related problems actually have the lowest rates of alcohol consumption (Al-Issa, 1995). Cockerham, Kunz, & Lueschen (1989) found that whereas for Americans, alcohol use was associated with depression, for West Germans (who have higher levels of alcohol consumption), it was not. Thus, it appears that cultural attitudes and norms regarding drinking influence the occurrence of alcoholism. Grant and Harford (1995) also found that within the United States, the relationship between alcohol abuse and depression was stronger for females and African-Americans than for males and non-African-American groups. Thus, drinking may also be a form of coping with life stress.

Interestingly, for some Hispanic groups, alcohol consumption is not related to acculturative stress. For example, Caetano (1994) found that the more acculturated to mainstream American culture Hispanic women were, the more they engaged in drinking. However, these higher alcohol consumption rates were related to more positive associations with drinking rather than to higher levels of acculturative stress (Cervantes et al., 1991). Specifically, American-born Mexicans associated drinking with social pleasure, assertiveness, elevated mood, decreased tension, and disinhibition (Caetano, 1994; Cervantes et al., 1991; Gilbert, 1991). These findings suggest that for Mexican groups, acculturating to American cultural norms may render alcoholism more culturally and socially acceptable behavior. The MAPSS figures (Vega et al., 1998) support this prediction: Rates of alcohol dependence were lowest for recent immigrants (8.6%), higher for immigrants residing in

the United States for 13 years or more (10.4%), and highest for U.S.-born Mexican-Americans (18.0%). The latter rates were most similar to the NCS U.S. National sample (15.1%).

In summary, most major mental disorders occur across cultures. Cases of schizophrenia, depression, anxiety, and substance abuse have been found in a variety of cultural and ethnic contexts. The prevalence rates of these disorders, however, vary among cultural and ethnic groups. Consistent with Marsella (1987), the prevalence rates of disorders that are more neurologically based (i.e., schizophrenia and bipolar depression) vary less than those that are less neurologically based (i.e., unipolar depression and generalized anxiety). These different prevalence rates may stem from a variety of sources. They may reflect greater exposure to life stress for some groups than others. Interestingly, several studies (Vega et al., 1998; Ying et al., 2000) have found that groups presumed to be under greater environmental stress (e.g., minority groups and recent immigrants) do *not* demonstrate higher rates of affective disorders. Another possibility is that cultures vary in how syntonic or dystonic specific disorders are with particular cultural values and beliefs. For example, the emphasis placed on interpersonal relationships in many Asian and Latino cultures may serve as a buffer against depression and explain why Mexican and Taiwanese nationals demonstrate lower levels of depression than their American counterparts. Yet another possible explanation is that the expression and meaning of symptoms related to major mental disorders may be culturally shaped. As a result, these symptoms may not be easily classified by Western diagnostic systems. We discuss these latter two possibilities next.

Does Culture Influence the Expression of Symptoms?

Both the biomedical and cultural idioms of distress perspectives acknowledge that culture may influence the expression of symptoms. For example, culture may influence the frequency with which specific symptoms are expressed. Biomedical perspectives view cultural differences in symptoms as peripheral aspects of universal syndromes. Cultural idioms of distress perspectives, however, view such differences as evidence that the disorders themselves are distinct.

Schizophrenia. Findings from the WHO study revealed interesting cultural variation in schizophrenic symptoms. Although schizophrenic patients of “developed” and “developing” countries reported having their thoughts stopped, taken away, “read” by alien agents, and “broadcast” publicly, the relative frequency of other symptoms varied across cultures. In “developed” countries, patients were more likely to manifest depressive affect, whereas in “developing” countries, patients were more likely to experience visual hallucinations (Jablensky, 1989). The latter findings were consistent with those of Ndeti and Vadher (1984), which suggest that auditory and visual hallucinations were more common in African, West Indian, and Asian schizophrenic groups than in English (i.e., from England) schizophrenic groups.

Despite the fact that the WHO study is the most widely cited cross-cultural study of schizophrenia, critics argue that the differences between “developed” and “developing” countries in the WHO study are at most speculative (Edgerton & Cohen, 1994). These critics argue that the WHO study did not measure specific cultural variables, wrongly assumed that countries within the “developing” and “developed” groups were more similar than different, and did not provide any compelling explanations for the cultural differences found (Edgerton & Cohen, 1994). More recent studies have provided clearer cultural explanations for cultural differences in symptomatology. For example, Tateyama, Asai, Hashimoto, Bartels, and Kasper (1998) compared schizophrenic patients (according to ICD-9 criteria) in Tokyo, Vienna, and Tubingen matched by sex, duration of illness, and mean age at onset and on admission. They found that across the three cities, similar percentages of patients reported having delusions (89.5%, 91.1%, and 87.3%, respectively). Furthermore, there were no cultural differences in the frequency of delusions of persecution/injury or of grandeur. City differences emerged in delusions of “belittlement” (e.g., being dead, feeling guilty or sinful), which were attributed to cultural differences in religion. Specifically, non-Christian Tokyo patients reported fewer delusions regarding guilt and sin than patients from European cities who were more influenced by Christianity. Not surprisingly, the specific religious figures in the delusions were culture-specific: whereas patients of European descent spoke of “Jesus Christ” or “The Father of Europe,” Tokyo patients spoke of “Shakyamuni” or “Nichiren.”

Furthermore, when Tateyama, Asai, Hashimoto, Bartels, and Kasper (1998) used a different classification scheme to decompose delusions of persecution/injury, Tokyo patients reported “being slandered by surrounding people” more than Europeans. The authors interpreted this difference as reflecting a greater desire for social approval in Japanese than in Western cultures. In a similar vein, Phillips, West, and Wang (1996) observed that Chinese schizophrenic patients (according to DSM criteria) are more likely to manifest “erotomania,” the delusion of being loved by another person from afar, than Western patients. They also attribute these differences to cultural factors: in general, Chinese may be more concerned with social approval and have greater restrictions on sexual expression than Westerners.

Other studies conducted before the WHO study proposed that cultural values and beliefs influenced the expression of schizophrenia. For example, Opler and Singer (1956) predicted that Irish and Italian patients would differ in their schizophrenic symptoms because of cultural differences in their expression of emotion and views of sex, and in which parent assumed the dominant role in the home. Their findings supported their predictions for a male sample and were subsequently replicated in a female sample by Fantl and Schiro (1959). For example, consistent with notions that Italians accept more emotional expression and impulsiveness than the Irish, these researchers found greater behavioral problems such as impulsiveness, open rebellion and physical assault among Italian patients than Irish patients. Unfortunately, these studies relied primarily on diagnoses that were not based on standard classification criteria; therefore, it is unclear whether members of the cultural groups would be diagnosed similarly according to ICD or DSM criteria. However, Enright and Jaekle (1961) compared Japanese and Filipino patients in Hawaii who were diagnosed with “schizophrenic reaction, paranoid type” according to DSM criteria and also found ethnic differences in symptomatology that were consistent with cultural differences in emotional expression and control. Filipino patients were more expressive, less restrained, and exerted more primary than secondary control compared to Japanese patients.

Affective Disorders. Cultural differences in the expression of bipolar disorder have been documented. For example, Mukherjee and colleagues

(1983) found that African-American and Hispanic patients with bipolar disorder manifested more auditory hallucinations than White patients. As a result, they were more frequently misdiagnosed with schizophrenia than White patients. Most research, however, has focused on cultural expressions of unipolar depression.

As with schizophrenia, the WHO conducted a study in the 1970s to examine whether the symptoms of unipolar depression varied cross-culturally (Sartorius, Jablensky, Gulbinat, & Ernberg, 1980). This study examined unipolar depression in 573 patients from Canada, Iran, Japan, and Switzerland, using the WHO Standardized Assessment of Depressive Disorders (SADD). Across sites, depressive patients demonstrated a "core" profile of depressive symptoms that included sadness, joylessness, anxiety and tension, lack of energy, loss of interest, inability to concentrate, and feelings of worthlessness. Beiser, Cargo, & Woodbury (1994) also found evidence of a core constellation of depressive symptoms in a community sample of 1348 Southeast Asian refugees and 319 Canadians. Participants completed questionnaires that contained items assessing depression, anxiety, and somatization, as well as items that tapped into culture-specific idioms of distress. Using grade-of-membership analysis, Beiser et al. (1994) found that for both Southeast Asians and Canadians, items loaded into three distinct categories: Major Depression, Depression with Panic, and Subclinical Depression.

Other evidence in support of the universality of depressive symptoms comes from studies of "culturally bound syndromes." Increasingly, researchers find that syndromes that were previously considered "culturally bound" resemble depressive disorders. For example, "dhat syndrome" in Indian culture, marked by the belief that semen is being lost, was initially regarded by Wig in 1960 as a culturally bound syndrome; however, recent work suggests that it is strongly associated with depressed mood, fatigue, and the DSM-III-R diagnosis of depression (Mumford, 1996). Similarly, "hwa-byung," considered a "Korean folk illness" marked by multiple somatic and psychological symptoms, is also strongly associated with DSM-III diagnoses of major depression (Lin et al., 1992).

Cultural variation has been found in the frequency of specific depressive symptoms, however. For example, the WHO study found that feelings of guilt and self-reproach were more fre-

quently reported in Western countries than in non-Western countries (Sartorius et al., 1980). As in schizophrenia, the lower frequency of guilt-related symptoms has been attributed to cultural differences in religious traditions. Hamdi, Amin, and Abou-Saleh (1997)'s findings were consistent with those of the WHO study. Although the general disorder of endogenous depression exists in Arab culture, the loss of libido, a distinct quality of depressed mood, and feelings of guilt are less common in Arab than in Western cultures. Again, these differences may be related to different religious and cultural traditions among the ethnocultural groups.

Other differences have been found between members of Asian and Western cultures. Members of Asian cultures have been described as "somatizing" their depressive symptoms more than members of Western cultures (Kleinman, 1986). This may be particularly true for Chinese samples. Ying and colleagues (2000) found that compared to Chinese Americans, Chinese who lived in Taiwan reported more somatic symptoms of depression (as assessed by the Center for Epidemiological Studies Depression Scale), despite no differences between the two groups in overall levels of depressive symptoms. Various hypotheses were posited to explain this cultural difference. Compared to their Western counterparts, Asians have been described as using more somatic terms to describe their emotional states (Tung, 1994), as believing that somatic complaints are a more culturally appropriate way to present their distress (Kleinman, 1986), and as suffering from a disorder (i.e., neurasthenia) that is distinct from depression (Ying et al., under review). Some recent evidence, however, suggests that Asian-Americans may not somatize more than White Americans. For example, Zhang, Snowden, and Sue (1998) found that Asian-Americans and White Americans in the ECA data for the Los Angeles community reported similar levels of somatic discomfort.

Anxiety Disorders. Cultural differences in the expression of anxiety have been documented. For instance, although posttraumatic stress disorder (PTSD) can be diagnosed in American populations and Southeast Asian refugees (Carlson & Rosser-Hogan, 1994), clinicians and researchers have found higher levels of dissociation among Southeast Asian refugees with PTSD (Carlson & Rosser-Hogan, 1994; Guarnaccia, 1997; Kirmayer, 1996). This may be due to the greater cultural acceptance of dissociative states in Southeast

Asian culture (Lewis-Fernandez, 1998). Similarly, among many African-American populations, isolated sleep paralysis is associated with anxiety. In some cases, these cultural expressions of anxiety were misinterpreted as psychotic symptoms and diagnosed as such (Friedman et al., 1994; Williams & Chambless, 1994).

Most studies have focused on the way culture influences the causes and content of anxiety, which may be related to specific cultural norms and values. For instance, the emphasis on interpersonal harmony and appropriate social behavior in many Asian cultures may result in distinct social triggers of anxiety. In Japan, allocentricism, issues of *amae* (i.e., dependence), the denial of the self, and the importance of harmonious interpersonal relationships (Russell, 1989) result in the existence of “*taijin kyofusho*.” “*Taijin kyofusho*” is marked by fear that one’s body is displeasing or offensive to others, fear of eye-to-eye confrontation, fear of giving off an offensive odor, and fear of having unpleasant facial expressions (Tanaka-Matsumi, 1979). Although “*taijin kyofusho*” has been compared to social phobia in the United States, the two disorders involve considerably different fears. Whereas social phobia is a fear of strangers and people, “*taijin kyofusho*” is a fear that one might not be acceptable to others (Russell, 1989). Moreover, many of the fears of social phobics are different from those harbored by sufferers of “*taijin kyofusho*” (Russell, 1989). Cultural differences also occur in the content of specific obsessions and compulsions. For example, in many cultural contexts, the content of obsessions and compulsions is related to the dominant religion (Al-Issa & Oudji, 1998).

Substance Abuse and Dependence. Almost no studies have examined how the expression of alcoholism and other forms of substance abuse vary across cultures. Studies are needed to fill this gap in the literature.

In summary, cultural values and beliefs, views of emotion, concerns about social relationships, and religious traditions appear to influence the expression of symptoms associated with major mental disorders.

Does Culture Influence the Meaning of Mental Illness?

Most of the research reviewed until now was conducted using translated Western instruments and classification systems by investigators who

view mental illness from a biomedical perspective. Proponents of cultural idioms of distress perspectives argue that mental illness cannot be separated from the cultural context in which it occurs. The cultural context may shape the meaning and subjective experience of mental illness, which may influence its prognosis.

Schizophrenia. Even though schizophrenic symptoms are similar across cultures, evidence suggests that the meaning that cultural and ethnic groups attach to these symptoms may differ. For example, Jenkins (1997) asked schizophrenic and depressed Latino and European-Americans who lived in Los Angeles to describe their “life situations.” She found that European-Americans, particularly those with schizophrenia, were more likely to characterize their life situations in terms of mental illness than Latinos. Latinos, on the other hand, particularly those with schizophrenia, were more likely to describe their life situations in terms of “*nervios*,” or nerves. “*Nervios*” is a culturally acceptable way of describing emotional distress in Latino cultures that imparts sympathy onto the suffering person (Jenkins, 1997). Thus, because Latino culture may view mental illness more sympathetically, Latinos who suffer from mental illness may be less alienated from their society and therefore, demonstrate better prognoses than their European-American counterparts. Similarly, based on interview data with schizophrenic patients and their families in Sri Lanka, Waxler (1979) found that the social and clinical outcome of Sri Lankan patients 5 years after their first hospital admission was better than that of schizophrenic patients in Denmark and Russia. Waxler attributes these findings to differences across the cultures in the meanings of deviance and mental illness. Deviance and mental illness are more culturally accepted in Sri Lanka than in Denmark or Russia.

Other studies suggest that individuals with schizophrenia also do better (e.g., are hospitalized less often) in cultures that view the self as dynamic and that afford individuals opportunities to move easily between reality and fantasy (Corin, 1990; Estroff, 1989). Presumably, these cultures give individuals with schizophrenia a “way of being” that promotes their mental health (Corin, 1990). **Affective Disorders.** Most research on the cultural meaning of affective illness has focused on unipolar depression. Findings from these studies suggest that the cultural context shapes the way specific depressive symptoms are understood. For

example, although “dhat syndrome” in India resembles depression, it exists in a cultural context that views semen as the vital source of male physical and mental energy (Mumford, 1996).

Ying (1988) provides additional evidence that cultural contexts influence conceptions of depression. She found that for a Chinese-American community sample, somatic and affective symptoms of depression were inseparable constructs, whereas for a White American community, they were distinct constructs. The mixing of somatic and affective symptoms is consistent with Chinese notions that the mind and body are one. Similarly, Ying et al. (2000) found that affective and somatic symptoms were inseparable for Chinese college students who lived in Taiwan; however, they were separable factors for Chinese-Americans who lived in the United States. Thus, although depressive symptoms themselves may not be invariant across cultures, how they are viewed and how they relate to each other may.

Anxiety Disorders. Cultural idioms of distress perspectives argue that anxiety symptoms are shaped by the cultural contexts in which they occur. Thus, because cultures differ in the events that trigger anxiety, the meanings of anxiety may vary across cultures. For example, Guarnaccia (1993) found that although “ataque de nervios” resembles depressive and anxious symptoms, it is defined by its triggering event—upsetting or frightening events in the family sphere. Russell (1989) and Tanaka-Matsumi (1979) argue that “taijin kyofusho” is unique to Japanese contexts because it can be understood only in terms of Japanese values and norms. Malgady, Rogler, and Cortes (1996) demonstrate that Puerto Rican adults use cultural idioms of anger (e.g., aggression and assertiveness) to express their depression and anxiety, suggesting that the cultural meanings of depression and anxiety may be different from those of European-American adults.

Substance Abuse and Dependence. Variation among cultures in the meaning of alcohol and substance use may influence consumption rates. For instance, Caetano (1989) found that although African-American, Hispanic, and White American adults in the United States (controlling for differences in income and education) agreed that alcoholism is a disease, the first two groups were more likely than White Americans to view alcoholics as morally weak. These findings are consistent with the ethnic patterns in alcohol consumption described earlier. Sigelman and colleagues

(1992) found that Native American schoolchildren were less likely to see alcoholism as serious, saw alcoholics as less responsible for their problems, and viewed alcoholism as a disease more than Hispanic or White American children. These findings are consistent with Pedigo’s (1983) assertions that alcohol and substance use and abuse have cultural meanings for Native Americans that render them more culturally acceptable in Native American culture than in White American culture. For instance, Native Americans are more likely to view individuals holistically and therefore to be more accepting and less critical of problem drinking than members of other cultural groups. Furthermore, in some Native American groups, drinking and other forms of substance use are often viewed as ways of coping with past and present stresses. In all likelihood, this explains why alcohol consumption rates are higher in Native American groups than in other ethnic groups in the United States. In other cultural contexts, the use of alcohol and other substances in spiritual and religious ceremonies may also influence the cultural meaning of alcohol and substance consumption.

In summary, cultures vary in their views of mental illness, tolerance of deviant behavior, and conceptions of emotion, the self, and the mind-body relationship. These cultural differences shape the meaning of and social response to mental illness and may influence the course of mental illness.

Do “Culture-Bound” Syndromes Exist?

Throughout this chapter, we referred to “culture-bound syndromes,” or syndromes that are found only in one culture. By definition, culture-bound syndromes are more than variants of “universal” disorders and are determined by the specific beliefs and practices of a particular culture (Ahktar, 1988). Originally, “culture-bound” syndromes were limited to syndromes observed in non-Western cultures, but more recent modifications of the term acknowledge that certain syndromes may occur only in Western cultures. Among these is multiple personality disorder (MPD). Although MPD is extremely rare in the United States, in Japan, it is virtually nonexistent. Takahashi (1990) found that among all inpatients in a Japanese hospital from 1983–1988, not one diagnosis of MPD was made, based on DSM-III and DSM-III-R criteria. Takahashi argues that MPD is inconsistent with Japanese cultural norms.

In such a culture where one's thinking, or identity in the sense of western cultures, is altered to fulfil society's needs, the need for an individual to develop a psychiatric disorder such as MPD might not be very strong. (Takahashi, 1990, p. 59)

Heated debate exists regarding whether culture-bound syndromes actually exist. The DSM-IV acknowledged the existence of such disorders by including a list of culture-bound syndromes as an appendix. However, recent evidence suggests that many syndromes that were previously considered "culture-bound" are variations of depression and anxiety (Mumford, 1996). Thus, many critics of the DSM-IV argue that the term "culture-bound syndrome" assumes that culture is a secondary process and exists only in extreme forms, when in fact, culture influences all aspects of mental illness (Guarnaccia, 1993). Whether or not one views a specific syndrome as "culturally bound" may depend largely upon what one considers the defining aspect of mental illness. If one focuses only on symptoms, many syndromes that were traditionally considered "culturally bound" could be considered cultural manifestations of depression and anxiety. However, if one focuses on cultural meanings, then to some degree, all syndromes are "culturally bound."

Does Culture Influence the Social and Psychological Impact of Mental Illness?

Compared to work on the incidence and prevalence of mental illness across cultures, little research has examined how the personal and social impact of mental illness varies across cultures. This is somewhat surprising, given that societal and community responses to mental illness may have the greatest influence on prognosis and may vary the most across cultures. In the WHO study described earlier, Jablensky and colleagues (1989) found that patients from "developing" countries had better outcomes 2 and 5 years after the initial onset of schizophrenia than patients from "developed" countries. It is possible that this finding reflects cultural variation in the social and personal impact of schizophrenia. Although a variety of cultural factors might influence the personal and social consequences of mental illness, we highlight three: (1) the value of social relationships, (2) views of mental illness, and (3) views of the self.

The extent to which cultures value social relationships and therefore provide social support to individuals with mental illness may influence psy-

chiatric outcome (Lefley, 1990). For example, having strong family ties reduces the risk of schizophrenic relapse (Birchwood, Cochrane, MacMillan, Copestake, Kucharska, & Cariss, 1992). Therefore, schizophrenia may have a better prognosis in cultures that place greater emphasis on the family unit. In addition, family interaction styles may vary across cultures and may also affect prognosis. In schizophrenia, for example, levels of expressed emotion in the family have been correlated with poor patient prognosis (Brown, Birley, & Wing, 1972). "Expressed emotion" is comprised of three components: criticism, emotional overinvolvement, and hostility. Although expressed emotion exists across cultures (e.g., Japan, India, England, Brazil, and Mexico), levels of expressed emotion vary across cultures. For example, compared to American households of schizophrenic patients, Japanese (Mino, Tanaka, Inoue, Tsuda, Babazono, & Aoyama, 1995) and Indian (Wig et al., 1987) households demonstrated less, whereas Portuguese-speaking Brazilian households demonstrated more expressed emotion (Martins, de Lemos, & Bebbington, 1992).

These differences can be further broken down into the specific components of expressed emotion. Greater levels of expressed emotion in the Brazilian households than in American households were due to greater levels of emotional overinvolvement in Brazilian than in American households (Martins, de Lemos, & Bebbington, 1992). Compared to British and Anglo-American families, Mexican families demonstrate less criticism (Jenkins, 1991). Moreover, the content of expressed emotion differs across cultures. Jenkins (1991) found that critical Mexican family members were less likely to make negative character attributions about schizophrenic patients' behavior than Anglo-Americans; instead, they were more critical of disruptive or disrespectful behavior toward the family (Jenkins, 1991). These differences may explain why schizophrenic patients who lived in "developing" countries improved more than those who lived in "developed" or industrialized countries.

The impact of mental disorder in a particular cultural context may depend on the way that culture views mental illness and those afflicted with mental illness. According to social labeling theory (Waxler, 1979), the way a society responds to patients influences their prognosis. This theory suggests that patients have better prognoses in societies that expect them to recover from mental

affliction and return to normalcy rapidly than in societies that view mental illness as a permanent condition and that ostracize and stigmatize patients. For example, in Spanish, the mentally afflicted are described as having “nervios,” a term that elicits sympathy in Mexican culture. In contrast, in English, mental illness connotes biological defects intrinsic to the individual (Jenkins, 1991). Social labeling theory predicts that the mentally ill have better prognoses in Mexican culture than in mainstream European-American culture.

Few studies examined whether the psychological impact of mental disorders generalizes across cultures. For instance, the impact of mental illness on one's self concept may depend on cultural views of the self. For example, Estroff (1989) and Fabrega (1989) argue that in cultures that value independence and view the self as a stable, context-independent entity, disorders that disorganize or fragment the self (e.g., schizophrenia) may have greater personal consequences than in cultures that view the self as a fluid, dynamic entity. Moreover, the latter cultures may be more accepting of mentally ill individuals' dependence on caretakers (Lin & Kleinman, 1988; Lefley, 1990). The impact of mental illness on psychological processes such as cognition and emotion may also vary across cultures. Unfortunately, few studies have examined this possibility. For instance, several empirical studies demonstrated that depression alters various aspects of emotional processing. Depressed individuals are less sensitive to both positive and negative emotional cues than nondepressed individuals (Wexler et al., 1994). Depression also alters the behavioral and physiological aspects of emotional response. However, these studies have been conducted primarily on European-American samples. No studies have examined whether the psychological impact of depression generalizes to other cultural contexts. Thus, significantly more research is needed to examine the cultural factors that influence the social and psychological impact of mental illness. Such studies may reveal whether and why the prognosis of specific mental disorders may be better or worse across cultural contexts.

How Do We Consider Culture in Diagnosis and Treatment?

Cultural variation (or the lack of cultural variation) in the occurrence and course of mental illness and in the presentation of psychiatric symptoms

all have implications for treatment. Most importantly, they highlight aspects of psychotherapy and other psychiatric treatments that may require modification to be effective with different cultural groups. Given that individuals vary in the extent to which they demonstrate culturally normative behavior and that there is considerable variability in empirically based knowledge about cultural influences on psychopathology, clinicians should use clinical recommendations judiciously. These recommendations should lead to culture-related hypotheses about client dysfunction that require additional data specific to the client (and to the specific form of distress) for support. Because cultural considerations become more salient when working with individuals of cultural backgrounds different from one's own, the next section will discuss diagnosis and treatment in multicultural settings such as the United States.

Cultural Patterns of Service Utilization. Ethnic groups in the United States vary in their rates of mental health service utilization. These rates may reflect cultural attitudes toward mental health treatment. For example, compared to White Americans, Asian-Americans tend to “underutilize” services (Sue et al., 1991). Asian-Americans tend to seek help from family members, medical services (Western and Asian), and community services before using mental health services. As a result, Asian-Americans may enter mental health treatment with little optimism about their recovery which may interfere with treatment outcome. Clinicians may have to consider these attitudes toward treatment when formulating a treatment plan. In addition, because Asian-Americans use mental health services as a last resort, those who enter mental health settings tend to be the most severely distressed. Thus, clinicians may have to provide more acute care to these individuals. Similar issues may arise for members of other cultural and ethnic groups.

Cultural Diagnosis. Although culture may shape the experience and expression of distress, this may vary across individuals. Individuals within cultural groups vary in the extent to which they endorse the values, norms, and beliefs of their cultural group and the meanings of their cultural identity (Tsai, Ying, & Lee, 2000). In diagnosis, understanding an individual's cultural orientation will help clinicians assess how an individual's expressions of distress are culturally shaped, as well as prevent errors of misdiagnosis (Dana,

1998). For example, although African-American and Hispanic clients with affective disorders often report more delusions and hallucinations than their White American counterparts, this may not hold for a specific African-American or Hispanic individual. It is possible that under specific circumstances, one's cultural heritage is less relevant to one's symptoms than other influences, such as one's socioeconomic status. Therefore, a critical aspect of diagnosis, especially with patients of different cultural backgrounds, is assessing the patients' cultural history, cultural identity and orientation, and subjective experience of culture (Dana, 1998).

Therapist and Client Interactions. The current DSM-IV contains guidelines for conducting a "cultural formulation," or assessing how cultural factors influence a client's psychology (American Psychiatric Association, 1994). These guidelines also emphasize the importance of assessing the cultural aspects of the therapist-client relationship. Cultures vary in their emphasis on and expectations of interpersonal relationships. Clinicians' ability to establish rapport with clients of different cultural backgrounds may hinge on their knowledge of the clients' cultural expectations for the therapist-client relationship. In some cases, this rapport is critical. For example, an overwhelming majority of Asian-American patients discontinue mental health treatment after the first session. These drop-out rates, however, are significantly reduced when the therapist has the same ethnocultural background as the client (Sue et al., 1991). Similarly, Takeuchi, Sue, and Yeh (1995) found that in Los Angeles, Asian-American, African-American, and Mexican-American patients were more likely to continue in mental health programs if the programs were oriented toward their specific ethnic heritage.

Culture may influence different aspects of the clinician-patient interaction. First, culture may influence nonverbal communication (e.g., interpersonal space, body movement, paralanguage, eye contact). For example, in Asian cultural groups, clinicians are considered authority figures, and therefore, clients may avert their gaze as an expression of deference and respect. This behavior is a culturally appropriate response, rather than an indication of abnormal interpersonal behavior. Second, culture may influence expectations of therapist credibility (e.g., expertise and trustworthiness). Certain groups may explicitly inquire

about clinicians' credentials or may require demonstration of clinical expertise before engaging in treatment. Again, this may be considered a culturally appropriate response rather than an anomalous response to treatment. Third, culture may influence expectations of the therapist-client relationship. For example, whereas some cultural groups may expect a formal interaction style between clinician and client, other cultural groups may expect an informal interactional style (Sue & Sue, 1990). In these cases, patients may expect clinicians to share personal information as a way of demonstrating their trustworthiness. Finally, cultural groups may vary in their exposure to and experience with mental health services; therefore, patients may require explicit education about the process of and regulations related to treatment.

Cultural Adaptations of Treatment. The most popular treatments for mental disorders in psychiatric settings were developed for use with mainstream European-American populations. Many clinicians have recommended ways of adapting Western treatments for culturally diverse populations. We discuss a few of these adaptations here.

Many Western treatments must be adapted for culturally diverse populations because their basic cultural assumptions may not apply to non-Western cultural groups. For example, Randall (1994) argues that the concepts of time and self that underlie cognitive therapy stem from a Western European cultural tradition that may differ for ethnic clients. Minority clients from cultures in which time is less salient and concepts of the self are more sociocentric than in Western cultures may not do as well in cognitive therapy. Randall (1994) proposes changes to traditional forms of cognitive therapy that may make it more relevant for one such cultural group, African-American women. Even in medication treatments, research has demonstrated that "standard" dosages of psychotropic medications must be modified when administered to specific ethnic groups. For example, Lin, Poland, and Lesser (1986) found that Asian-American patients often require only half of the standard "European-American" dosage of psychotropic medications.

Other adaptations include greater involvement of the family in treatment. In cultures that emphasize familialism, treating the individual without the family may be counterproductive and culturally inappropriate. In addition, when working with members of different cultural groups, clinicians

often must employ interpreters. In these cases, culturally sensitive nonverbal communication is even more critical in developing rapport with the client. Moreover, clinicians must develop a positive working relationship with the interpreter before obtaining rapport with the client. Finally, Western forms of treatment may have to work in collaboration with non-Western forms of treatment. Patients may be using traditional medicines or seeking the help of traditional healers while they are seeking treatment in Western psychiatric settings.

In summary, when working with individuals of cultural backgrounds different from one's own, it becomes imperative that clinicians entertain hypotheses that account for cultural differences at all stages of diagnosis and treatment. The extent to which cultural considerations should be included in diagnosis and treatment, however, depends on the specific individual.

Future Research Directions in Cross-Cultural Psychopathology

During the past few decades, significant advances have been made in studying psychopathology across cultures. However, after reviewing the literature, what becomes even more apparent is the dire need for future research. Thus far, we have reviewed studies that provide some answers to basic questions about psychopathology across cultures. Next, we discuss issues that must be addressed in future research to advance our understanding and treatment of psychopathology across cultures.

Methodological Issues

To gain a more comprehensive understanding of cultural influences on psychopathology, future empirical studies must use more sophisticated measures of culture, employ multiple methods of assessment, and integrate qualitative and quantitative research methods.

More Sophisticated Measurement of Cultural Variables. A common critique of cross-cultural studies of psychopathology is their poor measurement of cultural variables. Most studies assume that individuals who reside in specific countries also represent the cultural values and

beliefs associated with that country. For example, in epidemiological studies of mental disorders across countries, national differences in incidence and prevalence rates are attributed to cultural factors. Only by explicitly measuring cultural factors can we determine whether national differences are indeed due to culture. Thus, future studies of the incidence and prevalence of mental disorders across cultures or of cultural influences on symptom expression should explicitly measure the cultural variables of interest and then examine how they relate to the occurrence and expression of psychopathology. These cultural variables include individualism–collectivism, cultural orientation/acclulturation, and views of mental illness.

Multiple Methods of Assessment. Most cross-cultural studies of psychopathology rely on self-report data. Although self-report data are invaluable, they are also vulnerable to a number of biases, including self-presentation biases, unreliability, and contextual demands. Self-report data become even less reliable when collected across cultures. Given that the symptoms of mental disorder span various domains—cognitive, behavioral, and physiological—our assessments of psychopathology should reflect such variation. Thus, future studies should include physiological and behavioral assessments.

Examples of research that attempts to integrate physiological and cultural aspects of psychopathology are studies of the “psychobiology of ethnicity” (Lin, Poland, & Nakasaki, 1993). These studies have found ethnic differences in responses to psychotropic medications. Hispanic patients require less antidepressant medication and report more side effects at lower dosages than White patients (Marcos & Cancro, 1982; Mendoza, Smith, Poland, Lin, & Strickland, 1991). African-Americans respond better and more rapidly to tricyclic antidepressants than Whites (Lawson, 1986; Silver et al., 1993). Although studies have attempted to disentangle cultural (Smith, Lin, & Mendoza, 1993) and biological influences (Silver, Poland, & Lin, 1993) on responses to medication, more research is needed.

Integration of Qualitative and Quantitative Methods. A variety of methods has been used to study cultural variation in psychopathology, ranging from smaller scale ethnographic interviews to larger scale epidemiological studies. Each method has its advantages and disadvantages. Therefore,

multiple methods should be used. This may be particularly important if specific cultural groups respond more to one method than another. For instance, cultural groups that value personal contact may respond in more truthful and thoughtful ways during an interview than they would to a questionnaire, whereas cultural groups that are concerned with self-presentation may be more likely to respond truthfully to a questionnaire than to an interviewer. Thus, converging findings from studies that employ multiple research methods will allow a comprehensive understanding of the way culture shapes psychopathology.

Conceptual Issues

Future studies must address the following conceptual issues to advance our understanding of psychopathology across cultural contexts.

Cultural Differences in Response Styles or Psychopathology? Cultural differences exist in participants' responses to assessment instruments. For example, cultural differences exist in using standard rating scales in questionnaires and interview schedules. Compared to members of European-American culture, members of Asian cultures have been described as using the middle of rating scales (Chen, Lee, & Stevenson, 1995), whereas members of Latino cultures have been described as using the extreme ends of the scale. Thus, cultural differences in the reported intensity of specific symptoms may reflect culturally normative response styles rather than true differences in symptomology.

Cultural groups may also vary in their responses to particular treatment modalities. For instance, work by Hall and colleagues (1994) showed that for English-speaking, White smokers, adding a mood management component to a smoking cessation group intervention substantially increases quit rates for smokers with a history of major depression. However, Muñoz and colleagues (1997) found that this treatment was not effective with a Spanish-speaking group because they did not attend the group interventions. When Muñoz and colleagues (1997) conducted their intervention through the mail, the treatment was as effective for Spanish speakers as the group intervention was for English-speaking White Americans. Cultural groups may also respond more to specific instruments than others. For example, Vietnamese

women reported fewer depressive symptoms on the Diagnostic Interview Schedule than on the Edinburgh Postnatal Depression Scale or the General Health Questionnaire-30 (Matthey, Barnett, & Elliott, 1997).

It should be noted that although cultural differences in responses to questionnaires may exist, relationships across variables may still hold across cultural groups. For example, Spanish-speaking respondents scored much higher than English-speaking respondents on the Personal Beliefs Inventory (PBI), a self-report measure of what Albert Ellis termed "irrational beliefs" related to depression. In particular, Spanish speakers endorsed items regarding the desirability of being loved ("Everyone needs the love and approval of those persons who are important to them,") and of being accepted by friends and family ("What others think of you is most important") more than English speakers. In Albert Ellis' individualistic New York culture, high endorsement of these items was culturally inappropriate; however, in collectivistic Latino culture, high endorsement of these items was culturally desirable. Regardless, for both cultural groups, scores on the PBI were positively correlated with depression (Muñoz, 1986).

Do Mental Disorders Impair Psychological Functioning Similarly Across Cultures?

Previous studies of psychopathology across cultures have focused on cultural variation in incidence rates and symptom presentation. This work has advanced our knowledge of the existence of mental disorders across cultures. The next step in cultural studies of psychopathology is to examine the impact of such disorders on "basic" psychological processes related to emotion, memory, and cognition. Such studies will elucidate whether the mechanisms that underlie specific symptoms are the same across cultures.

Are the Clinical Recommendations Regarding the Treatment of Clients of Different Cultural Backgrounds Effective?

Volumes of clinical recommendations regarding the assessment and treatment of clients of different cultural backgrounds have been written (Sue & Sue, 1990; Tseng & Streltzer, 1997; Pedersen et al., 1996). In this chapter, we reviewed only a few recommendations. Unfortunately, we know very little about the way clinicians implement these clinical recommendations and whether they are actually effective (Dana, 1998). Clearly, such

knowledge would shape our future clinical interventions. Therefore, empirical studies of the implementation and effectiveness of culturally sensitive treatments are needed.

Conclusion

In this chapter, we examined cultural influences on various aspects of psychopathology—assessment, incidence and prevalence rates, symptom expression, meaning, prognosis, and treatment. Our review illustrates what we know and what we still have to learn about the cultural shaping of mental illness. We look forward to future research that will advance our understanding of human processes and also enhance our ability to treat and live with mental illness across cultures.

PART II

**Neurotic and Psychotic
Disorders**

This page intentionally left blank.

CHAPTER 6

Generalized Anxiety Disorders, Panic Disorders, and Phobias

Ronald M. Rapee and David H. Barlow

Introduction

Anxiety disorders encompass what is probably the most diverse group of psychopathological problems. Included among the anxiety disorders are such behaviors as repetitive hand washing, ritualizing, unexpected and apparently inexplicable bursts of panic, and an inability to eat or drink in front of other people. Anxiety disorders include a wide array of features, and the intensity of the disorders can also vary tremendously. They can range from relatively “normal” features such as worrying about bills to extremely debilitating problems such as a total inability to leave home. Yet, this seemingly diverse group of disorders all share a single, basic, common feature—*anxiety*. All of the seemingly bizarre thoughts, feelings, and behaviors in these disorders center around and are motivated by feelings of fear and anxiety.

This chapter will examine four of the major anxiety disorders: generalized anxiety disorder, panic disorder (including agoraphobia), social phobia, and specific phobia. Because these disorders share the basic feature of anxiety, there are a number of other commonalities among them,

such as similar symptomatology, similar cognitive styles, and similar treatment options and response. However, each disorder also has a number of unique features, perhaps best summarized by the specific focus of the anxious response. Thus, we will examine both the similarities and, in particular, the differences among these four disorders. Each section will be similarly organized and will cover the definition of the disorder, clinical features, maintaining factors, and treatment. Naturally, with such a broad topic and limited space, this chapter will simply provide a broad overview of the disorders.

Generalized Anxiety Disorder

Diagnosis

In many ways, generalized anxiety disorder (GAD) can be considered the basic anxiety disorder. It can be thought of almost as an expression of “pure” high trait anxiety. By definition, GAD is not characterized primarily by a focus on any specific situation or object. Rather, the central characteristic of GAD is what many people would see as the fundamental feature of anxiety: *worry*.

According to DSM-IV (American Psychiatric Association, 1994), a diagnosis of GAD requires a report of excessive worry over a number of events or activities, more days than not, over at least 6 months. In addition, the person must report difficulty controlling the worry and must also experi-

Ronald M. Rapee • Department of Psychology, Macquarie University, Sydney, New South Wales 2109, Australia. **David H. Barlow** • Center for Anxiety and Related Disorders, Boston University, Boston, Massachusetts 02215-2002.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

ence three out of a list of six symptoms. The symptoms are related mainly to various features of excessive arousal. However, these symptoms are probably not a particularly important defining characteristic of GAD because many subjects with other anxiety disorders report a number of the same symptoms (Barlow, Blanchard, Vermilyea, Vermilyea, & DiNardo, 1986). Thus, it seems that chronic worry is the best distinguishing characteristic of GAD. Of course, worry about specific areas is naturally present in all of the anxiety disorders; however, DSM-IV specifies that the source of worry must not be another Axis I disorder. For example, if someone met criteria for a diagnosis of social phobia, then worry about social situations would not count toward a diagnosis of GAD.

The exclusion of worry about other diagnoses is essential to distinguish GAD from other anxiety disorders, but this feature makes the diagnosis of GAD sometimes difficult. In addition, the overlap between many of the features of GAD and other anxiety disorders also adds to this difficulty (Brown, Barlow, & Liebowitz, 1994). For these reasons, agreement among raters regarding a diagnosis of GAD in an individual (measured by the kappa statistic) is generally the lowest for GAD of any of the anxiety disorders (kappas between .27 and .57) (DiNardo, Moras, Barlow, Rapee, & Brown, 1993; Mannuzza et al., 1989; Wittchen, Kessler, Zhao, & Abelson, 1995). It should be noted that these studies have all used DSM-III-R criteria, and studies using DSM-IV are still awaited.

Clinical Features

Epidemiology. Probably because of the “normality” of GAD, it is difficult to obtain estimates of its prevalence and incidence because such estimates are likely to be very dependent on minor definitional differences. Nevertheless, several studies in recent years have indicated that GAD is one of the more prevalent disorders; it is diagnosed at around 3% of the population over a given 12-month period and around 5% across the lifetime (Kessler et al., 1994). Similar figures are reported in children (Fergusson, Horwood, & Lynskey, 1993). Interestingly, despite its prevalence, it is one of the least common anxiety disorders presenting to mental health practitioners and accounts for around 10% of anxiety disorder patients (Barlow, 1988). GAD is found commonly,

however, among patients in general medical practice (Brawman-Mintzer & Lydiard, 1996).

Sex Distribution. As with most of the other anxiety disorders, GAD is more common in females. However, GAD has a more equal sex distribution than some of the other disorders; most populations of GAD contain around 60% females (Anderson, Noyes, & Crowe, 1984; Rapee, 1985). **Onset.** Most studies report that GAD generally begins around the midteens to early 20s (Anderson et al., 1984; Barlow et al., 1986; Rapee, 1985). However, calculation of a mean age of onset for this order is probably fairly meaningless because a large number of GAD patients report experiencing symptoms all of their lives. This indication of a lifelong existence for GAD is consistent with some growing speculation that GAD should actually be considered a lifelong psychological trait or personality disorder (Rapee, 1991). If this is so, then an average age of onset really does not provide any useful information.

Along similar lines, GAD patients generally describe the onset of their disorder as gradual and insidious (Anderson et al., 1984; Rapee, 1985). This evidence is also consistent with a personality orientation in GAD. Thus, we may describe GAD as a general characteristic of an individual that perhaps becomes more severe at some point in the person's life. Alternately, the disorder itself may not become more intense, but it may be that one of a number of reasons eventually leads the individual to decide to do something about the problem. For example, a change in life circumstances may cause people's usual behaviors to interfere with their lives.

Worry. Because worry is the central characteristic in GAD, these individuals will present as “chronic worriers.” But what do they worry about? One study that examined this question categorized the worries reported by twenty-two GAD patients during clinical intake interviews into common spheres (Sanderson & Barlow, 1990). The researchers came up with four major spheres in the following descending order of importance: family, finances, work, and personal illness. In addition, 91% of the patients reported “worrying excessively about minor things,” compared to 40% of subjects with other anxiety disorders.

A second study asked nineteen GAD patients and twenty-six nonanxious controls to record three instances of “significant” worry during a 3-week period (Craske, Rapee, Jackel, & Barlow,

1989). GAD subjects worried most about illness, second most about family, and least about finances. This seemed to be a slightly different pattern from that of the controls, who worried most about work and least about illness. Thus, although the worries reported by GAD patients cover very normal areas, the relative weight that these individuals give to these spheres may be somewhat different from that given by nonanxious subjects.

Another important difference emerged in the study comparing the worries of GADs and non-anxious controls (Craske, Rapee, et al., 1989) (note that this study was based on DSM-III-R criteria). The GAD subjects reported that their worries were significantly less controllable than the normals' worries and, similarly, that they were less able than the normals to stop or prevent their worrying. This uncontrollability aspect of chronic worrying was also reported in a college sample (Borkovec, Robinson, Pruzinsky, & DePree, 1983). It has been suggested that a general sense of uncontrollability is a fundamental characteristic of anxiety disorders (Barlow, 1988), and this quality may be the most distressing to persons with GAD and most responsible for making GAD into a "disorder." Recognizing this crucial role of uncontrollability, this feature is now included as a diagnostic criterion in the DSM-IV.

Etiology and Maintenance

Genetic and Familial Factors. Family studies of GAD indicated that these patients were more likely to have a first-degree relative with GAD than subjects with panic disorder or no anxiety disorder (Noyes, Clarkson, Crowe, Yates, & McChesney, 1987). Of course, family studies are influenced by both genetic and environmental factors. Twin studies demonstrated a moderate genetic influence in GAD; around 30% of the variance was attributable to genetic factors (Kendler et al., 1992a, 1995). Importantly, the genetic influence for any anxiety disorder is not likely to be specific. Rather, it is more likely that genetic factors influence the development of a general neurotic syndrome, and individual environmental factors are more important in the emergence of specific features of GAD (Andrews, 1996; Kendler et al., 1995).

Psychological Factors. Given the fact that a tendency to worry excessively is one of the main

defining features of GAD, there has been a wealth of research during the past few years to better understand this phenomenon (Borkovec, Shadick, & Hopkins, 1991). According to Borkovec and colleagues (1991), worry serves as a type of avoidance purpose and allows individuals to engage in excessive conceptual and semantic thinking, but avoid imagery and emotional processing. Therefore, worrying does not allow habituation, and this lack of habituation helps to maintain the anxiety experienced by people with GAD. The fact that worry is largely semantic and also uses up many resources in working memory has been demonstrated by several studies (e.g. Borkovec & Inz, 1990; Eysenck, 1985; Rapee, 1993a).

A related direction of research has focused on examining the way in which people with GAD process information (MacLeod, 1996; Mathews, Mackintosh, & Fulcher, 1997). In one of the earliest studies, Butler and Mathews (1983) found that GAD subjects were more likely than normal controls to interpret ambiguous events as threatening. In addition, the GAD subjects believed that there was a higher likelihood that threatening events would happen to themselves, but they did not believe there was a higher likelihood that threatening events would happen to someone else. Thus, in line with suggestions by Beck (Beck & Emery, 1985), anxious individuals have a tendency to see themselves in particular danger in the world.

There is also considerable evidence to suggest that persons with GAD have an attentional bias toward threatening cues. In other words, potentially threatening stimuli in the environment grab the attention of persons with GAD more easily and quickly than that of nonanxious people. This would suggest that such individuals are constantly scanning the environment (not necessarily consciously) for any signs of possible danger (Mathews et al., 1997). For example, one study demonstrated that anxious subjects were faster than controls in detecting a dot on a computer screen when it was immediately preceded by a threatening word in the same part of the screen, but were slower than controls in detecting the dot when the threatening word was in a different part of the screen (MacLeod, Mathews, & Tata, 1986).

For memory, the results have been somewhat less clear, and indeed it looks as though there may be little memory bias in people with GAD (MacLeod, 1996). For example, one of the earliest

studies found a trend whereby GAD subjects actually recalled *fewer* threatening words than normal controls (Mogg, Mathews, & Weinman, 1987). The authors suggested that once persons with GAD have detected a threat, they may cognitively avoid this information, leading to decreased memory. In a later study, no significant difference in memory for threatening words was found between GAD subjects and controls using a controlled memory task (i.e., one that requires attentional processes), but using a more automatic task, GAD subjects did have better memory for threatening words, perhaps suggesting that the information had been extensively processed (Mathews, Mogg, May, & Eysenck, 1989).

In summary, it seems that persons with GAD (and probably all individuals who are high in trait anxiety) are characterized by a tendency to interpret ambiguous information as threatening and to pay excessive attention to potential threats. Once they detect a threat, people with GAD elaborate the possibilities extensively in working memory, thereby reducing habituation. The crucial question, of course, is whether these processes are causal or are simply a consequence of anxiety. Research being conducted in several laboratories that is aimed at training people to shift their attention will help to answer this question during the coming years (MacLeod, 1996; Mathews et al., 1997).

Neurobiological Factors. There is little research into the biological factors associated with GAD specifically, although a large body of work has examined the role of biological factors in anxiety generally. The majority of the biochemical work has centered on the role of the benzodiazepine receptor complex (Insel, Ninan, Aloï, Jimerson, Skolnick, & Paul, 1984). Discovery of a specific brain receptor for the benzodiazepines (Squires & Braestrup, 1977) led to speculation that there must be a naturally occurring neurotransmitter that uses this receptor and therefore may be involved in producing anxiety. A number of chemicals were examined with this role in mind, and the research is still continuing.

A specific anxiety neurotransmitter has proven difficult to identify, but some researchers have attempted to examine the interaction between various neurotransmitter systems and neuroanatomical sites. The main research of this type has been conducted by Jeffrey Gray (e.g., 1982; Gray & McNaughton, 1996), who has been involved in a systematic course of research examining the neu-

ropsychology of anxiety. Although Gray's model is very involved, it centers largely around the septohippocampal system, which (according to Gray) acts as a type of comparator, comparing actual with expected stimuli. The system "turns on" (i.e., anxiety) when there is a mismatch between actual and expected stimuli or when the expected stimuli are aversive. Gray does not really apply his model to specific anxiety disorders, but it could be suggested that GAD involves some type of dysfunction in the septohippocampal system.

Whether one is specifying neurotransmitter systems or neuroanatomical pathways, it is clear that biological correlates of anxiety cannot be isolated to one neurotransmitter or one pathway. Any useful neurobiological model of anxiety will have to be very comprehensive (for a review, see Barlow, 1988, in press). Currently, Gray's model most closely approaches this characteristic.

Another interesting neurobiological process recently discovered in individuals with GAD is a distinct lack of autonomic reactivity, or what has come to be called "autonomic inflexibility" (Borkovec, 1994; Hoehn-Saric et al., 1989; Thayer, Friedman, & Borkovec, 1996). Interestingly, this process seems directly associated with the cognitive process of worry described before. Further investigations revealed that this psychophysiological characteristic is mediated by low vagal tone resulting in a high unstable heart rate and decreased heart rate reactivity, among other responses (Thayer et al., 1996). In fact, a similar relationship was noted by several researchers such as Kagan (Kagan et al., 1990) who observed autonomic inflexibility in behaviorally inhibited children. Borkovec (1994) relates autonomic inflexibility in GAD patients to the fact that the stimuli feared by these patients are not produced by external environmental stressors but are internally generated thoughts about potential future events. Thus, these individuals are caught up in a perpetual state of scanning for danger (Mathews, 1990). Sapolsky (1992) studying free ranging baboons in Africa observed a similar process in his baboons who were subject to chronic stress. He suggests that this process, if chronic, leads to hippocampal lesions. Brain imaging is beginning to confirm the generality of these observations in patients with anxiety disorders (Barlow & Durand, 1999). These findings supported the substantial change in the symptoms that comprise the somatic criteria for DSM-IV definitions of GAD (Barlow & Wincze, in press). Several studies demonstrated the con-

struct validity of these changes suggesting that symptoms of motor tension and vigilance and scanning are more strongly correlated with measures of GAD (e.g., the Penn State Worry Questionnaire) than symptoms that reflect autonomic hyperactivity (Brown, Martin, & Barlow, 1995). More recent structural equation modeling has demonstrated the unique and important contribution of autonomic inflexibility to generalized anxiety disorder in the context of all anxiety and mood disorders (Brown, Chorpita, & Barlow, 1998).

Treatment

Psychological Techniques. Psychological treatment of anxiety disorders has involved broadly similar techniques, where only the specific content differs. The main techniques used include relaxation, cognitive restructuring, and exposure. For GAD, most successful treatments used a combination of relaxation and cognitive restructuring because the seeming lack of response to external cues has made *in vivo* exposure seem inappropriate. However, it is certainly possible to use exposure to subtle cues (such as being late or making mistakes) with GADs, and more comprehensive programs have included this technique (Barlow & Rapee, 1991). Additional strategies were also included in some packages including time management, assertiveness training, and problem solving (Barlow & Rapee, 1991). In general, cognitive behavioral treatment packages for GAD produce moderate to large improvements in anxiety symptoms and related problems such as depression (Chambless & Gillis, 1993; Gould, Otto, Pollack, & Yap, 1997; Harvey & Rapee, 1995). In a quantitative analysis of twenty-two controlled trials of cognitive behavior therapy for GAD, Gould et al. (1997) found that the best cognitive behavioral treatments resulted in a reduction in anxiety that was 0.9 standard deviations greater than that produced by control conditions. Furthermore, several studies showed that cognitive behavior therapy is more effective than other supposedly active treatments. For example, cognitive behavior therapy is more effective in reducing GAD than analytic psychotherapy (Durham et al., 1994), nondirective counseling (Blowers et al., 1987; Borkovec & Costello, 1993), and treatment with diazepam (Power et al., 1989, 1990). Perhaps even more important is the demonstration that the effects of treatments last for up to one year and that this maintenance is greater than that achieved with

medication (Chambless & Gillis, 1993; Gould et al., 1997). Despite these impressive results, treatment effects for GAD are not quite as large as for some of the other anxiety disorders, and the area will benefit from further development. One potential innovation involves exposure to the actual behavior of worrying (Craske, Barlow, & O'Leary, 1992). In this program, the uncontrollable process of worry itself is the principal source of chronic anxiety, rather than the rapidly changing content. Treatment involves regaining a sense of control of this out-of-control, anxiety-driven process. Evaluation of this strategy is continuing (Barlow, in press).

Pharmacological Treatment. Medication has also proven generally effective in treating GAD, although the effects have not been quite as strong as for cognitive behavior therapy (Gould et al., 1997). The most widely used drugs have been benzodiazepines, and the average effect size improvement is around 0.7 (Gould et al., 1997). However, despite the fact that the benzodiazepines produce good short-term changes, they tend to result in relatively rapid tolerance, and the effects decrease within a few weeks (Rickels, Downing, Schweizer, & Hassman, 1993). Other medications such as buspirone and the tricyclics produce a slower response that tends to last for a longer period. In one study that compared the tricyclic drug imipramine with the benzodiazepine diazepam, diazepam produced a significantly greater reduction in anxiety during the first two weeks but was no better than placebo from three weeks on (Rickels et al., 1993). In contrast, imipramine showed significantly greater effects than placebo from week 4 until the end of the trial (week 8). Despite these promising results with medication, the major limitation of this form of treatment is the tendency for subjects to relapse after administration of the drug stops (Schweizer & Rickels, 1996; Tyrer, Owen, & Dawling, 1983). As Schweizer and Rickels (1996) point out, the fact that GAD is a chronic disorder that begins at an early age, provides major problems for drug therapy.

Panic Disorder

Diagnosis

In its original conceptualization, agoraphobia was seen as a fear of external situations such as a marketplace (Westphal, 1871). Consequently, much

attention has been focused on the phobic (behavioral) aspects of agoraphobia over the years. Before the publication of DSM-III (APA, 1980), panic attacks were largely ignored, although panic disorder existed under a wide range of names (including anxiety neurosis, neurocirculatory asthenia, effort syndrome, soldier's heart, irritable heart, etc.; see Barlow, 1988).

With the publication of the DSM-III-R (APA, 1987) it was officially acknowledged that agoraphobia and panic attacks were most often manifestations of the same disorder (panic disorder with agoraphobia). With publication of the DSM-IV, it was officially recognized that panic attacks could occur across a number of anxiety disorders. According to the DSM-IV, a panic attack involves a discrete period of fear or anxiety accompanied by a number of physiological and cognitive symptoms. There is some discussion about the actual number of symptoms necessary to constitute a panic attack: DSM-IV requires four or more symptoms at the same time. However, it has been found that patients themselves do not distinguish attacks with more than four symptoms from attacks with less than four (Rapee, Craske, & Barlow, 1990). A diagnosis of panic disorder requires that the individual experience recurrent panic attacks and worries about the next possible panic attack or consequences of the attack for at least 1 month. Importantly, for making a diagnosis of panic disorder, the individual must experience attacks that are unexpected or appear to be "out of the blue." In addition to the attacks, these individuals may display a range of phobic avoidance from no avoidance at all (panic disorder without agoraphobia) to being almost totally housebound (panic disorder with extensive agoraphobic avoidance).

Panic disorder is a very recognizable disorder, and studies of diagnostic reliability have generally indicated good agreement among raters; kappas range from .72 to .81 (DiNardo et al., 1993; Mannuzza et al., 1989). Generally, agreement is slightly better for subjects with more extensive avoidance (agoraphobia) than for those with less avoidance (panic disorder).

Clinical Features

Epidemiology. One of the original epidemiological studies found that agoraphobia occurs in 0.6% of the population (Agras, Sylvester, & Oliveau, 1969). More recently, the National Comor-

bidity Survey reported a lifetime prevalence of 3.5% (Kessler et al., 1994). The reason for the discrepancy between these studies is more likely attributable to the interviewing techniques and criteria than to any increase in the prevalence of agoraphobia.

Though panic disorder is less prevalent than several other anxiety disorders, it is the most common anxiety disorder presenting to anxiety disorder clinics and is one of the most common disorders in any outpatient facility (Barlow, 1988). This is an indication of the tremendous distress and interference that panic attacks can cause in an individual's life (Norton et al., 1996).

Sex Distribution. By far, the majority of panic disorder sufferers are female. This ratio varies, however, depending on the degree of avoidance. Subjects with more extensive avoidance comprise a higher proportion of females (around 75% to 90%), whereas subjects with less avoidance comprise a slightly lower proportion of females (around 60% to 75%; Barlow et al., 1985; Craske & Barlow, 1988; Rapee & Murrell, 1988). The reasons for this sex difference are not clear but may reflect either a real difference in fear levels or a difference in reporting and presentation that is attributable to cultural influences.

Onset. Panic attacks most commonly begin around the middle to late 20s (Anderson et al., 1984; Rapee, 1985; Thorpe & Burns, 1983). In most cases, the onset is sudden and unexpected (Anderson et al., 1984; Rapee, 1985), and most individuals can clearly recall their first panic attack (Rapee, 1985). Despite the fact that most patients will report that the panic attacks are different from anything they have experienced before, several studies show that many patients may have a somewhat somatic or even hypochondriacal focus before their panic attacks begin (Ehlers, 1993; Fava, Grandi, & Canestrari, 1988; Schmidt, Lerew, & Jackson, 1997a).

Cognitive Symptoms. Panic disorder is characterized by a specific type of cognitive focus. Specifically, a number of studies demonstrated that panic disorder cognitions center around thoughts of dramatic and immediate threats such as death or insanity (Hibbert, 1984; Ottaviani & Beck, 1987; Rapee, 1985). For example, Hibbert (1984) found that compared to individuals with GAD, subjects with panic disorder were more likely to experience thoughts related to physical, psychological, or social disaster. Similarly, some

studies showed that people with panic disorder are more likely than others to interpret ambiguous situations as indicating physical danger (Harvey, Richards, Dziadosz, & Swindell, 1993; McNally & Foa, 1987).

Somatic Symptoms. As mentioned before, panic disorder patients are very somatically focused and typically report a large number of somatic symptoms (Barlow et al., 1985; King, Margraf, Ehlers, & Maddock, 1986). In fact, studies find that panic disorder subjects report more somatic symptoms than subjects with almost any other anxiety disorder (Anderson et al., 1984; Barlow et al., 1985; Hibbert, 1984). When the specific patterns of symptoms are compared, it has been found that panic disorder subjects report more symptoms related to the respiratory and cardiovascular systems during their panic attacks than GAD patients during their high levels of anxiety (Anderson et al., 1984; Hoehn-Saric, 1982; Rapee, 1985). Most studies have found no differences in the somatic symptoms, nor the frequency of panic attacks, between extensive and minimal avoiders (Barlow et al., 1985; Craske, Sanderson, & Barlow, 1987; Rapee & Murrell, 1988). Interestingly, some studies demonstrated a relationship between cognitive and somatic symptoms in panic disorder such that certain types of somatic symptoms were more likely to be found together with specific cognitive symptoms (e.g., palpitations, chest pain, and thoughts of a heart attack) (Lelliot & Bass, 1990).

Behavioral Features. Typically, panic disorder is associated with avoidance of a large number of external situations, although there is large individual variation in the extent of avoidance. Some commonly avoided situations include shopping malls, driving, theaters, being alone, and going far from home. Although it has often been assumed that individuals diagnosed with panic disorder without agoraphobia do not avoid; clinical observation in fact suggests that these individuals avoid a large number of subtle situations that produce somatic sensations (e.g., saunas, aerobic exercise, or inflating balloons) (Rapee, Craske, & Barlow, 1994).

Etiology and Maintenance

Genetic and Familial Factors. A series of early studies conducted by a group of researchers in Iowa indicated that panic disorder subjects were more likely to have first-degree relatives with

panic disorder (or agoraphobia) than nonanxious controls or subjects with other anxiety disorders (Noyes, Crowe, Harris, Hamra, McChesney, & Chaudhry, 1986). Such data have often been cited as evidence for a genetic basis to panic disorder (Pauls, Bucher, Crowe, & Noyes, 1980), but methodology of this type cannot distinguish genetic from environmental factors. At least one study demonstrated greater concordance for panic disorder among monozygotic twins than dizygotic twins (Kendler et al., 1995). Thus, there is some evidence of a role for genetic factors in panic disorder. However, as discussed earlier, it is most likely that any genetic factors are general to all of the anxiety disorders.

Environmental Factors. A number of uncontrolled trials have suggested that agoraphobic avoidance (and thus probably the first panic attack) is preceded by a major life event in a majority of subjects (Klein, 1964; Roth, 1959; Thorpe & Burns, 1983). Controlled retrospective trials, however, have not been completely consistent. One study found that panic disorder subjects reported a greater number of stressors during the year before onset of their symptoms compared with normal controls (Faravelli, 1985). Similarly, more symptoms were reported by one group of agoraphobics in the year before onset of the disorder compared with another group of agoraphobics in a year not immediately before onset (Pollard, Pollard, & Corn, 1989). However, other studies have not found a greater number of stressors reported by panic disorder subjects compared with individuals with other anxiety disorders (de Loof, Zandbergen, Lousberg, & Griez, 1989; Hibbert, 1984; Rapee, Litwin, & Barlow, 1990). Simply experiencing a stressor may not be the important factor: Two studies found that panic disorder subjects report a greater impact of stressors than normal controls (Rapee et al., 1990; Roy-Byrne, Geraci, & Uhde, 1986) but not more than individuals with other anxiety disorders (Rapee et al., 1990). Of course, these results may have been influenced by retrospective distortion, and final decisions will have to await prospective studies.

Psychological Factors. Despite certain specific differences, most psychological models of panic disorder see the central problem as the individuals' fear of their own physical sensations (e.g., Barlow, 1988; Clark & Ehlers, 1993; Rapee, 1993b). In this way, panic disorder is seen as almost a phobic disorder, and the feared (phobic) stimuli

are internal (somatic symptoms) rather than external. Basically, these models suggest that somatic symptoms are experienced for a number of possible reasons such as normal activities (e.g., exercise), hyperventilation, or normal bodily fluctuations. Individuals with panic disorder are especially likely to notice any such symptoms because they are hypervigilant for bodily sensations (Schmidt, Lerew, & Trakowski, 1997b). In other words, such individuals constantly scan their bodies (not necessarily consciously) for any possible internal danger, in much the same way that persons with GAD scan the environment for potential external danger. Thus, whenever a physical symptom occurs, those with panic disorder will notice it far more quickly and efficiently than other people, in turn triggering panic.

A large amount of research supports these psychological models of panic attacks. We can briefly mention only some of this research; the reader is encouraged to consult more detailed reviews (e.g., Barlow, 1988; Clark & Ehlers, 1993; McNally, 1990).

As mentioned earlier, questionnaire studies have shown that individuals with panic disorder are more likely than those with GAD to have thoughts related to dramatic outcomes such as death or insanity (Hibbert, 1984; Rapee, 1985). Related studies demonstrated that individuals with panic disorder find that these catastrophic outcomes have high emotional salience and preferentially allocate attentional resources to them (Asmundson, Sandler, Wilson, & Walker, 1992; Hope, Rapee, Heimberg, & Dombeck, 1990).

It has also been shown that individuals with panic disorder experience greater anxiety when they undergo procedures that produce bodily sensations such as breathing carbon dioxide and hyperventilating than subjects with other anxiety disorders (Holt & Andrews, 1989; Liebowitz et al., 1985; Rapee, Brown, Antony, & Barlow, 1992). Further, for people with panic disorder, simply believing that their heart rates have increased is sufficient to produce considerable anxiety regardless of any actual change in their heart rates (Ehlers, Margraf, Roth, Taylor, & Birbaumer, 1988). Importantly, several studies demonstrated the role of psychological factors in these procedures by showing that the degree of anxiety in response to physical sensations can be altered by manipulating various psychological parameters (Rapee, 1995a).

Putting these two areas of research together, it has been found that when individuals with panic disorder are given part of an ambiguous sentence relating to physical sensations, they are more likely than normal controls to complete the sentence with catastrophic outcomes (Clark & Ehlers, 1993). Similarly, using a questionnaire measure, people with panic disorder report misinterpreting their physical sensations as indicators of extreme catastrophe (Clark et al., 1997). However, some recent research has questioned whether, at an automatic level, people with panic disorder associate somatic sensations with threat to a greater extent than nonclinical controls (Schniering & Rapee, 1997). Finally, some recent research has begun to indicate that a tendency to interpret somatic sensations as a sign of threat may actually precede the first panic attack (Ehlers, 1995; Maller & Reiss, 1992; Schmidt, Lerew, & Jackson, 1997a). Such a finding suggests that this cognitive style may cause the development of panic disorder.

There has been considerably less research examining reasons for agoraphobic avoidance. First, many studies failed to demonstrate differences between people with panic disorder who do not avoid external situations and those with extensive avoidance (agoraphobia) on several parameters to do with the actual panic attack, such as the frequency of attacks or the location of the first attack. Differences have been found in the mental association between attacks and external situations. Subjects who show more extensive avoidance report a greater expectancy of experiencing a panic attack in particular situations (Craske, Rapee, & Barlow, 1988; de Jong & Bouman, 1995; Rapee & Murrell, 1988; Whittal & Goetsch, 1997). In addition, marked avoiders also score higher on measures of social anxiety and lower on assertiveness and extraversion than minimal avoiders (Chambless, 1985; de Jong, & Bouman, 1995; Rapee & Murrell, 1988; Whittal & Goetsch, 1997).

Biological Factors. There is a long history of research into biological aspects of panic disorder. Most of the evidence in humans has come from biological challenge procedures and pharmacological treatment and manipulation studies. More recently, evidence has accumulated from neuroimaging studies of people with panic attacks (Bourin, Baker, & Bradwejn, 1998; Klein, 1993; Krystal, Niehoff, Deutsch, & Charney, 1996; Nutt & Lawson, 1992).

A large number of chemical substances, it has

been found, produce panic attacks in individuals with panic disorder (Bourin et al., 1998; Rapee, 1995a). These substances include sodium lactate (Liebowitz et al., 1985), carbon dioxide (Gorman, Papp, & Coplan, 1994), yohimbine (Gurguis & Uhde, 1990), flumazenil (Nutt, Glue, Lawson, & Wilson, 1990), and caffeine (Charney, Heninger, & Jatlow, 1985). Yohimbine is a relatively specific alpha-2-adrenergic receptor antagonist that, by blocking the alpha-adrenergic autoreceptors in the locus coeruleus, results in increased levels of norepinephrine in the central nervous system (CNS). The fact that this substance can produce panic attacks provides evidence for the role of increased firing of the locus coeruleus in panic (Goddard & Charney, 1997; Krystal et al., 1996). However, it must be remembered that the response to biological challenge procedures is also markedly influenced by psychological factors (Rapee, 1995a). Other research provided evidence for the importance of serotonin in panic attacks (Evans, 1990; Krystal et al., 1996). Pharmacologically, it has been found that drugs that block panic attacks affect both the noradrenergic and serotonergic systems (Krystal et al., 1996). Obviously, locating the biological basis of any disorder in one or two broad neurochemical systems is too simplistic. Recently, some researchers have begun to develop more extensive and detailed models of panic disorder. One example described a model in terms of both neurochemistry and brain structures, centering on the amygdala and all of its afferent and efferent pathways, including the noradrenergic system (Goddard & Charney, 1997).

Many of the biological challenge substances have also been linked to panic attacks through their putative action on the central medullary carbon dioxide (CO₂) chemoreceptor (Gorman, Liebowitz, Fyer, & Stein, 1989; Klein, 1993). Specifically, it has been suggested that the CO₂ receptors of individuals with panic disorder have greater sensitivity. Anatomically, it has been found that the CO₂ chemoreceptors in the medulla and the norepinephrine receptors of the locus coeruleus are closely linked (Gorman et al., 1989). A recent model of the neurobiology of panic disorder has argued that the main pathology in people with panic disorder is hypersensitivity of their central CO₂ chemoreceptors (Klein, 1993). These receptors act as a suffocation alarm mechanism, and this alarm fires in people with panic disorder earlier than it should. Therefore, people with panic dis-

order will frequently experience breathlessness as their respiratory mechanisms try to keep their CO₂ levels lower and even a relatively minor increase in CO₂ can trigger a suffocation alarm (panic attack).

Treatment

Psychological Treatments. During the past 10 years, there has been extensive evaluation of the psychological treatment of panic disorder, with and without extensive agoraphobic avoidance. This evaluation has overwhelmingly demonstrated that cognitive behavioral packages are extremely successful in managing panic disorder (Barlow, 1997; Margraf, Barlow, Clark, & Telch, 1993). In general, following treatment, around 80% of participants are free of panic attacks and 60–70% of those who exhibit severe avoidance behavior are markedly improved in their degree of avoidance. In addition, relatively good results can also be obtained from very brief interventions (four sessions) (Craske, Maidenberg, & Bystritsky, 1995) and even from treatments offered in a self-help format (Hecker, Losee, Fritzier, & Fink, 1996). More importantly, treatment results continue for up to two years (Barlow, 1997). However, there are still considerable improvements to be made. Despite the fact that cognitive behavioral treatments produce excellent results with respect to panic attacks and very good results with respect to agoraphobic avoidance, the overall individual picture is far from perfect. Recent longitudinal follow-up of individuals who completed a cognitive behavioral program for panic disorder has shown that more than 50% do not meet criteria for high end state functioning and/or continue to seek treatment during the following two years (Brown & Barlow, 1995).

Several studies also demonstrated that cognitive behavioral treatment packages result in greater and longer lasting improvements than medication (Barlow, 1997). One large study demonstrated that 90% of patients treated with cognitive therapy were free of panic attacks at the end of treatment (85% at 1 year follow-up) compared with 55% treated with imipramine (60% at follow-up) (Clark et al., 1994). In a recent multicenter comparison, 56% of people treated with cognitive behavior therapy alone were considered “treatment responders” compared with 49% of those treated with imipramine alone and 67% of those

treated with a combination of CBT and imipramine. At 12-month follow-up, these figures were 92%, 75%, and 63%, respectively, among those who completed treatment (Barlow, Gorman, Shear, & Woods, 1998). The surprising tendency for those treated with a combination of cognitive behavior therapy and medication to show slightly worse outcome at follow-up has been demonstrated elsewhere (Otto, Pollack, & Sabatino, 1996) and requires further investigation.

Pharmacological Treatment. In one of the earliest studies in this area, Klein and Fink (1962) found that imipramine, a tricyclic antidepressant, blocked "spontaneous" panic attacks but did not affect more chronic or anticipatory anxiety. Since that time, a number of studies have been conducted indicating the value of tricyclics and monoamine oxidase inhibitors (MAOIs) in reducing panic attacks (van Balkom et al., 1997). These results, together with the early work by Klein, led to the suggestion that panic attacks were specifically affected by the tricyclics and MAOIs, whereas the benzodiazepines were more effective for anticipatory anxiety (Liebowitz & Klein, 1981). More recently, however, this simple formula has been challenged by the finding that many benzodiazepines are effective in reducing panic attacks when given in large enough doses (Ballenger et al., 1988; Noyes et al., 1984). Recent interest has begun to focus more closely on the selective serotonin re-uptake inhibitors as the treatment of choice for panic disorder. Controlled treatment outcome studies are currently still few, but preliminary data suggest that the effects are at least as good as the tricyclics and with fewer side effects (Sheehan & Harnett-Sheehan, 1996).

Social Phobia

Diagnosis

Social phobia was first identified in the DSM system with the publication of DSM-III, although it had been described clinically by a number of authors well before this time (e.g., Marks, 1969; Shaw, 1979). Social phobia is described as a fear and/or avoidance of situations involving the possibility of scrutiny by others (APA, 1994; Marks, 1969). It is diagnosed reliably and demonstrates good diagnostic agreement between clinicians based on DSM-III-R criteria (DiNardo et al., 1989, kappa = .79; Mannuzza et al., 1989, kappa = .68).

In addition to research into social phobia as a clinical disorder, there has been extensive investigation for many years into the nature of social anxiety in nonclinical populations (Buss, 1980; Zimbardo, 1986). This extensive literature is likely to have major relevance for the clinical disorder of social phobia because some researchers have noted that the two lie along a continuum of severity (Rapee, 1995b; Turner, Beidel, & Larkin, 1986). Thus, much can be learned about the clinical disorder, social phobia, by examining research into social anxiety in nonclinical populations.

Clinical Features

Epidemiology. Social anxiety and reports of shyness in general populations are particularly common; they occur in around 40% of college students (Pilkonis & Zimbardo, 1979). In addition, social anxiety is a common accompaniment of all of the anxiety disorders (Rapee et al., 1988). Based on DSM-III-R criteria, social phobia has a lifetime prevalence of 13.3% in the general adult population (Kessler et al., 1994) and a point prevalence of around 2–4% in adolescents (Fergusson et al., 1993; Verhulst, van der Ende, Ferdinand, & Kasius, 1997).

Sex Distribution. Both epidemiological and questionnaire studies of the general population reported higher levels of social anxiety and social phobia in females than males (Lovibond & Rapee, 1993; Schneier et al., 1992; Verhulst et al., 1997). Yet, clinical studies regularly report a relatively equal gender distribution or even a preponderance of males (Heimberg et al., 1990; Turner, Beidel, Cooley, Woody, & Messer, 1994). It is likely that Western cultural factors result in greater interference from social avoidance for males than for females, and result in a greater proportion of socially anxious males who seek treatment (Rapee, 1995b).

Onset. Studies reported signs of onset for social phobia that range from early (Rapee et al., 1988; Thyer et al., 1985; Turner, Beidel, Dancu, & Keys, 1986) to late adolescence (Amies et al., 1983), and the most common consensus is that social phobia begins, on average, in late childhood or early adolescence (Turner & Beidel, 1989). Nevertheless, extreme shyness and social reticence can be seen by the time a child is 2 or 3 years of age (Kagan, Snidman, Arcus, & Reznick, 1994), and many people report shyness for as long as they can re-

call. As with GAD, the onset is generally gradual, and clinically, many social phobics report that they cannot specifically remember the beginning of their symptoms. However, there are certainly some social phobics who report specific traumatic experiences before the onset of their disorder (Ost, 1987). It may be that these latter individuals are more likely to develop a fear of a few circumscribed situations rather than a broad range of situations (designated as "generalized social phobia" in the DSM-IV).

Somatic Symptoms. People with social phobia report experiencing a number of somatic symptoms, including palpitations, sweating, tension, nausea, and blurred vision (Amies et al., 1983; Barlow et al., 1986; Heimberg, Dodge, & Becker, 1987; Liebowitz et al., 1985). Nevertheless, people with social phobia report greater concern over those symptoms that are visible to others such as trembling, shaking, blushing, twitching, and sweating (Alden & Wallace, 1995; McEwan & Devins, 1983). Physiological measures generally support these reports by demonstrating that social phobics have greater increases in physiological activity than normal controls when confronting social situations (Borkovec et al., 1974; Turner, Beidel, & Larkin, 1986). Interestingly, however, some research has shown that people with social phobia overestimate the degree of visibility of their symptoms (McEwan & Devins, 1983; Mulken, de Jong, & Bögels, 1997).

Cognitive Symptoms. In terms of broad assessment, social phobics report more negative thoughts and less positive thoughts than non-anxious controls before and during a social interaction (Cacioppo, Glass, & Merluzzi, 1979; Heimberg, Acerra, & Holstein, 1985; Turner, Beidel, & Larkin, 1986). More specifically, Hartman (1984) found that the thoughts of social phobics fell into four factor analytically derived categories: general physiological discomfort and social inadequacy, concern with others' awareness of distress, fear of negative evaluation, and perceptions of autonomic arousal.

A number of studies showed that the thoughts and beliefs entertained by social phobics about their own appearance or performance are generally not accurate. More specifically, people with social phobia, it has been found, rate their own performance significantly worse than that performance is rated by independent judges, despite the fact that they can rate other people's performance

accurately (Rapee & Lim, 1992; Stopa & Clark, 1993). Similarly, people with social phobia see themselves as less attractive than others (Montgomery, Haemmerlie, & Edwards, 1991), even though their attractiveness is not rated any differently by independent observers (Jones, Briggs, & Smith, 1986).

Behavioral Features. By definition, social phobics fear or avoid situations in which scrutiny by others is possible. The more common situations include parties, meeting members of the opposite sex, public speaking, lecture halls, using the telephone, and public transport (Amies et al., 1983; Rapee et al., 1988; Turner, Beidel, Dancu, & Keys, 1986). In addition, there is a subgroup of social phobics who fear specific activities such as eating, drinking, or writing in public (Mattick & Peters, 1989; Turner, Beidel, Dancu, & Keys, 1986). More than 90% of social phobics fear more than one social situation (Mattick, Peters, & Clarke, 1989; Turner, Beidel, Dancu, & Keys, 1986) demonstrating that it is seldom a monosymptomatic phobia.

It is often assumed that social phobia is a relatively nondistressing problem, probably due to the continuum with social anxiety. However, this is not necessarily the case, and the consequences of social phobia can be extreme and varied (Rapee, 1995b). On average, social phobics rate at an intermediate level of severity when compared to other anxiety disorders (Marks, 1969; Turner, McCann, Beidel, & Mezzich, 1986). This average, however, is made up of individuals that range from those who only fear speaking in front of large crowds to those who are virtually housebound and are almost as distressed as the most severe agoraphobic. Some research has shown that on various measures, people with social phobia are actually more debilitated than people with panic disorder (Norton et al., 1996). Clinically, it is often found that social phobics are engaged in occupations that are considerably below the level of their qualifications and many people with social phobia have little social support, long-term partners, and financial independence (Schneier et al., 1992). Further, social phobia, probably more than any other anxiety disorder, is often associated with excessive alcohol consumption (Amies et al., 1983; Heimberg et al., 1987; Turner, Beidel, Dancu, & Keys, 1986).

A more controversial issue is whether people with social phobia lack social skills. Empirical findings relating to the social performance of so-

cial phobics has been mixed (Rapee, 1995b). Some studies have shown clear differences between social phobics and nonclinical subjects on overall performance (Twentyman & McFall, 1975; Stopa & Clark, 1993), but others have failed to show a difference (Burgio, Glass, & Merluzzi, 1981; Rapee & Lim, 1992). It may be that the nature of the situation is important in determining whether a difference in performance will be detected; some studies have shown differences between groups on some tasks but not others (Beidel, Turner, & Dancu, 1985; Pilkonis, 1977). It is most likely that people with social phobia do not actually have a deficit of skills but rather their social performance may be affected by both their degree of anxiety and the parameters of the situation (Rapee & Heimberg, 1997).

Etiology and Maintenance

Genetic and Familial Factors. As for the other anxiety disorders, family studies showed a higher concordance for social phobia among the first-degree relatives of people with the disorder (Reich & Yates, 1988). In contrast, twin studies typically demonstrated that most of the genetic variance is consistent with the importance of a general neurotic syndrome. However, there has also been some suggestion of the possibility of a specific genetic loading for social phobia (Kendler et al., 1992b). These findings have been supported by a wealth of studies demonstrating a genetic influence in nonclinically shy populations (Hudson & Rapee, 2000). In general, these studies supported the importance of both genetic factors and nonshared environmental variables in the development of shyness. Finally, one adoption study supported the importance of both genetic and family variables in shyness and sociability (Daniels & Plomin, 1985).

Family Factors. Parental factors have been suggested as potentially important in producing social anxiety (Allaman, Joyce, & Crandell, 1972; Bruch, 1989). In an early study, Parker (1979) found that social phobics perceived their parents as overprotective and low in emotional support compared to a nonanxious control group. Several studies have now replicated these results (Arrindell, Emmelkamp, Monsma, & Brilman, 1983; Bruch & Heimberg, 1994). Further, in some research, social phobics report that their parents isolated them

from social experiences, overemphasized the opinions of others, and deemphasized socializing with others as a family (Bruch & Heimberg, 1994; Bruch, Heimberg, Burger, & Collins, 1989). Of course, the main problem with all of these studies is that they utilize retrospective self-report, and as such, it is impossible to know how much of the results are due to reporting (or recall) biases caused by the disorder (Hudson & Rapee, 2000). A few studies demonstrated similar findings in children with social fears, but data are still sparse (Hudson & Rapee, 2000). More importantly, some observational research is now beginning to show that mothers of children with any anxiety disorders (including social phobia) show overintrusive behaviors in a laboratory situation compared with mothers of nonclinical children (Hudson & Rapee, 1998). Of course, determining the causality of any of these effects is extremely difficult.

Psychological Factors. Several models of social phobia have argued that the central problem in social phobia is the belief by individuals that they cannot measure up to the audiences' expectations of them (Clark & Wells, 1995; Rapee & Heimberg, 1997; Schlenker & Leary, 1982). As a result, individuals believe that audiences will evaluate them negatively, despite the fact that people with social phobia do not hold unrealistic expectations for their own performance—nor do they believe that the audiences hold an excessively high standard for them (Alden, Bielings, & Wallace, 1994; Wallace & Alden, 1995).

An important factor in these models is the role of self-focused attention. People with social phobia pay excessive attention to their own outward appearance (often referred to as public self-consciousness) (Hope, Gansler, & Heimberg, 1989; Woody, 1996) and hold negative images of their appearance when in social situations (Hackman, Surawy, & Clark, 1998). According to Rapee and Heimberg (1997), a negative mental image is likely to be very important in producing anxiety in social phobics, but is not necessarily veridical. In fact, based on the research described earlier, people with social phobia frequently see themselves as less capable than they are viewed by others.

In addition to an attentional focus onto their own appearance, people with social phobia are likely to preferentially allocate attentional resources to external indicators of negative evaluation (Asmundson & Stein, 1994; Mattia, Heimberg,

& Hope, 1993; McNeil et al., 1995). In one *in vivo* study, socially anxious individuals were more accurate at detecting indicators of negative evaluation from their audiences (e.g., frowns) while giving a speech than low anxious subjects (Veljaca & Rapee, 1998). As a result, people with social phobia will attend less to the task at hand, possibly resulting in poorer performance (Heimberg, Acerra, & Holstein, 1985).

People with social phobia are likely to hold strong expectations of negative evaluation by others and to interpret ambiguous social information negatively (Amir, Foa, & Coles, 1998). In addition, the consequences of negative evaluation by others are seen to be especially dire by people with social phobia (Foa, Franklin, Perry, & Herbert, 1996; Lucock & Salkovskis, 1988; Poulton & Andrews, 1994). In addition, change in the fear of negative evaluation or in the perceived consequences of negative evaluation is a very strong predictor of treatment response (Foa et al., 1996; Mattick & Peters, 1988).

Biological Factors. Research into central biochemical factors associated with social phobia has not been as extensive as that for panic disorder, and many studies provided mixed findings (Nicholas & Tancer, 1995; Potts, Book, & Davidson, 1996). The most consistent results implicated serotonin in the pathogenesis of social phobia (Jefferson, 1996; Potts et al., 1996). The most obvious evidence came from treatment with serotonin-reducing agents (see later). However, because many of these drugs also affect other neurotransmitter systems, based on this evidence, the neurobiology of social phobia cannot be narrowed down to a single neurotransmitter system (Nickell & Uhde, 1995). Other evidence has included challenges with fenfluramine, a serotonin agonist, and brain imaging studies.

Based on the large number of symptoms reported by social phobics that are mediated by the sympathetic nervous system and the beneficial effects of beta-blockade on performance anxiety, there is some suggestion that social phobics may have elevated peripheral sympathetic activity (Levin, Schneier, & Liebowitz, 1989; Stein, Tancer, & Uhde, 1992). However, socially anxious individuals and controls do not differ in catecholamine response to social stimuli (Dimsdale, Hartley, Ruskin, Greenblatt, & LaBrie, 1984; Levin et al., 1989), and infusions of epinephrine do not pro-

voke excessive reports of anxiety in people with social phobia (Papp et al., 1988).

Treatment

Psychological Techniques. A number of studies demonstrated the value of cognitive behavioral treatment packages for reducing social phobia, compared with wait list and with a credible placebo treatment (Beidel & Turner, 1998; Feske & Chambless, 1995; Heimberg & Juster, 1995; Taylor, 1996). In addition, follow-up assessment indicated that in most studies continued improvement is seen following the end of treatment (Taylor, 1996).

In terms of specific techniques, *in vivo* exposure is generally considered an essential component of successful treatment (Butler, 1989; Beidel & Turner, 1998). Role-playing within a group treatment has also been found useful (Heimberg et al., 1990), perhaps simply as a more structured form of exposure. As mentioned earlier, there is some question whether social phobics actually lack social skills or whether their anxiety simply interferes with performance. Thus, the specific inclusion of social skills training is questioned (Heimberg, 1989), and more research will be required to ascertain when it is necessary and how it works. Nevertheless, some treatment packages have focused on this technique as a major component of treatment (Turner et al., 1994). Cognitive restructuring (aimed especially at the fear of negative evaluation) is considered essential by some researchers (e.g., Butler, 1989; Mattick et al., 1989), though some studies have questioned its unique contribution (Feske & Chambless, 1995).

Finally, a large, recent multicenter trial compared group cognitive behavioral therapy with phenelzine in treating social phobia (Heimberg et al., 1998). Phenelzine resulted in a more rapid effect. However, at the end of treatment, both active treatments resulted in similar effects that were considerably greater than that of placebo. However, at follow-up, the cognitive behavior therapy condition maintained greater gains than phenelzine (Liebowitz et al., 1999).

Pharmacological Treatments. Although a considerable literature suggests that beta-blockers are effective in reducing performance anxiety (Gorman & Gorman, 1987) that is related to social anxiety, these results have generally been observed

in subjects without extreme levels of performance anxiety. Furthermore, any significant results are confined to performance involving motor activity, which suggests that beta-blockers may work mainly for nonclinical subjects by improving performance rather than reducing anxiety (Barlow, 1988). More recent studies that examined the effectiveness of beta-blockers for social phobia have shown minimal effects compared with placebo (Turner, Beidel, & Jacob, 1994). The major medications that have been tested for treating social phobia are the MAOIs. In general, studies demonstrated good results with these medications (Potts & Davidson, 1995). Unfortunately, their potentially dangerous side effects mean that they must be used together with severe dietary restrictions. More recently, reversible MAOIs were developed that do not require dietary restrictions and are considerably safer. Early data with these medications show some positive effects, but not all results have been positive (Potts & Davidson, 1995). Several studies also demonstrated positive effects from the serotonin specific reuptake inhibitors (SSRIs) (Potts & Davidson, 1995). At this stage, studies are still relatively few and have included small numbers; further research is required.

Specific Phobias

The DSM diagnosis of specific phobia refers to a heterogeneous collection of fears and/or avoidance of a broad range of specific objects or situations. Recent attempts to make sense of the heterogeneity centered on trying to identify subgroups of specific phobias that share characteristics. Thus, some researchers distinguished blood and injury fears from other phobias because of the unique physiological response accompanying the former (Ost, Sterner, & Lindahl, 1984; Page, 1994; Thyer, Himle, & Curtis, 1985). Similarly, factor-analytic studies of agoraphobics' fears often identify a claustrophobia factor (Hamann & Mavissakalian, 1988), suggesting that claustrophobia may have much in common with agoraphobic fears. In a recent factor analysis, three subtypes of fears were identified: situational phobias, animal phobias, and mutilation phobias (Fredrikson, Annas, Fischer, & Wik, 1996). Based on these considerations, the DSM-IV has distinguished four subtypes of specific phobia: animal fears, natural environment fears, blood-injection-injury fears, and situational

fears (e.g., flying, small spaces). However, despite the implication of independence among fears, at least one study showed that people with one specific phobia are likely to be comorbid for other specific phobias (Hofmann, Lehman, & Barlow, 1997), calling into question the "specificity" of specific phobias (Harvey & Rapee, in press).

Not surprisingly, given their heterogeneity, specific phobias show varied diagnostic reliability estimates among studies. Mannuzza et al. (1989) found a kappa of .29, whereas DiNardo et al. (1993) found a kappa of .82. It should be noted that studies to date have used DSM-III-R criteria in which subtypes of specific phobias were not distinguished. It remains to be seen whether the specification of subtypes in DSM-IV improves the diagnostic reliability.

Clinical Features

Epidemiology. Mild fears of specific objects or situations are extremely common in the general population (Agras et al., 1969; King et al., 1989). Fears that are considered clinically severe are still relatively common compared to the other anxiety disorders. The National Comorbidity survey found a lifetime prevalence for specific phobias of approximately 11% in adults (Kessler et al., 1994) and the 6-month prevalence in adolescents was around 5% according to self-report (Fergusson et al., 1993; Verhulst et al., 1997).

Despite the common occurrence of specific phobias in the community, this problem rarely provides the impetus for presentation to treatment centers (Merkelbach, de Jong, Muris, & van den Hout, 1996). This is possibly partly because specific phobic stimuli can often be avoided by most people with little interference in their lives and most people with specific phobia have few difficulties outside of the immediate phobic situation (Harvey & Rapee, in press).

Sex Distribution and Age of Onset. Both mild fears in the general population and specific clinical phobias are considerably more common in females than in males (Fredrikson et al., 1996; Kessler et al., 1994). Estimates of the proportion of females in clinical populations generally range around 75 to 95% (Barlow et al., 1985; McNally & Steketee, 1985; Ost, 1987; Thyer, Parrish, et al., 1985). Differences in the proportion of females among the various specific phobia subtypes have been reported (Fredrikson et al., 1996; Ost, 1987).

Age of onset is generally quite early in specific phobia and averages around the early to middle teens (Ost, 1987; Thyer, Parrish, et al., 1985). However, an average age of onset for specific phobia ignores the heterogeneity of the disorder. In fact, consistent differences are found among the ages of onset for different types of specific phobias. Claustrophobia usually begins around the early to middle 20s, an age closer to panic disorder (Ost, 1987), whereas blood/injury and animal phobias typically begin in childhood (Ost, 1987; Thyer, Himle, & Curtis, 1985).

Cognitive Symptoms. Studies of cognitive symptoms in specific phobics have not been very common, possibly because it has been assumed that any thoughts would naturally be related to the phobic object and because thoughts have not usually been considered etiologically important. Nevertheless, a few studies have asked specific phobics about their thoughts when confronting phobic stimuli and found that, although the majority are primarily concerned with harm in the immediate situation, a number engage in other types of thoughts such as concerns over their own sensations (Last & Blanchard, 1982; McNally & Steketee, 1985; Thorpe & Salkovskis, 1995). Other research showed that phobic fear and avoidance is mediated either by beliefs over the ability to complete a particular action (self efficacy) (Williams & Watson, 1985) or by beliefs relating to the likelihood and consequences of danger in the situation (Menzies & Clarke, 1995a).

Somatic Symptoms. When specific phobics are not confronting their feared object, they experience the least severe and debilitating anxiety disorder (Barlow et al., 1985; Turner, McCann, et al., 1986), generally demonstrating relatively normal levels of trait anxiety. Such subjective reports are supported by physiological assessment, which also demonstrates that specific phobics in chronic arousal are not different from normal controls (Lader & Mathews, 1968).

When confronting their feared situations, specific phobics report a number of common anxiety-related somatic symptoms, including palpitations, trembling, and sweating (Rachman, Levitt, & Lopatka, 1988). Physiologically, many studies demonstrated increases in indexes of arousal in specific phobics upon exposure to their feared cues (Cook, Melamed, Cuthbert, McNeil, & Lang, 1988; Ost, 1987), although results are not always consistent, and desynchrony between response

systems has commonly been noted (Sartory, Rachman, & Grey, 1977). In one careful and detailed study, ten animal phobic females were scored on a series of measures (e.g., state anxiety, blood pressure, epinephrine, and cortisol) during *in vivo* exposure sessions (Nesse, Curtis, Thyer, McCann, Huber-Smith, & Knopf, 1985). Most measures showed marked increases during exposure compared to control periods, although the measure of subjective units of discomfort evidenced the most consistent increase.

As mentioned before, many blood and injury phobics are characterized by a unique physiological response to their feared cues (Ost et al., 1984; Page, 1994; Thyer, Himle, & Curtis, 1985). Page (1994) argued that there may be two subtypes of blood/injury phobia. One group shows the usual sympathetic reaction to blood/injury cues described before. The other group shows an initial increase in heart rate and blood pressure followed by a dramatic drop in these measures, often leading to fainting. Associated with this different physiological reaction, many blood/injury phobics report a feeling of disgust on exposure to their feared cues, distinct from the more usual reports of fear found with other phobias (Tolin, Lohr, Sawchuk, & Lee, 1997). In fact, several types of phobias are characterized more strongly by the emotion of disgust rather than fear, and it is possible that this is an alternate method of subtyping phobias (Matchett & Davey, 1991).

Etiology and Maintenance

Genetic and Familial Factors. First-degree relatives of people with specific phobias are more likely themselves to have a specific phobia providing evidence for the importance of either genetic or environmental family factors in the disorder (Fyer et al., 1990). More specifically, a few twin studies demonstrated a genetic involvement in specific phobias but the importance of environmental factors was also shown by these studies (Kendler et al., 1992; Torgersen, 1979).

The nature of the genetic influence has not been demonstrated, and it is likely that some of the genetic involvement is mediated via the general neurotic aspects of other anxiety disorders. However, some authors have argued for the possibility that specific phobias represent the emergence of specific, innate fears (Menzies & Clarke, 1995b). The fact that certain normal fears emerge innately

at specific periods of developmental history has been clearly demonstrated (e.g., Berenthal, Campos, & Barrett, 1984). Therefore, it has been suggested that some individuals simply have a greater degree of these innate fears constitutionally or that normal fears are not extinguished for certain reasons (Menzies & Clarke, 1995b). Evidence for this approach has come from interview studies of adults and children with specific phobias in which a majority of subjects reported having the phobia for as long as they could remember (Menzies & Clarke, 1993a,b), but these reports have been criticized by many as reflecting overly narrow views of associative learning (Mineka & Zinbarg, 1996; Barlow, in press).

Environmental Factors. Since the demonstration by Watson and Rayner (1920) that a fear of white, furry objects could be produced in a child, conditioning theories of phobias have abounded (e.g., Mowrer, 1939). More specifically, it has been suggested that phobic concerns could be acquired through three basic methods: verbal information, vicarious learning, and direct conditioning (Rachman, 1977). Support for this suggestion has come from studies that asked specific phobics to state retrospectively what they consider the cause of their disorder. Most of these studies find a large proportion of subjects reporting that their phobias began suddenly following a conditioning episode (including an unexpected burst of fear), whereas a smaller proportion report seeing a traumatic event or hearing about the dangers of the object or situation (Merkelbach et al., 1996). However, some authors pointed out that the method of collecting these data has often been flawed because subjects are forced into one response and are often not given the opportunity to state that they have always had the fear (Barlow, 1988; Menzies & Clarke, 1995b). Studies in which this alternative was given to subjects showed a considerably smaller number reporting acquisition via the three main pathways (Menzies and Clarke, 1993a,b), although these studies are subject to the strong criticisms alluded to before.

Preparedness. Many objects that are in the subject's immediate environment when traumatic events occur do not acquire fearful properties. Subsequently, phobias are usually found in response to a limited set of all of the possible cues in the world. Observations such as these led Seligman (1971) to propose that certain stimuli are

biologically "prepared" to become associated with danger. According to Seligman, these prepared stimuli can acquire fearful properties after a single traumatic pairing and, once conditioned, are extremely difficult to extinguish. The types of stimuli that possess prepared properties are those that have ecological validity (such as heights or snakes), as opposed to more modern dangers (such as guns or electrical outlets). Although Seligman's theory makes considerable intuitive sense and there has been considerable laboratory support for his predictions (Cook & Mineka, 1989; Ohman, 1994, 1996), studies that examined the preparedness hypothesis have had mixed results (McNally, 1987). The only one of Seligman's predictions that has found consistent laboratory support has been the difficulty in extinguishing responses to prepared stimuli, and this phenomenon could find alternate explanations (McNally, 1987; Bond & Siddle, 1996).

Combining cognitive data with the concept of preparedness, some interesting data have shown that fearful subjects are more likely to believe that aversive experiences are associated with phobic stimuli than with nonphobic stimuli (de Jong, Merkelbach, Arntz, & Nijman, 1992; Tomarken, Sutton & Mineka, 1995). In the typical paradigm, subjects are shown slides of fear-relevant images (e.g., snakes) and fear-irrelevant images (e.g., flowers) and are given random outcomes that are either aversive (e.g., electric shock) or nonaversive (e.g., nothing). Even though there is no relationship between slides and outcomes, subjects are more likely to perceive an association between fear-relevant slides and aversive outcomes, and this effect is stronger for highly fearful subjects. This may suggest that the preparedness phenomenon is mediated by biases in the way stimulus information is processed. However, some research has shown that these biased perceptions can be demonstrated before any experience the subject has with slides or outcomes (de Jong, 1993; Honeybourne, Matchett, & Davey, 1993; McNally & Heatherton, 1993), suggesting that the effect is based on preexperimental expectancies and not biased processing (Davey, 1992). More recently, some research has demonstrated that both preexperimental expectancies and experience play a role in the covariation phenomenon, indicating a possible role for both expectancy and processing bias in the effect (Kennedy, Rapee, & Mazurski, 1997).

Treatment

There is widespread agreement that the treatment of choice for phobic fear and avoidance is *in vivo* exposure (Barlow, 1988; Marks, 1981). Some evidence has even suggested that excellent gains can be achieved through a single session of intensive exposure (Arntz & Lavy, 1993; Ost 1996). Some attempts have been made to match the reported mode of acquisition or individual differences to specific types of treatment (Jerremalm et al., 1986; Ost et al., 1982), but these have provided mixed success. Further, the addition of cognitive restructuring, relaxation, or drug treatment has generally not provided increased gains over basic exposure (Barlow, 1988). The one exception may be blood and injury phobia for which the addition of applied tension improved gains, especially for some subjects (Ost, Fellenius, & Sterner, 1991; Page, 1994).

Few studies have tested psychopharmacology in treating specific phobias (Harvey & Rapee, in press). Some research has shown minimal, short-term effects from using benzodiazepines and beta-blockers (Bernadt, Silverstone, & Singleton, 1980; Campos, Solyom, & Koelink, 1984), but improvements did not generalize or last.

Conclusions

We discovered much in the past decade about the nature of anxiety. We also devised new psychological and pharmacological treatments that are effective in varying degrees for anxiety disorders. Nevertheless, we are only beginning to understand the riddle of anxiety. As Freud (1917) noted, the solution to this riddle "must cast a flood of light upon our whole mental life" (p. 401).

Current interest is beginning to focus on improved understanding of the origins and development of anxiety and anxiety disorders. This will allow the development of early intervention and prevention programs so that the life course of people with anxiety disorders and the subtle but extensive interference that these disorders cause can be reduced from an early age. Most importantly, we should develop a deeper understanding of the meaning and purpose of anxiety and the very nature of emotion. It is only by thoroughly understanding the nature of normal and patholog-

ical emotion that we will be able to cope effectively with anxiety disorders, which are the most common psychological disorders known to humans.

Obsessive-Compulsive Disorder

**Samuel M. Turner, Deborah C. Beidel,
Melinda A. Stanley, and Nancy Heiser**

Introduction

The past two decades were characterized by enormous advancement in understanding the nature of mental illness. In particular, findings from basic neuroscience raised the possibility of eventually unraveling the pathophysiology of mental disorders. Similarly, cognitive theories have taken on increasing prominence in explanations for maladaptive psychological functioning. With respect to the anxiety disorders in general, and obsessive-compulsive disorder in particular, there has been a virtual explosion of research since the introduction of DSM-III in 1980; much of which is biological and cognitive. In this chapter, we will discuss the syndrome of OCD, which has remained remarkably consistent during the many decades since its description. Specifically, we will describe the syndrome and its manifestation, discuss diagnosis and the emerging literature on the comorbidity of OCD and other disorders, as well as the concept of OCD Spectrum Disorder. We will devote considerable time to discussing and evaluating findings

from biological and cognitive research with respect to the impact these findings have had in furthering our understanding of the nature and phenomenology of OCD.

Diagnosis and Phenomenology

Diagnosis of the Disorder

Obsessive-compulsive disorder (OCD) is one of the most severe and chronic of the anxiety disorders delineated in the current psychiatric nomenclature (American Psychiatric Association [APA], 1994). It is characterized by the presence of obsessions or compulsions, although the majority of patients report both types of symptoms (Foa & Kozak, 1995). An *obsession* is any recurrent, intrusive thought, image, or urge that is unwanted but cannot be controlled. Obsessions differ from the excessive preoccupation with real-life worries that characterizes generalized anxiety disorder (GAD) in content, form, resistance, and precipitating stimuli (Turner, Beidel, & Stanley, 1992). Patients with the two disorders are also easily distinguishable based on core clinical features (Brown, Moras, Zinbarg, & Barlow, 1993). The most common types of obsessions involve themes of contamination, dirt or illness (e.g., fearing that one will contract or transmit a specific disease, such as cancer or HIV, or a more general, vague fear of not being clean enough), and pathological doubting (e.g., that some action has not been performed adequately and will consequently result in harm to

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

self and/or others) (Rasmussen & Eisen, 1994). Other common themes include the need for symmetry or orderliness, somatic concerns, and aggressive, sexual, or religious ideation. Generally, patients try to suppress or ignore the thoughts, and diagnostic criteria require that patients realize that the obsessions are products of their own minds (APA, 1994).

A *compulsion* is any purposeful, repetitive behavior or mental activity that is performed in a ritualistic or stereotypical way, generally with the goal of reducing anxiety associated with obsessive ideation. As such, compulsions can be conceptualized as escape or avoidance mechanisms, although it should be noted that not all conceptualizations of the disorder include a central role for anxiety (Antony, Downie, & Swinson, 1998). The most frequently reported compulsive behaviors include repetitive washing (e.g., handwashing, showering, house cleaning) and checking (e.g., of locks, appliances, numerical figures, or mathematical calculations) (Rasmussen & Eisen, 1994). These classes of behaviors generally are associated, respectively, with obsessive thoughts of contamination and excessive doubting (Baer, 1994; Rachman & Hodgson, 1980). Other common types of compulsions include repeating rituals (e.g., getting up and down from a chair repeatedly, going in and out of doorways), ordering/arranging behaviors, and hoarding. Cognitive compulsions (e.g., mental counting or repetition of certain words, phrases, or images) also occur frequently and generally serve the same function as behavioral rituals (Foa & Kozak, 1995). However, mental rituals often go unnoticed by inexperienced clinicians. To differentiate obsessions from cognitive compulsions, it is essential to determine the function of the mental activity. If the function is to reduce discomfort about an obsessive thought, characterization of the cognition as a compulsion should be considered.

To diagnose OCD, patients must acknowledge at some point that the symptoms are/were excessive and unreasonable. However, diagnostic criteria call for specification of *poor insight* when the patient fails to recognize the irrationality of the thoughts or behaviors at the time of diagnosis (APA, 1994). Patients in this subgroup also are often classified as exhibiting *overvalued ideation* (OVI). Although early clinical data indicated that OVI was associated with poor response to behavioral treatment (Foa, 1979), more recent studies

addressing this issue have not been consistent (Kozak & Foa, 1994). This literature is difficult to interpret, however, given that patients with OCD exhibit a wide range of insight and fixity of beliefs (Eisen & Rasmussen, 1993; Foa & Kozak, 1995) that make categorization into OVI and non-OVI subgroups challenging at best. Moreover, until recently, no psychometrically sound measure of OVI was available. Due to the lack of well-standardized assessment tools, it has been difficult to interpret and integrate findings across studies. However, preliminary data on a new measure created by Eisen and colleagues show promise in this regard (Eisen et al., 1998). The Brown Assessment of Beliefs Scale is a seven-item clinician-rated scale that assesses degree of delusionality in OCD and other psychiatric disorders. Initial psychometric data suggested strong interrater agreement, internal consistency, convergent and divergent validity, and sensitivity to change (Eisen et al., 1998). As such, this measure should provide a solid tool for further investigation into the role of overvalued ideation in OCD.

As with other psychiatric disorders, to diagnose OCD, the symptoms need to create significant distress and/or interfere with functioning. Numerous studies have documented that patients with OCD experience significant disruption in social and family relationships, impaired work performance, and decreased quality of life (Antony, Roth, Swinson, Huta, & Devins, 1998; Calvocoressi et al., 1995; Hollander et al., 1997; Koran, Thienemann, & Davenport, 1996). Economic costs of the disorder are also high due to inappropriate treatments, unemployment, absenteeism from work, and increased use of welfare or family support (Hollander et al., 1997; Steketee, Grayson, & Foa, 1987). In these instances, OCD should be considered a severe psychiatric disorder that has pervasive and serious impact on the individual and society.

Symptom Subtypes

Given the wide variety of symptom patterns that may be present in OCD, a number of attempts have been made to subclassify the disorder to enhance understanding of its pathophysiology and treatment. Most often, attempts to identify subtypes have been based on the predominant type of rituals reported by the patient. In these schemes, subgroups of patients always include (but are not

limited to) those with predominant washing and checking rituals. As noted earlier, these types of rituals are the most commonly reported by clinic patients (Rasmussen & Eisen, 1994). As such, it is not surprising that much of the evidence that supports the utility of behavioral treatment for OCD has been obtained largely with patients who can be classified as “washers” or “checkers” (Ball, Baer, & Otto, 1996). Studies of the potential utility of subclassifying OCD in this manner have indicated a variety of differences in demographic and clinical variables for patients classified as “washers” and “checkers.” For example, patients in these two subgroups differ in age of onset and gender distribution (Khanna & Mukherjee, 1992; Minichiello, Baer, Jenike, & Holland, 1990), frequency of personality disorders (Horesh, Dolberg, Kirschenbaum-Aviner, & Kotler, 1997), triggers for obsessional fears, and retrospective reports of parental style (Steketee, Grayson, & Foa, 1985). These data suggest the potential utility of a symptom classification scheme to enhance understanding and treatment of OCD.

Recent factor analyses of OCD symptoms in larger groups of patients suggested three or four major subgroups of symptoms. Baer (1994) reported an analysis of symptoms in 107 patients that yielded three factors characterized by symmetry/hoarding (symmetry and saving obsessions, and ordering, hoarding, repeating, and counting rituals), contamination/cleaning, and pure obsessions (aggressive, sexual, and religious obsessions). Leckman and colleagues (Leckman et al., 1997) reported four factors in two independent samples of more than 300 patients with OCD. These factors included obsessions/checking (aggressive, sexual, religious, and somatic obsessions and checking rituals), symmetry/ordering (including also repeating and counting compulsions), cleanliness/washing, and hoarding. Overlap in the factor structures of these two reports is evident, although no data yet have addressed the utility of subclassifying patients according to these broader subgroups of symptoms. In fact, despite evidence of meaningful differences between washers and checkers, the general utility of classifying patients according to symptom subtypes has been questioned, given that symptom clusters generally are not mutually exclusive and constellations of symptoms may change over time (Baer, 1994; Rettew, Swedo, Leonard, Lenane, & Rapoport, 1992).

Other subclassification schemes have also been suggested, the most viable of them probably is

based on coexistent diagnoses. In particular, coexistent Tourette's syndrome or chronic tic disorder in OCD has been associated with differential obsessive-compulsive symptom profiles (Baer, 1994; Leckman et al., 1997), gender distribution (George et al., 1993; Zohar et al., 1997), age of onset for OCD and neurochemical findings (Leonard et al., 1992), and treatment response (McDougle, Goodman, Leckman, Barr, Heninger, & Price, 1993). This literature taken together supports the potential utility of subclassifying patients with OCD who also have a chronic tic disorder to enhance clinical understanding and treatment of patients. Similarly, patients with some coexistent personality disorders or features have unique patterns of OCD symptoms (Baer, 1994; Stanley, Turner, & Borden, 1990) and differential treatment response (McDougle, Goodman, Leckman, Lee, Heninger, & Price, 1994). This literature is less well developed, however, and requires further study.

Possibly of even more heuristic value are subclassification schemes based on function rather than content of symptoms. Such systems allow subclassification of patients regardless of specific symptom constellations that may vary over time. Mavissakalian (1979) proposed such a system that included four forms of obsessive-compulsive symptoms: (1) obsessions only, (2) obsessions plus anxiety-reducing compulsions, (3) obsessions plus anxiety-increasing compulsions, and (4) compulsions independent of anxiety and/or obsessions. Although this type of system holds some promise for treatment refinement (Mavissakalian, 1979), very little relevant empirical work has addressed the utility of functional classification schemes. In the context of a DSM-IV field trial, Foa and Kozak (1995) examined the usefulness of subcategories of OCD including *predominantly obsessions*, *predominantly compulsions*, and *mixed obsessions and compulsions*. Results revealed that more than 90% of patients reported both obsessive and compulsive symptoms, although based on interview data, clinicians categorized 30% of patients with predominantly obsessions, 21% with predominantly compulsions, and 49% with mixed obsessions and compulsions. Significant differences in the frequency of various specific symptoms occurred across these subgroups, although data overall were equivocal with regard to the utility of this type of classification.

In summary, numerous models have been pro-

posed for subclassifying OCD. To date, the most promising of these involve subgroups based on the presence or absence of co-occurring chronic tic disorders and the predominant type of symptom reported; the majority of data here address differences between patients with primary washing or checking compulsions.

Comorbidity, Differential Diagnosis, and the Obsessive-Compulsive Spectrum Disorders

OCD is frequently accompanied by increased levels of anxiety and depression; estimates of co-existent disorders range from 42–83% (Antony et al., 1998). Despite these high rates of overlap with other disorders, the diagnosis of OCD can be made quite reliably, particularly when behavioral compulsions are present (Brown, 1998). Key differential diagnostic issues still are relevant, however, and these will be reviewed briefly here.

Generally, the differentiation of OCD from other anxiety disorders is fairly straightforward. First, although there is clearly overlap between obsessional thinking and worry, as already noted, the diagnostic differentiation of OCD and GAD can be made reliably (Brown et al., 1993). In differentiating these disorders, it is of note that obsessions generally are associated with a greater degree of resistance and increased perceptions of unacceptability than worry (Turner et al., 1992). Obsessions are also less likely to be precipitated by and focused on circumstances of daily living (Turner et al., 1992). Even when GAD is diagnosed in patients with principal OCD, it is associated with more frequent worries about daily life events (Abramowitz & Foa, 1998). Moreover, although repetitive checking may be present in GAD, rituals that accompany OCD are usually more pervasive and intrusive.

Differentiation of OCD and other disorders with more focal fears (e.g., specific phobia, social phobia, specific subtype) is usually not difficult because any obsessional ideation that accompanies these syndromes revolves around a single fear. Ritualistic behavior also typically does not accompany fears with a more specific focus. The distinction between OCD and specific phobias of illness, however, can be slightly more complicated because fears of contamination/illness are the most prevalent form of obsessions generally reported (Brown, 1998). In these cases, differentia-

tion can be relatively straightforward if rituals accompany the fear. In addition, specific phobias of illness involve more focused health-related fears than the pervasive concerns usually evident in OCD.

Differentiating OCD and depression is also an important issue, given the high rates of comorbidity between these conditions. Although figures vary across studies, as many as one-third of patients with OCD also meet criteria for coexistent depression or dysthymia (Antony et al., 1998a). In these cases, it can be important for treatment planning to identify which disorder is considered principal. Generally, the principal disorder is assumed to be that with the earlier onset (Turner & Beidel, 1988). Using this criterion, OCD more often is considered the principal diagnosis when both disorders are present (Antony et al., 1998a). There is support, however, for the notion that all anxiety and affective disorders share a similar biological pathophysiology, although environmental factors shape symptom expression (Kendler, Heath, Martin, & Eaves, 1987).

Of more recent interest in the literature, however, are issues concerning the relationship between OCD and a wide range of other psychiatric and neuropsychiatric disorders that, it is hypothesized, comprise a group of disorders known as the obsessive-compulsive spectrum disorders (Hollander, 1993; McElroy, Phillips, & Keck, 1994). Disorders proposed as members of this spectrum include the somatoform disorders (e.g., body dysmorphic disorder, hypochondriasis), eating disorders (e.g., anorexia nervosa, bulimia nervosa, and binge-eating disorder), impulse control disorders (e.g., trichotillomania, pathological gambling) and related symptoms (skin picking, nail biting, and compulsive buying), and movement disorders (e.g., Tourette's disorder, Sydenham's chorea). These disorders, it has been hypothesized, share common phenomenological features, patterns of comorbidity, family history, clinical course, treatment response, and neurobiological mechanism with OCD.

The proposed concept of obsessive-compulsive spectrum disorders has generated much controversy in the field. In particular, some authors have argued that this classification scheme is vague, overinclusive, and characterized by a lack of clear inclusion and exclusion criteria (Rasmussen, 1994). Other authors have argued that the spectrum disorders are part of an even broader class

of affective disorders (McElroy, Hudson, & Pope, 1992). Subclassification schemes have also been proposed, and some include disorders of altered risk assessment, incompleteness/habit spectrum disorders, and psychotic spectrum disorders (Piggott, L'Heureux, Dubbert, Bernstein, & Murphy, 1994). Another perspective suggests that disorders along the obsessive-compulsive spectrum vary across a continuum of compulsivity versus impulsivity (Hollander & Cohen, 1996). In this scheme, compulsive disorders, it is proposed, reflect excessive harm avoidance and risk aversion, whereas impulsive disorders are characterized by minimization of harm and risk.

Empirical literature addressing the potential overlap between OCD and the other proposed spectrum disorders is limited at present. Nevertheless, in some cases, the apparent overlap is more striking than in others. It has been suggested that those disorders that would be classified along the compulsive end of the spectrum (e.g., the somatoform and eating disorders) are more similar to OCD than those proposed that fall along the impulsive end (e.g., impulse control disorders) (Goldsmith, Shapira, Phillips, & McElroy, 1998). The extant literature supports this notion, at least in part because of striking phenomenological similarities between OCD and body dysmorphic disorder (BDD), hypochondriasis, and eating disorders. In particular, preoccupations with perceived physical defects, serious disease, and food or body weight that are present in BDD, hypochondriasis, and eating disorders, respectively, strongly resemble the obsessions that occur in OCD. In addition, ritualistic behavior generally accompanies these other syndromes. For example, patients with BDD frequently check their appearance in the mirror, seek reassurance about the imagined physical defect, and perform excessive grooming behaviors. Patients with hypochondriasis often repetitively check physical symptoms, request medical treatment, and seek reassurance regarding health. Individuals with eating disorders also regularly report repetitive behaviors surrounding eating behaviors. In addition to these striking phenomenological similarities, there is some evidence that these disorders respond to pharmacological interventions (e.g., serotonergic reuptake inhibitors) and behavioral treatments (exposure and response prevention) that are the treatments of choice for OCD (Goldsmith et al., 1998).

Despite these areas of overlap between OCD and those spectrum disorders proposed, potentially important differences in these conditions are also evident. For example, both BDD and hypochondriasis generally are associated with greater levels of impaired insight than is typically seen in OCD. Additionally, bulimia nervosa and binge eating disorder are associated with more frequent impulsive behaviors than OCD. Finally, there is some evidence that hypochondriasis and eating disorders also respond to nonserotonergic antidepressants that have not demonstrated efficacy in OCD (Goldsmith et al., 1998). Nevertheless, the possibility that these disorders are related in some way to OCD deserves additional empirical attention.

In the case of those disorders proposed that lie along the impulsive end of the spectrum, it is our opinion that differences among these disorders in phenomenology, neurobiology, and treatment far outweigh any similarities. The impulse control disorders (ICDs; e.g., pathological gambling, kleptomania, trichotillomania) and possible ICDs (e.g., nail biting, repetitive self-mutilation, skin picking) are characterized by repetitive behaviors over which patients report no control. These behaviors often, it is reported, have an anxiety-relieving function, and it is in these domains that there is some overlap with OCD. Other data also have suggested overlap between the ICDs and OCD in family history and treatment response (Goldsmith et al., 1998).

Despite these areas of overlap, other phenomenological, neurobiological, and treatment data suggest important differences between OCD and ICDs. The majority of literature in this area has addressed the potential overlap between OCD and trichotillomania (TM), a disorder characterized by repetitive hair pulling. In a review of this literature, Stanley and Cohen (1999) summarized areas of similarity and dissimilarity between these conditions. One major phenomenological difference included the fact that obsessional thoughts usually do not accompany repetitive hair pulling, although this type of cognitive activity is central to the diagnosis of OCD. In addition, hair pulling occurs in response not just to anxiety, but also to a variety of affective states, and the behavior frequently produces feelings of pleasure that are not characteristic of OCD. Moreover, sensory stimuli (e.g., itching, burning) are important precipitators of hair pulling, although these have no central role in OCD. Neurobiological and neuropsychological

correlates of OCD and TM are also different, although the literature addressing these issues in TM is still somewhat limited. Finally, pharmacological treatment data for TM do not provide a consistent picture of the efficacy of serotonergic reuptake inhibitors, and the modes of behavioral treatment for TM (habit reversal training) and OCD (exposure and response prevention) are quite different. In summary, the range of important differences between these two syndromes calls into question the utility of combining them under a single spectrum of obsessive-compulsive-related disorders. However, Stanley and Cohen (1999) highlighted the notion that some subtypes of TM may reflect more overlap with OCD and further suggested that any appearance of association between these disorders may result from the heightened states of negative affect that accompany each. These hypotheses require further study.

Overall, the notion of an obsessive-compulsive spectrum of disorders continues to generate controversy in the field. Difficulties in assessing the utility of this scheme reflect in part the fact that there are not yet any established criteria for membership in this family of disorders. Furthermore, the amount of literature that has provided direct comparisons between patients with OCD and those with proposed related disorders remains limited.

Epidemiology

The now well-known Epidemiological Catchment Area (ECA) survey conducted during the early 1980s indicated lifetime prevalence rates for OCD of 1.9 to 3.3% in five U.S. communities and an overall rate of 2.5% (Karno, Golding, Sorenson, & Burnam, 1988). These rates were much higher than any previous estimates and were confirmed by similar epidemiological, albeit smaller scale, surveys conducted at approximately the same time in the United States and Canada (Bland, Orn, & Newman, 1988; Henderson & Pollard, 1988). In all of these studies, however, interviews were conducted by lay interviewers, and it is notable that prevalence estimates were considerably lower in surveys using clinician interviewers (Favelli, Degl'Innocenti, & Giardinelli, 1989; Nestadt, Samuels, Romanoski, Folstein, & McHugh, 1994). In fact, a more recent study confirmed that prevalence rates for OCD within a single sample were indeed lower when clinicians, rather than lay interviewers, conducted diagnostic interviews (Stein, Forde, Anderson, & Walker, 1997). Issues

such as lay interviewers' inexperience in establishing and labeling psychiatric symptoms and difficulty in estimating degree of dysfunction and distress are particularly relevant in this regard (Stein et al., 1997).

The limitations of the ECA study are well known and have been discussed in detail elsewhere (Beidel & Turner, 1991; McNally, 1994). The most striking of these, however, are the aforementioned potential for overdiagnosis due to use of lay interviewers and diagnostic structured interview tools that do not allow for follow-up questions to clarify patient reports. Of even more concern are recent data suggesting poor temporal stability of OCD diagnoses for a subset of ECA survey participants who were reassessed 12 months after the initial interview (Nelson & Rice, 1997). Taken together, these data call into question prevalence rates based on the ECA survey. It is unfortunate that the only subsequent large epidemiological survey conducted in the United States, the National Comorbidity Survey, failed to assess the prevalence of OCD (Kessler et al., 1994). As a result, the true prevalence of this disorder is now uncertain.

At least partly due to general difficulties in estimating prevalence rates, data are mixed with regard to the impact of ethnicity on the prevalence of OCD. Across all five ECA sites, figures indicated that lifetime OCD was significantly less prevalent among Black respondents than non-Hispanic White respondents (Karno et al., 1988). Data from the Los Angeles site alone indicated no difference in prevalence rates for OCD among Mexican-Americans and non-Hispanic Whites (Karno et al., 1989). When ECA data were compared with surveys that used similar methodology in Canada, Puerto Rico, Germany, Taiwan, Korea, Hong Kong, and New Zealand, relatively consistent prevalence figures emerged (1.9–2.5%), except Taiwan where the prevalence of OCD was only 0.7% (Weissman et al., 1994). In a more recent survey of more than 800 residents of Baltimore, OCD tended to be more prevalent among Whites (2.1%) than non-Whites (0.8%) (Nestadt et al., 1994). Clinical data also routinely show a greater prevalence of OCD among Whites than non-Whites (e.g., Antony et al., 1998a). It is not clear, however, that interview questions are always sensitive to ethnic differences in the experience or description of relevant symptoms. It is known, for example, that members of various minority groups tend to focus on somatic complaints in descriptions of anxiety-related symptoms and

often present for assistance to medical rather than psychiatric clinics (Friedman, Hatch, Paradis, Popkin, & Shalita, 1993). Other sociocultural variables, including religious background, can also significantly impact the presentation and assessment of OCD symptoms (Okasha, Saad, Khalil, Seif El Dawla, & Yehia, 1994). Thus, more research using culturally sensitive diagnostic tools is needed to ascertain the impact of ethnicity on prevalence rates of OCD.

Epidemiological data generally have indicated that community prevalence rates are slightly higher for women than men (Henderson & Pollard, 1988; Karno et al., 1988; Weissman et al., 1994). However, data from the ECA survey indicated that gender effects were eliminated when other demographic variables were controlled statistically (Karno et al., 1988). Nevertheless, consistent gender differences have been demonstrated in the prevalence of specific obsessive-compulsive symptoms. In particular, women are significantly more likely than men to report washing and cleaning rituals (Khanna & Mukherjee, 1992; Minichiello et al., 1990), and there is some suggestion that men report more frequent sexual obsessions (Antony et al., 1998a). These findings further support the potential role of sociocultural variables in the presentation of OCD.

Gender differences have also been noted in the onset of OCD. Although the disorder most often begins between late adolescence and early adulthood, onset is earlier for males than females (Rasmussen & Eisen, 1990). Retrospective data have suggested that later onset for women may result from the appearance of initial symptoms during pregnancy or after childbirth (Neziroglu, Anecone, & Yaryura-Tobias, 1992; Sichel, Cohen, Dimmock, & Rosenbaum, 1993). However, these findings simply may reflect the notion that OCD often has its onset after a period of significant life stress, although data addressing this issue are almost uniformly collected retrospectively and produce questionable conclusions. Although few longitudinal studies have been conducted, the course of OCD is generally chronic and unremitting without treatment.

Biological Contributions

In 1985, Turner, Beidel, and Nathan reviewed the available data that addressed biological factors in OCD. Included in the review were genetic and

family studies, neurophysiological and neuropsychological studies, neuroanatomical studies, and biochemical and pharmacological studies. Turner et al. (1985) concluded that although biological factors correlated with OCD from the evidence available then, it did not appear that the disorder was strictly a biological abnormality. Rather, the most parsimonious explanation was that there might be a biological predisposition that leaves the individual more vulnerable to the development of OCD, perhaps from psychological and/or environmental stress. One important limitation of the studies reviewed in 1985 was that there were few data that directly assessed brain function, and inferences had to be made from indirect measures such as blood or plasma neurochemistry. During the past 15 years, advances in scientific and medical technology offer heretofore unavailable opportunities to directly assess brain structures and functions. In this section, the biological basis of OCD will be examined using biochemical and neuropharmacological studies, neuropsychological assessment, structural and functional neuroanatomy literature, and psychosurgery follow-up studies.

Biochemistry and Neuropharmacology

Although they are an indirect assessment of brain function, data from biochemical challenge studies and pharmacological treatment outcome studies suggest that the orbital and cingulate cortex may be potential neuroanatomical sites of dysfunction in OCD. Data that address the neurochemistry of OCD have been collected under three conditions: steady-state assessment in untreated patients and comparisons to normal controls, pharmacological challenge studies in untreated patients, and changes in neurochemistry after pharmacological treatment. Each of these categories is discussed here.

Biochemistry. Initially, cerebral spinal fluid (CSF) studies of adult patients with OCD primarily assessed serotonin levels and activity, but the findings were inconsistent (e.g., Thoren, Asberg, Bertilsson, Mellstrom, Sjoqvist, & Traskman, 1980; Yaryura-Tobias, Neziroglu, & Bergman, 1976). Whereas some studies found higher levels of serotonin among OCD patients, others reported reduced levels. More recently, a broader range of substances has been investigated. For example, Swedo et al. (1992) examined eight different neurochemicals and their various combinations and found only a few significant differences between

patients with OCD and normal control subjects including a significant negative correlation between 5-HIAA concentration and one of eight baseline OCD severity ratings (whereas three of eight correlations were significant after 5 weeks of treatment with clomipramine). Before treatment, the concentration of arginine vasopressin (a stress-responsive neurohormone) was negatively correlated with OCD symptoms, whereas corticotropin releasing hormone (another stress-responsive neurohormone) did not differentiate the two groups. The authors concluded that arginine vasopressin might be related to OCD symptom severity whereas 5-HIAA might be associated with treatment response. However, as discussed in greater detail in the functional neuroanatomy section, the only comparison group used consisted of normal controls. Thus, it is unclear if the negative correlation is specific to OCD or whether it is present in other disordered mood states. Using similar methodology, Altemus et al. (1992) reported that those with OCD had significantly higher levels of arginine vasopressin and corticotropin releasing hormone compared to normal controls, similar to the findings of Swedo et al. (1992). However, in contrast to that study, Altemus et al. (1992) did not find a relationship between arginine vasopressin and any clinical rating of OCD. Corticotropin releasing factor level, on the other hand, was significantly related to scores on the Yale–Brown Obsessive–Compulsive scale but not with several other ratings of OCD. Thus, like the earlier studies that assessed serotonin, the relationship of these neurohormones to OCD is unclear.

Another CSF neuropeptide, somatostatin, has also been the subject of investigation (Altemus et al., 1993). As noted by these authors, when somatostatin is administered centrally to animals, it delays extinction of various behaviors or produces stereotyped behaviors that appear topographically similar to OCD rituals. When compared to those without a disorder, drug-free adult outpatients with OCD had higher levels of CSF somatostatin, a finding that is consistent with an earlier study of children with OCD (Kruesi et al., 1990). As Altemus et al. (1993) noted, the functional importance of the high somatostatin levels for patients with OCD is not known. What is known is that animal studies indicate an association of increased somatostatin with increased repetitive behaviors and that following pharmacotherapy with antidepressants, reductions occur in both OCD behav-

iors and somatostatin across multiple brain regions. However, the specificity of this decrease in somatostatin for reduction of OCD symptomatology is unclear (i.e., change also might occur in behaviors unrelated to OCD).

In contrast to assessment consisting solely of resting levels, a second series of studies used neuroendocrine challenge tests, most of which assessed serotonin (5-HT) function. These studies also produced inconsistent findings. Some reported increased 5-HT mediated responses after administering various pharmacological agents, whereas others reported normal or decreased responses (e.g., Fineberg et al., 1994; Fineberg, Roberts, Montgomery, & Cowen, 1997; Hewlett et al., 1992; Hollander et al., 1992; Lopez-Ibor et al., 1994; Lucey et al., 1992). As noted by Fineberg et al. (1997), these conflicting results indicate that 5-HT mediated neuroendocrine responses are inconsistent and probably do not play an important role in the pathophysiology of OCD.

Neuropharmacology. Numerous studies that date back to the late 1970s examined the response of various neurochemicals after treatment with selective serotonin reuptake inhibitors (SSRIs). A review of this extensive literature is beyond the scope of this chapter, and the interested reader is referred to Blier and de Montigny (1998). Two studies are presented here for illustration. In an early study, treatment with clomipramine produced decreases in platelet serotonin concentration and an increase in standing plasma norepinephrine (Flament, Rapoport, Murphy, Berg, & Lake, 1987). More recently, patients treated with fluvoxamine had a normalized plasma prolactin response to *d*-fenfluramine (a pharmacological challenge agent), in contrast to the abnormal (decreased) response before treatment (Monteleone, Catapano, Bortolotti, & Maj, 1997). Overall, this literature suggests that treatment with SSRIs may result in “normalization” of neurohormonal and neuroendocrine responses and that these changes are evident in areas of the brain that have been previously associated with dysfunction. For example, SSRIs enhance 5-HT release in the orbitofrontal cortex, but this enhanced release occurs only after a period of prolonged drug administration (e.g., after 8 weeks for paroxetine; Blier & de Montigny, 1998). These authors noted that because this neurochemical change in brain function occurs only after several weeks of pharmacotherapy, it is theoretically very important. It suggests that the mech-

anism of drug action is not simply by blocking serotonin re-uptake at the level of the individual synapse (which occurs almost immediately after drug ingestion). If this were the important mechanism of action, there should be an immediate decrease in OCD symptoms from taking the medication. Rather, the delayed onset of the clinical change is correlated with the time necessary to produce desensitization of the 5-HT terminals in the orbitofrontal cortex (Blier & de Montigny, 1998). Potentially, this is a very important finding in understanding brain pathology, but further studies are needed to verify this hypothesis.

In summarizing the literature on biochemistry and neuropharmacology, one of the most important limitations is that there are few studies that have used clinical control groups in addition to those without a psychiatric disorder. Thus, it is impossible to associate neurochemical changes specifically with OCD. For example, patients with anorexia nervosa show the same increased dysregulation in arginine vasopressin as that of patients with OCD. Similarly, the positive correlation between arginine vasopressin and the dopamine metabolite HVA found in patients with OCD is also found in patients with schizophrenia (Altemus et al., 1992). Similarities in neurochemistry across individuals with diverse types of disorders suggest that reported significant differences between patients with OCD and normal controls may reflect a general stress response rather than the pathophysiology of a specific disorder.

Neuropsychology

It is beyond the scope of this chapter to review all of the individual tests that have assessed cognitive functioning in OCD patients. Therefore, the discussion will be restricted to four general categories: general intellectual functioning, an "underinclusive" thinking style, frontal lobe impairment, and memory (Tallis, 1997). With respect to general intellectual functioning, some early studies reported above average intellect among patients with OCD. However, more recent studies have not supported these early findings. Furthermore, a few studies reported lower IQ scores in those with OCD (see Tallis, 1997 for a review). However, it is important to note that performance deficits usually occur on subtests that are timed, making it difficult to disentangle specific cognitive processing deficits from nonneurological influences on process-

ing speed such as obsessional slowness or meticulousness (see limitations section later).

Neuropsychological assessment has also addressed the concept of underinclusion, defined as the inability to organize and integrate experiences. As discussed by Tallis (1997), it has been hypothesized that the formal characteristics of obsessional thinking result in an inability to organize experiences, thus leading to an overdefinition of categorical boundaries. Thus, those with OCD are expected to be too exclusive in their classification strategies and thereby produce too many categories. Most data in support of this hypothesis come from studies of "anacastic personalities" or those with obsessive-compulsive personality disorder. Only one study that consisted of seven patients reported support for underinclusiveness in patients with a DSM-III diagnosis of OCD (Persons & Foa, 1984). As Tallis (1997) noted, the relationship of underinclusion to OCD etiology or symptomatology is unclear. Thus, although it might represent a particular cognitive style, it is unclear how underinclusiveness represents a biological abnormality.

A third type of neuropsychological testing assesses frontal lobe function and includes tests of abstract thinking, visual attention, response inhibition, and shifting of mental set (Tallis, 1997). Only in this latter category (i.e., shifting of mental set or the ability to choose an alternative strategy when the first is no longer effective) have there been consistent reports of differences between those with OCD and normal controls. However, these tests usually are timed, and again, the differences must be interpreted cautiously (see later).

Neuropsychological assessment has also addressed memory (also known as mnemonic) deficits, but again there is little consistency with respect to outcome. For example, Purcell and her colleagues (Purcell, Maruff, Kyrios, & Pantelis, 1998), using an extensive test battery, reported that patients with OCD had deficits only in spatial working memory, spatial recognition, and motor initiation and execution, particularly when there was increasing task difficulty. These differences were not affected by medication, clinical severity, or general levels of anxiety and depression. The deficits reflect an inability to develop a strategy to meet task demands and were similar to, but less severe than, those found in individuals with documented focal frontal lobe lesions. Interestingly, PET studies assessing brain activation for this type

of task in normal subjects implicated the dorso-lateral frontal cortex, an area identified as a possible site for psychosurgery for intractable OCD (Owen, Evans, & Petrides, 1996). Overall, Purcell et al. (1998) concluded that the pattern of cognitive deficits exhibited by OCD patients suggests a syndrome of frontal-subcortical dysfunction. However, another recent study that used a similar sample of adults with OCD found differences in cognitive processing that reflected involvement of the anterior cingulate but not the dorsolateral prefrontal circuit (Schmidtke, Schorb, Winkelmann, & Hohagen, 1998). Thus, these two recent studies using similar patient samples report very different results and illustrate the inconsistency in findings across the literature.

Tallis (1997) succinctly reviewed the neuropsychological assessment literature and reached a number of conclusions. First, some studies have not identified cognitive deficits in patients with OCD; however, those data are often discounted in favor of studies that show positive differences. Second, appropriate control groups are not always used, and when they are, deficits are apparent only when patients with OCD and normal controls are compared. Few differences emerge when other types of anxiety disorder patients constituted the control group. This suggests that differences found in comparison to normal control subjects reflect anxiety or general distress, rather than deficits specific to OCD. Third, Tallis (1997) argued that group differences based on timed tests should be discounted because "obsessional slowness" might also result from nonneurological factors such as intrusive cognitions or indecisiveness. When time penalties were excluded from analyses, performance differences between OCD patients and normal controls were substantially reduced (e.g., Christiansen, Kim, Dyksen, & Hoover, 1992). Fourth, memory deficits were most commonly documented, particularly memory related to visual and visuospatial functioning, and suggest basal ganglia involvement. Even if one hypothesizes that the checking behaviors in patients with OCD result from memory deficits, it does not explain why those who feel compelled to check do so selectively (e.g., locks, doorknobs or electrical appliances; Tallis, 1997). Furthermore, there is no documented relationship between memory deficit severity and clinical symptom severity in OCD patients, again suggesting that these deficits may be a correlate of, but not the cause of, OCD.

In summary, it is clear that some patients with OCD sometimes exhibit cognitive deficits. However, there is no consistent pattern of results, although deficits or abnormalities in frontal-striatal functioning are the most commonly implicated. Few studies have used clinical control groups, and thus it is unclear if reported deficits are specific to OCD or merely reflect an abnormal mood state. Furthermore, neuropsychological assessment does not indicate whether these deficits result from neuroanatomical structural or functional abnormalities. We now turn our attention to these studies.

Neuroanatomy

In this section, we will examine the long-term follow-up of psychosurgery for OCD patients in an attempt to understand neuroanatomical contributions to OCD. In addition, the results from recent sophisticated neuroimaging techniques will be presented.

Psychosurgery. One of the earliest associations between OCD and brain function is the use of psychosurgery to ameliorate intractable symptoms. Although not developed specifically for OCD, psychosurgery for this disorder has its roots in the initial prefrontal leukotomies first introduced by Moniz in the mid-1930s. Four different surgical procedures have been most commonly used: anterior cingulotomy, subcaudate tractotomy, limbic leukotomy, and anterior capsulotomy. The different operating procedures, their neuroanatomical basis, their effectiveness, and potential side effects are reviewed in detail by Chiocca and Martuza (1990). Briefly, anterior cingulotomy interrupts fibers in the cingulate bundle. This area is part of the Papez circuit which theoretically is linked to anxiety but not specific OCD symptoms. Anterior cingulotomy results in few side effects, and the treatment success rate is approximately 50%. A different surgical procedure, limbic leukotomy, with an 89% success rate, combines the production of lesions to the bilateral cingulate area (as in anterior cingulotomy) with lesions to the orbito-medial frontal areas. Neurons in these latter areas are believed critical in the formation of specific OCD symptoms (as opposed to general anxiety). The other two procedures, subcaudate tractotomy and anterior capsulotomy, have improvement rates that range from 50–70%, lower than for limbic leukotomy. Furthermore, as noted by Chiocca and Martuza (1990), these latter two procedures were

more likely than either anterior cingulotomy or limbic leukotomy to result in negative "personality changes" such as increased aggressiveness, lack of inhibition, hypomania, irritability, outspokenness, and emotional shallowness.

Several studies have reported long-term follow-up of patients treated with psychosurgery. Sachdev, Hay, and Cummig (1992) reported 10-year follow-up data for twenty-six patients who had surgical lesions involving the cingulate area, the bilateral orbitomedial cortex, or their combination. Consistent with the results presented by Chiocca and Martuza (1990), the cingulate lesion alone group was less improved at follow-up compared to those who had orbitomedial or combined cingulate and orbitomedial lesions. Again, this may suggest that cingulate lesion target sites are associated with general anxiety but not with specific OCD symptoms. In another follow-up study, Irle and her colleagues (Irle, Exner, Thielen, Weniger, & Ruther, 1998) evaluated sixteen patients who had received leukotomies during the 1970s. Patients had either ventromedial frontal lesions, ventral striatum plus ventromedial frontal lesions, or dorsally extended lesions (to isolate the precallosal part of the cingular gyrus) plus ventromedial frontal lesions. Those with frontostriatal lesions (i.e., subjects in one of the first two groups) were the most improved. Interestingly, those with OCD plus obsessive-compulsive personality disorder were the least improved. A substantial percentage of those with ventral striatum lesions developed substance abuse postoperatively, which led the authors to suggest that this area may be associated with addictive behaviors, although this suggestion involves a good deal of circular logic.

As noted by Sachdev et al. (1992), recent MRI scans of some of the surgical sites indicated that the original lesions missed their mark (e.g., the cingulate bundle). Similarly, among their follow-up sample, Jenike and Baer (1992) also reported MRI confirmation that not all of the original lesions were precisely placed. Although now MRI confirmation of the surgical site is obtained before initiating surgery, conclusions based on the currently available follow-up data must be interpreted cautiously. For example, is the procedure itself ineffective or are the lower success rates the result of inaccurate lesion placement? Obviously, controlled trials are not appropriate, but MRI technology will allow more accurate placement and in the future, help clarify this issue. Second, although

individuals may improve, the follow-up studies do not allow for a determination of the patients' final clinical status, that is, evaluation of improvement is based on percentage change on the Yale-Brown Obsessive Compulsive Inventory (Y-BOCS), but actual scale scores are not presented. Therefore, the findings are difficult to interpret because mere reporting of change scores does not allow determining whether the patient is still symptomatic. Relatedly, improvement ratings from the current long-term follow-up studies are based on changes in pre- and posttreatment scores, primarily using the Y-BOCS. However, many of the pretreatment ratings were made retrospectively and therefore are subject to all of the biases of this form of assessment. Third, there is indication of a circular argument in the conclusions that are drawn from these findings. For example, if a lesion at a particular site results in a decrease in activity, is that concrete evidence that this is the site of the disorder? There is evidence, for example, that those who have had psychosurgery have lower IQ scores and lower scores on the Wisconsin Card Sorting Test than those who have not undergone the procedure (Irle et al., 1998). In this case, psychosurgery results in a decrement in a broad range of purposeful behaviors and abilities, not just a decrease in OCD symptoms. A final issue that must be noted is that these surgical procedures typically are performed on only the most intractable cases, patients who do not respond to any other form of therapy. This suggests that these patients have the most complicated form of OCD and findings from this group do not necessarily represent the pathology of all patients with this disorder.

Structural Neuroanatomy. Structural imaging studies primarily use computerized tomography (CT) or magnetic resonance imaging (MRI). Compared to CT, MRI produces enhanced spatial resolution, better distinction between gray and white matter and greater visualization of neuroanatomic structures (Saxena et al., 1998). For example, three CT studies (Behar et al., 1984; Insel et al., 1983; Luxenberg et al., 1988) were negative for the presence of anatomical lesions, although Luxenberg et al. (1988) reported atrophy at the head of the caudate nucleus. However, MRI studies (Garber et al., 1989; Kellner et al., 1991) reported that the caudate nucleus of OCD patients appeared normal. Breiter et al. (1994) reported retrocallosal white matter abnormalities in six patients with OCD. Scarone et al. (1992) reported increased

right caudate volume in twenty treated patients with OCD, whereas Robinson et al. (1995) reported bilateral reduced mean caudate volumes using a sample of twenty-six patients with OCD. Aylward et al. (1996) examined caudate nucleus and putamen volumes of twenty-four adults with OCD and twenty-one control subjects using MRI. There were no differences between those with OCD and normal controls in any of the areas assessed. Finally, using the more powerful short echo ^1H magnetic resonance spectroscopy (^1H -MRS), Bartha et al. (1998) did not find reduced caudate volumes. There was evidence, however, of lower *N*-acetylaspartate levels (a brain metabolite whose decline might indicate a decrease in neuronal density) in the left corpus striatum, suggesting reduced neuronal density in this region, but the significance of this finding is unclear. As noted by Insel (1992) and Trivedi (1996), the results of CT and MRI studies do not consistently document structural brain abnormalities in patients with OCD who did not have a concurrent neurological disorder (Insel, 1992). Methodological variations across studies, variations in illness chronicity, and prior psychotropic medication use may contribute to the inconclusive data (Rosenberg & Keshavan, 1998). Because of the overall lack of positive findings, researchers have turned their attention to the possibility of abnormalities in neuroanatomical function, as opposed to structure.

Functional Neuroanatomy. In contrast to the lack of consistent findings using structural imaging techniques, there is a growing consistent literature on functional imaging. Functional imaging techniques use either single photon emission computed tomography (SPECT), positron emission tomography (PET), or functional MRI. SPECT and PET use trace amounts of ligands that are "labeled" with radiation-emitting isotopes that measure cerebral metabolism or cerebral blood flow (Saxena et al., 1998). This material is injected into the blood stream, and the PET or SPECT scanners detect the radiation that the isotopes emit, thereby quantifying their concentration in various brain regions. Because SPECT uses single photon emitters and the PET isotopes emit positrons and two gamma protons (i.e., PET uses a double rather than a single signal; see Saxena et al., 1998), PET has higher spatial resolution than SPECT. With respect to the activity being measured, in nonstarvation conditions, cerebral glu-

case is a highly sensitive indicator of cerebral function, and cerebral blood flow is highly correlated with glucose metabolism (Saxena et al., 1998). As with the biochemical and neuropharmacological studies, functional imaging assessments are usually conducted under one of three sets of conditions: symptomatic patients in a resting state, symptomatic patients under challenge conditions, and symptomatically improved patients (after treatment). With these caveats and conditions in mind, the results of functional imaging studies are examined here.

The majority of studies examined symptomatic patient samples under resting conditions. The series of studies by Baxter and his colleagues illustrate this approach. Baxter et al. (1987, 1988, 1989) assessed cerebral glucose metabolic rates in patients with OCD. Specific sample characteristics differed slightly across the three studies, but the results were fairly consistent. Those with OCD had increased F-fluorodeoxyglucose uptake (indicative of elevated metabolic rates) in the overall cerebral hemispheres, heads of the caudate nuclei, orbital gyri, and ratio of orbital gyrus relative to the ipsilateral hemisphere. Other studies reported increased perfusion in the prefrontal cortex and cingulate (Machlin et al., 1991) and increased normalized regional glucose metabolism in the right orbitofrontal cortex and left anterior frontal cortex (Nordahl et al., 1989). Rubin et al. (1992) reported elevated uptake in the dorsal parietal cortex, the left posterofrontal cortex, and the orbitofrontal cortex, whereas Swedo et al. (1989) reported decreased uptake in the head of the caudate nuclei and increased metabolic rates in the right prefrontal and left anterior cingulate regions. Furthermore, in this latter study, there was a significant relationship between metabolic activity and both state and trait measures of OCD and anxiety. As illustrated before and noted by Trivedi (1996), taken together, the results of resting studies suggest abnormal activity in the orbitofrontal cortex, anterior cingulate, and caudate nuclei.

A second functional imaging strategy assessed symptomatic OCD patients under challenge conditions. For example, Zohar and his colleagues (Zohar et al., 1989) assessed 10 OCD patients at rest, when exposed to actual "contamination," and during imaginal flooding. Compared to resting, there was increased regional cerebral blood flow (rCBF) only in the temporal region after

imaginal flooding, whereas there was a decrease in rCBF across a wide cortical area, including the temporal lobes, during *in vivo* exposure. Why these two forms of exposure, which are functionally equivalent with respect to treatment effects, should produce such different types of brain activity is unclear. Similarly, McGuire et al. (1994) used brief exposures to contaminants and found the urge to perform rituals increased rCBF in the orbitofrontal cortex, neostriatum, globus pallidus, and thalamus. Feelings of anxiety were related to increases in rCBF in the hippocampus and the posterior cingulate. Rauch et al. (1994) reported that, compared to resting, exposure to individually tailored stimuli resulted in increased rCBF in the right caudate nucleus, left anterior cingulate cortex, and the bilateral orbitofrontal cortex.

In addition to psychological challenges, pharmacological challenges such as *meta*-chlorophenylpiperazine (*m*-CPP) challenge have been used. Usually, *m*-CPP increases symptoms in OCD patients. In addition to confirming increases in OC symptoms, Hollander et al. (1991) reported an increase in rCBF, particularly in the frontal lobes following *m*-CPP challenge. In contrast, a study by Pian and his colleagues (Pian, Westenberg, Den Boer, De Bruin, & van Rijk, 1998) compared patients with OCD to healthy controls. In this case, *m*-CPP did not induce or exacerbate OC symptoms. In addition, rather than an increase in rCBF, there was a decrease in rCBF across various brain regions, including the cerebellum and whole brain, and in the frontal cortex, caudate nucleus, putamen, and thalamus. Thus, although the psychological challenge studies implicate the orbitofrontal cortex, anterior cingulate, striatum, and thalamus (Trivedi, 1996), the results of pharmacological challenges do not implicate any one particular area.

Finally, assessing patients with OCD after successful pharmacological or behavioral treatment, or optimally, pre- and post treatment, provides another approach to functional brain imaging studies. Studies that assess patients treated with MAOIs or SSRIs indicate that remediation of OCD symptoms also results in decreased regional cerebral blood flow or cerebral metabolism in the caudate nuclei, orbitofrontal cortex, medial-frontal cortex, cingulate cortex, thalamus, caudate nucleus, posterofrontal and dorsal parietal regions, right lateral temporal, and left posterior

thalamic regions (Baxter et al., 1988, 1992; Benkefalt et al., 1990; Hoehn-Saric et al., 1991; Perani et al., 1995; Rubin et al., 1995; Swedo et al., 1992; Trivedi, 1996). Similarly, PET scans of patients who successfully completed behavior therapy (flooding and response prevention) also indicated bilateral decreases in caudate glucose metabolic rates (Baxter et al., 1992). In addition, decreases were significantly greater in those who had a good, as opposed to a poor response (Schwartz, Stoessel, Baxter, Martin, & Phelps, 1996). Furthermore, when the patients from these latter two studies were combined, there were pretreatment significant correlations in glucose metabolic rates among the right orbital gyri, head of the caudate nucleus, and thalamus. At posttreatment, these correlation coefficients were no longer significant. The significance of this finding is that in samples of normal controls and patients with untreated unipolar depression, brain activity in these regions is not correlated. The fact that there is such a correlation among untreated patients with OCD "suggests that 'coupling' of activity among elements in this cortico-striato-thalamic circuit may be related to the expression of OCD symptoms" (Schwartz et al., 1996, p. 112). Using a different approach, Aylward et al. (1996) conducted a quantitative meta-analysis of the functional neuroimaging literature. The results indicated no consistent abnormalities of the caudate nucleus. These authors concluded that although theories of OCD suggest a dysfunction of the caudate nucleus, structural and functional MRI studies currently do not support this hypothesis. Trivedi (1996) concluded that, despite some discrepancies, the results of functional imaging studies implicate dysfunction in the prefrontal cortex, cingulate, and basal ganglia and that these neurocircuitry loops are hyperactive in OCD. Inconsistencies may be due to the use of different technologies, scanning environments, or methods for analyzing and comparing regions.

Insel (1992) also noted a number of other methodological and theoretical caveats that must be considered when interpreting these data. First, many of the studies use small sample sizes and make multiple comparisons, thereby increasing the experimental error rate. Second, there is the issue of anatomical ambiguity. For example, the orbitofrontal cortex is often defined somewhat differently by different investigators and although some of the areas represent contiguous regions

topographically, they also represent areas that are “cyboarchitecturally and functionally distinct” (Insel, 1992, p. 740). Furthermore, again there is the issue of epiphenomenon versus causality, that is, abnormality does not equal causality. Increases in metabolic activity in some areas of the brain may be compensating for decreased function in other areas, as is the case for neurodegenerative disorders (Insel, 1992).

In addition to these limitations, a close perusal of this literature requires even further consideration of these outcomes. In all of the studies mentioned, those with OCD were compared to individuals without a psychiatric disorder or in one case, patients with untreated mood disorders. Thus, an alternative interpretation for the findings is that the increased blood flow or glucose metabolism is not specific to OCD but may be the result of any type of psychological disorder, and in particular, an anxiety disorder. In a recent SPET (single photon emission tomography) study, Lucey et al. (1997) examined cerebral blood flow in patients with OCD, panic disorder with agoraphobia, posttraumatic stress disorder (PTSD), and normal controls. Those with OCD or PTSD had significantly higher rCBF but only in the bilateral superior frontal cortex and the right caudate nuclei. Whole brain blood flow correlated positively with anxiety but not with any specific disorder. These authors suggested that the similarities in blood flow between the OCD and PTSD groups were consistent with the shared cognitive symptomatology of these two groups (obsessive thinking, intrusive imagery). Another hypothesis is that they could represent groups with the most severe anxiety symptoms. Consistent with the latter hypothesis, because increased whole brain activity did not differ among the three anxiety groups, the most parsimonious explanation is that increased rCBF in certain brain regions is common across all of the anxiety groups. Thus, some elevations in brain activity reflect abnormal mood state and not necessarily a particular disorder. Only when appropriate comparison groups are used can conclusions about disorder specificity be made. Finally, it is important to remember that despite these sophisticated approaches, PET and SPECT basically assess ongoing biochemical activity in the brain, not the cause of a disorder (Baxter et al., 1988). Thus, the data from functional neuroimaging studies merely identify sites of abnormal cerebral activity and do not identify etiology.

A Neurodevelopmental Model of Obsessive-Compulsive Disorder?

Rosenberg and Keshavan (1998) recently tried to draw together these various literatures into a neurodevelopmental model of OCD. First, they noted that several lines of evidence suggest that OCD may result from a neurodevelopmental rather than a degenerative process: (1) a number of cases of OCD begin in childhood; (2) there is a similarity between many OCD rituals and “developmentally normal” childhood rituals; and (3) neurological soft signs present at the onset of the disorder do not show any exacerbation, even when OCD symptoms progress and increase in severity. Second, as noted from the data presented earlier, if there is a region of the brain involved in OCD, it is probably part of the ventral prefrontal cortical region (VPFC). Recall that this region has been identified from psychosurgery (e.g., Jenike & Baer, 1992) and functional neuroimaging studies (e.g., Baxter et al., 1988), as well as treatment response studies (e.g., Baxter et al., 1992). This zone is also connected to limbic structures in the cingulate and anterior lobes (Rosenberg & Keshavan, 1998). Importantly, developmental brain morphology studies indicate that there is substantial maturation in the brain cortex from birth up to about 20 years of age. To test their hypothesis, Rosenberg and Keshavan (1998) conducted an MRI study of twenty-one treatment-naïve pediatric outpatients with OCD and twenty-one normal control subjects. Those with OCD had significantly larger anterior cingulate volumes than normal control subjects but did not have differences in posterior cingulate, dorsolateral prefrontal cortex, amygdala, hippocampal, superior temporal gyral, or whole temporal lobe volumes. Additionally, there was a significant positive correlation between anterior cingulate volume and severity of obsessional, but not compulsive symptoms. Furthermore, there was a trend ($p = .055$) for a significant correlation between age and cingulate volumes among the control patients ($r = .45$), but not among the patients with OCD ($r = -.12$). Rosenberg and Keshavan (1998) suggested that the lack of correlation between age and anterior cingulate volumes in patients with OCD may represent a delay in the normal neuronal “pruning” process (i.e., the normal developmental reduction in the number of neuronal circuits), leading to larger caudate volumes and more neuronal cir-

uits. Because these circuits are involved in regulating purposive behaviors, abnormality in these circuits (as evidenced by dysplasia) could manifest itself clinically as an inability to regulate behavior or conversely, the production of excessive behaviors such as excessive washing or checking behaviors.

Although this is an interesting model, as the authors noted, it is not without its limitations. First, again the study is based on a small number of patients, and it is one of the few studies to date with a pediatric population. As illustrated throughout this chapter, initial positive findings are often followed by negative findings. Second, the relationship between age and anterior cingulate volume was a statistically significant trend but did not meet the traditional criterion for significance. One or two additional subjects could substantially affect the correlation coefficient. Thus, replicative studies are necessary before one can draw firm conclusions. Third, more sophisticated neuroimaging techniques such as PET are necessary to delineate the relationship more clearly between developmental neurochemical changes in serotonin and the neurobehavioral and functional neuroanatomic development in OCD (Rosenberg & Keshavan, 1998).

PANDAS

If there are no structural brain abnormalities, then what might cause abnormal brain functioning? Recently, there has been increased speculation that at least some children who develop obsessive-compulsive disorder may do so in response to an external pathogen (in this case β -hemolytic streptococcal infection). Studies of Sydenham's chorea, childhood onset OCD, and Tourette's syndrome isolated a subgroup of children with either OCD or Tourette's who had a symptom course marked by abrupt, dramatic exacerbations which were temporally related to β -hemolytic streptococcal infection (Swedo et al., 1997). Additional studies then identified a group of children whose first onset of OCD occurred after streptococcal infection. This group was identified by the term PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections; for a review, see Swedo et al., 1998). Several studies (Murphy et al. 1997; Swedo et al., 1997) identified an antigen marker (D8/17) which appears more frequently in children with PANDAS

or Sydenham's chorea compared to normal controls. Importantly, those with PANDAS did not have Sydenham's chorea, thus leading the authors to suggest that these two disorders may share a similar poststreptococcal autoimmunity. Although these findings are intriguing, it is important to recognize that even if PANDAS is associated with one form of OCD, it apparently accounts for only a small percentage of childhood OCD cases. For example, beginning by soliciting 270 children who had a sudden onset of symptomatology, fifty (18.5%) had PANDAS. However, even among that fifty, only ten (20%) had OCD only, whereas 16% had tics alone and the remainder of the sample (64%) had subclinical OCD and tics or OCD and tics. Therefore, this means that only 3% of those originally identified by this abrupt onset symptom picture had "classic" OCD. Furthermore, because the rate of streptococcal infection decreases dramatically after puberty, this explanation would not account for onsets of OCD that occur during adolescence and adulthood.

Summary of Biological Contributions

In summary, the conclusions that could be drawn from the current literature are remarkably similar to those drawn by Turner et al. (1985). In short, much of the current evidence regarding altered brain functioning in patients with OCD is conflictual. Although some data suggest that the ventral prefrontal cortical region is the most likely area that is involved, the evidence is far from overwhelming. As presented earlier, Tallis (1997) noted that a number of neuropsychological investigations have not found differences in those with OCD, but these negative studies are often discounted in favor of those finding group differences. Similarly, Aylward et al. (1996) did not find any consistent abnormalities of the caudate nucleus when meta-analytic procedures were used to analyze the available data. They noted that, although there might be a theoretical basis suggesting a dysfunction of the caudate nucleus, structural and functional MRI studies do not provide empirical support. The issue of a theoretical basis is important because in many instances, it appears that the biological assessment studies are not grounded in any theory explaining why abnormalities might be expected. Rather, much of the data generated appear to have been collected because of the availability of technology or proce-

dures rather than a clear theory-driven research program.

Another major issue is that even if specific abnormalities are identified, do these abnormalities represent activity specific to OCD, or do they merely reflect a general stress response? Certainly, the few studies that used clinical comparison groups did not identify any abnormalities specific to OCD. Furthermore, none of these data necessarily indicate a biological etiology for this disorder and, except for Rosenberg and Keshavan (1998) and perhaps Swedo et al. (1997), no one has yet addressed the question of what produces the altered or abnormal brain function. Even if the D8/17 antigen plays a role, PANDAS accounts for only a few cases of those who meet diagnostic criteria for OCD. In conclusion, it is clear that all of the data presented are fully consistent with the alternative proposal that these data represent epiphenomena, or correlates of this disorder and although biological structures and functions might be altered as a result of the disorder, the current database indicates that it is premature to refer to OCD as a neuropsychiatric disorder.

Cognitive Contributions

A second major development during the past 20 years was the emergence of cognitive theory as a theoretical explanation for anxiety disorders (Beck, Emery, & Greenberg, 1985). Just as there is no one behavioral theory, there are different cognitive conceptions of anxiety. However, the basic premise of all approaches is that emotional disorders develop from distorted and maladaptive thought processes and that treatment of anxiety states requires altering these dysfunctional thought processes. In many ways, the development of an effective treatment approach for OCD is one of the real success stories of this century. Although OCD had been a clearly identified syndrome for at least a century (e.g., Rachman, 1985), it remained the most retractable nonpsychotic mental disorder until the 1970s. During this decade, Victor Meyer described the successful treatment of OCD at Middlesex Hospital in London, relying on strategies rooted in the two-factor theory of learning (Mowrer, 1939) and findings from basic laboratory studies of avoidance learning. The success of this treatment approach, which has come to be known as response prevention and exposure (flooding), has been well documented and is considered the

standard psychological treatment at this time (Stanley & Turner, 1995).

It has been said that during the past 20 years or so, psychology has undergone a cognitive revolution, and the influence of cognitive approaches have heavily influenced clinical theorizing and treatment. Actually, it is somewhat surprising that it took so long for cognitive theories regarding OCD to develop because a major part of the phenomena of OCD is cognitive (i.e., obsessions). One explanation for the failure of cognitive theorists to address OCD might be the success of behavioral treatments. However, despite that success, clearly not all of those who suffer from OCD benefit from the treatment, and clearly there are major gaps in current behavioral conceptions of the disorder. One of the primary deficiencies of behavioral explanations of OCD is reliance on the equipotentiality principle, that is, all stimuli have the equal potential to be conditioned and capable of instigating the OCD syndrome. There is considerable evidence that this is not the case because certain types of stimuli are much more likely to serve this role than others. Salkovskis (1985) discussed these issues and concluded that behavioral theory was inadequate to account for the OCD syndrome, and although his critique of behavioral outcome data led him to a conclusion different from most others, it seems clear that there are major deficiencies in current behavioral theory regarding the nature of OCD. Although several theorists have proposed cognitive conceptualizations (e.g., Carr, 1974; McFall & Wollersheim, 1979), Salkovskis provided the most elaborate cognitive explanation, maintaining that treatment derived from this model should improve outcome for those suffering from OCD. We will examine this theory and then turn to an evaluation of treatment derived from this model.

As noted, Salkovskis (1985, 1996) proposed the most comprehensive cognitive theory of OCD, which begins with the premise that intrusive thoughts are everyday occurrences, experienced by almost everyone. In some individuals, the intrusive thoughts activate preexisting cognitive schemata, which in turn, evaluate the intrusive thoughts in a negative light (e.g., it is bad to have a thought about killing my spouse). In addition to appraising the thought as "bad," individuals believe that they have the "pivotal power" to bring about or prevent the negative consequences (i.e., killing the spouse). These beliefs and cognitive schemata generate distress that leads to efforts to

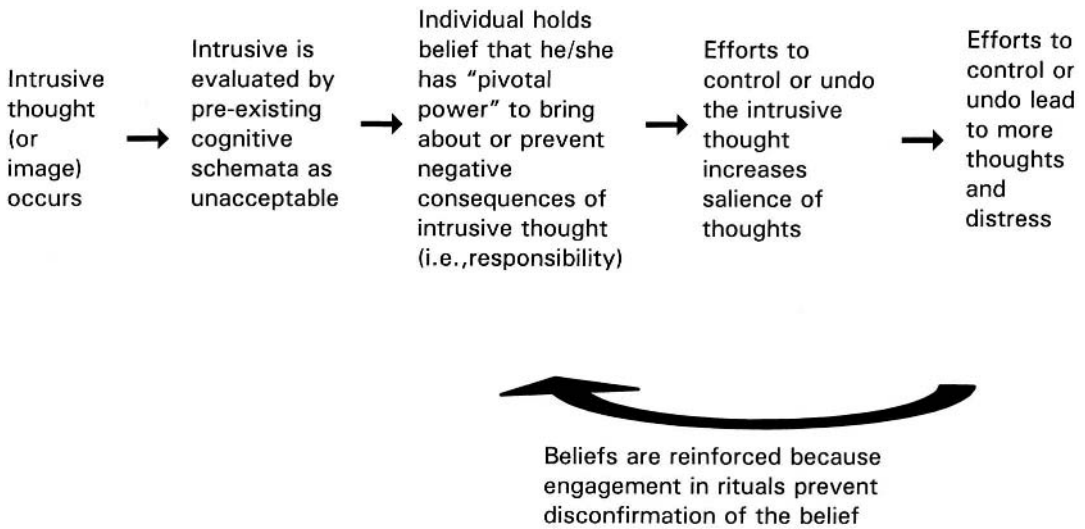

Figure 1. Salkovskis' cognitive model of OCD.

control or undo the thoughts (i.e., avoidance and ritualistic behavior) thereby (1) increasing their salience and frequency and (2) creating emotional distress. The theory also postulates a feedback loop; beliefs about "pivotal power" (i.e., responsibility) actually are reinforced because the rituals designed to eliminate the thoughts prevent disconfirmation of the responsibility beliefs. The theory is based on several basic assumptions to which we now turn our attention (see Fig. 1).

Everyday Intrusive Thoughts. The first, and perhaps the most crucial, premise is that obsessional thoughts are commonplace and are experienced by everyone; those with and without OCD. However, important questions surround the content and frequency of intrusive thoughts in individuals without OCD (or any type of emotional distress). In the earliest study that assessed form and content, Rachman and DeSilva (1978) reported that those without OCD endorse the presence of intrusive thoughts and that the intrusions are similar in form to abnormal obsessions. This basic conclusion has been consistently cited as evidence that normals and obsessional patients do not differ in experiencing intrusive cognitive phenomena. However, there are a number of questions regarding the nature of the data generated in this seminal study. For example, the sample was not random, and although the individuals were described as "normal people," no diagnostic interviews were conducted to screen out the presence

of psychological disorders. It is well known that samples of unselected participants often include those who suffer from numerous disorders. In this study, participants were given a list of intrusive thoughts and were asked (1) to indicate if they had experienced these thoughts and impulses, (2) how frequently they had the thoughts, and (3) whether they could be easily dismissed. However, it does not appear that these terms were further operationalized. Eighty percent of the respondents endorsed having either thoughts or images in the past month; 66% of that group reported that the thoughts occurred ten times per month or less. Stated differently, only 20% of this nonclinical sample reported intrusive thoughts as often as once per day. Similarly, only 9% of those reporting intrusive images reported their occurrence as often as once per day. Thus, although the form and content of these intrusive cognitive phenomena were endorsed by individuals who ostensibly did not have OCD, the frequency was substantially less than that found in those with the disorder.

It appears that as the results of this study have been cited in subsequent years, there has been a "drift" in the manner in which the outcome has been described. Rachman and DeSilva's (1976) outcome has been cited as evidence that "repetitive, intrusive thoughts" are common in normal populations, but considering the questions raised above, this conclusion might be premature. Indeed, recent studies (e.g., England & Dickerson,

1988; Freeston, Ladouceur, Thibodeau, & Gagnon, 1991, 1992) that are cited as supportive of the "normal, everyday" occurrence of intrusive thoughts actually do not examine the frequency with which these thoughts occur. For example, England and Dickerson (1988) described intrusions as repetitive, spontaneous thoughts and asked undergraduate students to identify the most memorable intrusive thought experienced in the past 2 weeks. However, no data were reported regarding the actual frequency of the identified thought and the instructions did not request the students to identify their most repetitive thought, only the most memorable one. Similarly, the studies by Freeston et al. (1991, 1992) also defined cognitive intrusions as repetitive phenomena. Yet, the data presented indicate that over a 1-month period, the frequency of "repetitive thoughts" averaged 4.5 occurrences. Thus, in this case, repetitive means one intrusive thought per week, which is far less than the definition of repetitive necessary for a diagnosis of OCD. Therefore, even if those without a disorder sometimes experience cognitive phenomena resembling the form and content of obsessions, the frequency and distress are substantially less. The issue of cognitive intrusions among those without OCD remains very much open and in our judgment, extant data call into question this critical component of the Salkovskis theory.

Evaluation of the Intrusive Thoughts as "Bad" Using Preexisting Cognitive Schemata. If one accepts the premise that cognitive intrusions are common in the general population, it is possible that what differentiates those with OCD is their negative evaluation of the thoughts, as Salkovskis theorizes. However, what is not clear from existing cognitive explanations is why some individuals apply negative evaluations, whereas others do not. Put another way, why is it that some people have "OCD schemata" and some do not? This is an issue for all of cognitive theory of emotional disorders and the premise seems to be that the cognitive schemata are pre-existing and dormant and are activated by the intrusive thoughts. Cognitive theorists have argued that such schemata are not "hard wired" but have failed to clearly articulate their origins.

Schemata May Include the Belief That One Has the "Pivotal Power" to Bring About or Prevent Negative Consequences. Within the cognitive framework, the negative automatic

thoughts are related to ideas of personal responsibility to produce OCD. The appraisal of personal responsibility is what produces OCD, rather than anxiety or depression. Again, as with the etiology of the cognitive schemata, the cognitive theorists are silent on the origins of this pivotal power belief. Despite this uncertainty about their origins, the issue of responsibility has received considerable attention in recent years, and studies have been conducted using both clinical and nonclinical samples.

With respect to clinical samples, Lopatka and Rachman (1995) examined how exposure to different levels of responsibility affected urges to check and the level of discomfort, using a within-subject design. Subjects were asked to encounter their most feared event. In the low responsibility condition, the subject was informed that the experimenter would take complete responsibility for any untoward event, would make any necessary reparations, and signed a statement to that effect. In the high responsibility condition, the patient had to sign a statement assuming full responsibility for any untoward event that occurred. Following this manipulation, the level of perceived responsibility was rated on a verbal analogue scale ranging from 0 to 100. Those in the low condition averaged 16.47 on the rating scale versus 90.17 for the high condition, suggesting that the manipulation was successful. When compared to the control condition, decreased feelings of responsibility were associated with decreased anxiety and urges to check. However, increased feelings of responsibility (over the control condition) did not produce statistically higher levels of anxiety and urges to check. Interestingly, the authors noted that the strong influence of reduced responsibility on decreased compulsive checking may not be replicable for compulsive cleaners. Interestingly, a similar conclusion was drawn by Rheaume, Ladouceur, Freeston, and Letarte (1995).

In another study of responsibility and OCD, Shafran (1997) used a modified between-subject design and manipulated the level of responsibility through the presence/absence of the experimenter when the subject was exposed to a feared stimulus. In the absence of the investigator, responsibility for the perceived threat while engaged in an exposure task was rated higher (60.9 on a scale of 0–100) than when the participant was in the presence of the experimenter (44.54). This difference, though statistically significant, did not produce the mag-

nitude of same group differences as the Lopatka and Rachman (1995) study, and it is not clear why the mere presence of the experimenter would be sufficient to change beliefs about responsibility. Those with trichotillomania or tics, for example, can often control their repetitive behavior when in the presence of others, but it would be difficult to accept that the reason for the control is that they turn over "responsibility" for their tics/hair pulling to others. Nevertheless, subjects in the high responsibility condition reported significantly more discomfort/anxiety, were more fearful that the consequences would happen, and had a significantly higher urge to perform the compulsion. However, there were no significant differences in ratings of responsibility for their thoughts or ratings of control over the threat. Furthermore, the correlation between perceived responsibility and the urge to neutralize was $r = .42$ for the high responsibility condition and $r = .38$ for the low responsibility condition. Although not tested statistically, it is unlikely that these correlations are significantly different. Finally, this study did not find differences in responsibility based on type of compulsion; however, subsample sizes consisted of fourteen checkers and eight cleaners, and thus, there may have been insufficient power to determine group differences.

Most of the studies of responsibility have used nonclinical (i.e., undergraduate student) populations. Ladouceur et al. (1995) randomly assigned participants to high and low responsibility conditions and had them perform a sound recognition task. In a replicative sample, a manual classification task was used. In the high responsibility condition, subjects were told that their responses were very important because they would be used by an insurance company (experiment one) or a pharmaceutical company (replicative sample) and could significantly impact the health and safety of others. In both tasks, the manipulation was judged successful. Those in the high responsibility group reported more anxiety during the tasks. However, only in the manual classification task did participants also check more often and report more preoccupation with errors. One problem with the interpretation of this study is that the authors did not discuss why the manipulation was successful in one instance but not the other. Thus, the results must be considered equivocal.

In a similar study, Ladouceur et al. (1997) noted that Salkovskis' definition of responsibility in-

cludes both the constructs of pivotal power and potential negative consequences. Therefore, in an effort to examine the influence of these two variables more closely, the authors created four combinations of perceived influence and negative consequences. Then, each group engaged in a sorting task. In the high negative consequences, high influence condition, subjects were told that their role was crucial to the project's success and their results would be decisive and directly influential. In the high influence only condition, subjects were told that they were part of a small sample and their results would directly influence the project but that consequences would be minimal. In the high negative consequences only condition, subjects were told that there were high negative consequences but their direct influence was minimal because 2000 people were included in the sample. Subjects in the fourth condition were told that they were part of a large group and the consequences were minimal. The manipulation was successful in that the four groups varied significantly in the independent variable ratings of perceived influence and negative consequences. Only when there were both high levels of perceived influence and negative consequences did the subjects perceive themselves as more responsible, endorse more doubt, and were more preoccupied with errors, suggesting that both variables (influence and negative consequences) were necessary for an inflated sense of responsibility.

Two other studies directly attempted to assess the responsibility definition put forth by cognitive theorists. Rheaume et al. (1995) examined Salkovskis' definition (responsibility is the belief that one possesses pivotal power to provoke or prevent subjective crucial negative outcomes). Using fourteen situations relevant to OCD patients and non-clinical samples, participants rated possible negative outcomes in terms of severity, probability, personal influence, pivotal influence, and responsibility. Ratings of personal influence and pivotal influence were highly correlated with ratings of responsibility, whereas correlations of ratings of severity and probability of outcome were only weakly and moderately correlated, respectively. The findings were generally replicated in a second sample and may be interpreted to indicate that the definition of responsibility may be reduced to whether or not individuals perceive that they have the power to control the events.

In the strongest study that examined the rela-

tionship of responsibility to OCD, Rachman and his colleagues (Rachman, Thordarson, Shafran, & Woody, 1995) developed a reliable self-report scale (the Responsibility Appraisal Questionnaire; RAQ). Unlike previous investigations, care was taken to develop a responsibility scale that was free of OCD-related items. Thus, the scale assessed five content areas: responsibility for property damage, responsibility for physical harm to others, responsibility in social contexts, positive outlook for responsibility, and thought-action fusion (TAF). The results indicated that only the TAF subscale was associated with measures of responsibility. When RAQ scores of those with high levels of obsessionality were compared to the rest of the sample, again only scores on the TAF subscale differentiated the groups. As noted by these authors, the results indicate that the original view of inflated responsibility in OCD patients requires revision. Feelings of broad overresponsibility were not substantiated. In fact, in contrast to cognitive theories, these authors noted that there does not appear to be a unitary factor of responsibility. The inflated responsibility associated with obsessions is situation-specific, idiosyncratically connected primarily to checking behaviors, and does not preclude that an individual with OCD may easily accept other forms of responsibility.

Belief in Pivotal Power Leads to Efforts to Control or Undo the Thoughts and Creates Emotional Distress. Returning to the tenets of cognitive theory, one of the loopholes in the cognitive explanation of OCD is that if individuals believe that they have the power of prevention, why should the mere thought of such an event elicit such negative distress and produce rituals? Why do reassuring thoughts counteract the negative thought? In other words, why does the negative thought, coupled with a belief in personal power to prevent the event, still result in the levels of distress commonly seen in OCD patients? According to O'Kearny (1998), the Salkovskis theory needs some revision because it disregards Rachman's (1993) thought-action fusion concept as a component of responsibility. With respect to the latter, those with OCD consider thinking about an unacceptable behavior as the equivalent of carrying it out. Those with OCD often describe feeling that thinking about the behavior is the same as actually committing the behavior and that the feelings of responsibility extend to having the thoughts in addition to actually committing the act. Simply

put, those with OCD often confuse having the thought about an abhorrent behavior with actually carrying out the behavior and are distressed by the occurrence of the thought. According to O'Kearny (1998), it is only if this thought-action fusion is included will cognitive theories provide an appropriate cognitive explanation of OCD.

Efforts to Control or Undo Increase the Salience of Thoughts and Result in More Thoughts and Distress. A comprehensive review of this aspect of the theory is beyond the scope of this chapter but is provided by O'Kearny (1998). As one example, laboratory studies of the paradoxical effects of controlling or suppressing thoughts reveals that there is an increased frequency of a thought when an attempt is made to suppress it. However, subjects in these studies do not report volitional disturbances or compulsions. To summarize this discussion, cognitive theory, like every other theory of OCD, must account for the apparent failure of the patient's ability to neutralize the intrusive thought as evidenced by the repetitious and compulsive qualities of the behavior. Cognitive theory fails to do so because it does not recognize the importance of self-doubt and ambivalence. By focusing exclusively on cognitions, it fails to recognize the affective and motivational bases of the disorder. The premise of all cognitive theories (including Salkovskis') is that initial intrusive thoughts are emotionally neutral but, as noted by O'Kearny (1998), the content almost always has to do with harm happening to another or oneself. O'Kearny (1998) identified the absence of an account of affect as a major deficiency of the theory. In short, this argument returns, once again, to the age-old argument of the prominence of cognition versus affect.

One recent study provides support for the notion that any theory of OCD will need to account for the variable of affect. Scarrbelotti, Duck, and Dickerson (1995) examined the impact of extraversion, neuroticism, psychoticism, and responsibility in predicting discomfort from obsessions and compulsions. The results indicated that, among undergraduate students, the more emotionally labile (i.e., neurotic) and responsible a person is, the more likely that person is to be distressed by obsessions and compulsions. These findings point to characteristics of the individual outside of the cognitive dimensions that are apparently important. Although this study does not determine whether emotionality or cognition "came first," it

is clear that affect, in addition to cognition, is necessary to explain the distress experienced by those with obsessions and compulsions and attempts to foster a purely cognitive explanation are likely to fall short.

Treatment Based on Cognitive Theories

We mentioned earlier that treatments based on a behavioral conception have resulted in remarkably positive outcomes. In recent years, positive outcomes for cognitive strategies have been reported but supportive empirical data often are lacking. Several authors (Freeston, Rheaume, & Ladouceur, 1996; van Oppen & Arntz, 1984) described how traditional cognitive strategies such as disputing catastrophic and responsibility beliefs by examining their rational basis or by using behavioral experiments could be used to treat OCD. Similarly, Shafran and Somers (1998) described two cases of "cognitive intervention" for adolescents with OCD. The therapist explained to the patient that attempting to suppress thoughts often led to an increase in thoughts, just as trying not to think of a "white bear" produced images of a white bear. It was reported that patients understood the connection to their own attempts to suppress their intrusive obsessions and that being provided with an alternative, benign explanation for the significance of intrusive thoughts resulted in "marked" or "excellent" improvement (not further defined), although it appears that in at least one of the cases, behavioral interventions also were used.

There are few studies where the effectiveness of cognitive therapy for OCD has been examined empirically. In the earliest studies, Emmelkamp and his colleagues (Emmelkamp, Visser, & Hoekstra, 1988; Emmelkamp & Beens, 1991) compared Rational Emotive Therapy (RET) with self-controlled exposure *in vivo*. Furthermore, in the 1991 study, all subjects later received exposure *in vivo*. The results indicated that both interventions produced improvement in self-report measures of affect and OCD symptoms. Improvement was maintained at a 6-month follow-up, and there were no significant differences between the groups. However, inasmuch as RET includes behavioral procedures, it is impossible to untangle exactly what the effective components were.

More recent studies attempted to apply cognitive interventions that do not include behavioral procedures such as exposure. Ladouceur and his

colleagues (Ladouceur, Leger, Rheaume, & Dube, 1996) used a multiple baseline design to evaluate "pure" cognitive therapy (e.g., identification and correction of automatic thoughts and development of adequate perceptions or responsibility) to treat four OCD patients with checking rituals. No exposure or response prevention procedures were used. Up to thirty-two treatment sessions were used and at posttreatment, Y-BOCS scores were decreased by 52–100%, and gains were maintained at 12-month follow-up for two of the four patients. The other two had some relapse, although only one required additional treatment in the form of traditional behavior therapy. Jones and Menzies (1998) treated eleven patients with washing/contamination rituals using a procedure called danger ideation reduction therapy (DIRT), which was directed solely at decreasing danger-related expectancies and did not include behavioral procedures. Compared to a wait list control group, those treated with DIRT had significant decreases in several self-report inventories of affect and OCD symptoms, although examination of actual raw scores revealed that the changes were quite minimal in clinical significance. In the only large, randomized trial, seventy-one patients were randomized to either cognitive therapy or self-controlled exposure *in vivo* (van Oppen, de Haan, van Balkom, Spinhoven, et al., 1995). Both groups evidenced significant improvement. Finally, two recent reviews (James & Blackburn, 1995; Sica, 1998) and one meta-analysis (van Balkom et al., 1994) all suggest that it is premature to draw conclusions about the efficacy of cognitive interventions (without the inclusion of behavioral procedures) for treating OCD. Thus, although there is much enthusiasm for using cognitive interventions to treat OCD, at the present time empirical data are lacking.

In summary, it was noted in the biological section of this chapter that patients with OCD do not appear to have basic cognitive deficits. In this section, cognitive theories of OCD were examined and the cognitive phenomena that are part of this disorder were highlighted. Interest in the cognitive aspects of this disorder has resulted in the creation of an Obsessive Compulsive Cognitions Working Group (1997). Although their concept is not a cognitive theory, this group has put forth the following conceptualization regarding cognitive phenomena. First, there are three levels of cognitions: intrusions, appraisals, and assumptions or beliefs. Appraisals are involved in perceiving

threat, and different levels of assumptions interact with one another and influence the contents and processes of appraisal. Thus, appraisals are defined in part from one's beliefs. Second, there are seven belief domains relevant to OCD: inflated responsibility, overimportance of thoughts, beliefs about the importance of controlling thoughts, overestimation of threat, intolerance of uncertainty, perfectionism, and fixity of beliefs (overvalued ideation). Like the cognitive theories that have been proposed, this statement of cognitive phenomena does not explain the etiology of the disorder. However, it does provide the basis for a series of testable hypotheses that might further understanding of this disorder. Furthermore, although there is widespread acceptance that cognitive interventions alone are useful for OCD, to date few controlled, randomized group trials have examined this issue. Thus, final conclusions on the usefulness of these procedures, either alone or in combination with traditional behavioral procedures, await further investigation.

Conclusions

Descriptions of OCD have remained remarkably consistent throughout the years with very little variation in the various iterations of the DSM. Indeed, as discussed here, there have been no significant empirical findings to alter the basic way in which OCD has been defined since its description in DSM-III. However, recent studies have raised important questions in need of further study, and some of these were discussed. These include the concept of overvalued ideation, the possible importance of symptom subtyping, and the issue of subclassification schemes. Studies that address these issues could reveal information important for the way we think about the psychopathology of the condition as well as for the way treatment is conceptualized.

The issue of comorbidity of mental disorders is critical for the field because the presence of high overlap of symptoms and syndromes raises interesting questions regarding the nature of mental disorders but also the adequacy of our current diagnostic system of categorical disorders. Overlapping anxiety symptoms and syndromes are commonplace among the anxiety disorders, including OCD. Of particular interest in OCD is the controversial concept of OCD Spectrum Disorder,

the suggestion that a number of disorders share the basic ingredient of obsessionality. Although the relationship between OCD and many of the disorders discussed in this regard seems less than compelling, its relationship to others (e.g., Tourette's Syndrome, Somatoform Disorders) rests on a stronger empirical foundation. Here, too, however, despite symptom similarity, important differences exist. Hence, based on the current empirical literature, it is somewhat premature to think of OCD as a spectrum of disorders.

The past two decades have been marked by a resurgence of interest in the biology of mental illness. Similarly, within psychology, cognitive approaches to understanding and treating emotional disorders have been prominent. With respect to biology, there has been intense study, but to date there has been no clear delineation of the pathophysiology of the disorder. At this juncture, the findings are disparate and do not cohere meaningfully or provide insight into possible biological mechanisms of OCD. The most consistent findings are that serotonin plays some role and the portion of the brain most likely involved is the orbitofrontal cortex. Yet, even findings in these areas are not consistent, and there is no clear indication as to whether serotonin is involved in the etiology of OCD or whether the noted anomalies are secondary effects of some other disordered system. Similar conclusions pertain to abnormalities of the orbitofrontal cortex. In our view, one reason for the lack of progress in this area is that much of the research has taken place outside the context of cohesive biological theories. Much of the research has emerged from the availability of new technology (e.g., PET) or as the result of sweeping attempts to find relevant biological variables. Our understanding of the basic biological underpinnings of OCD are not likely to be revealed until more systematic theory-driven studies are conducted.

Cognitive research in OCD has been very similar to biological research. That is to say, very little has been based on cognitive theory rooted in basic cognitive science. The only cognitive explanation of OCD that approaches the formality of a theory is that of Sakovskis. As was discussed here, this explanation falls short of providing a full explanation of OCD, and there is a lack of unequivocal empirical support for its basic premises. Furthermore, there is no evidence that treatments that embody cognitive principles improve outcome

above that of response prevention and flooding (James & Blackburn, 1995; Sica, 1998).

Overall, we must conclude that recent biological and cognitive research have not significantly improved our understanding of the phenomenology, etiology, or treatment of OCD. Although it is true that pharmacological treatment using selective serotonin inhibitors produces positive treatment outcomes in OCD, it is not more effective than response prevention and flooding, and it has a considerably higher relapse rate. Thus, response prevention and flooding remain the treatment of choice for OCD (Stanley & Turner, 1995).

Posttraumatic Stress Disorder

John A. Fairbank, Lori Ebert, and Juesta M. Caddell

Traumatic Experiences

In the field of mental health, the word “trauma” generally connotes a wide range of intensely stressful experiences that involve exposure to levels of danger and fear that exceed normal capacity to cope (Brett, 1993; Kleber & Brom, 1992; van der Hart, Brown, & van der Kolk, 1995). In the DSM-III (American Psychiatric Association, 1980) and DSM-III-R (American Psychiatric Association, 1987), the American Psychiatric Association (APA) defined trauma as an event that is “outside the range of usual human experience” and likely to “evoke significant symptoms of distress in most people.” The DSM-III/III-R definitions of trauma were based on the notion that most people exposed to catastrophic, but presumably uncommon, events such as rape, war, torture, or natural disaster would be likely to show signs and symptoms of serious psychological distress. However, subsequent research on the prevalence of exposure to potentially traumatic events in the general population showed that exposure to such events is much more common than assumed. Indeed, a majority of adults experiences at least one potentially traumatic event over the course of a lifetime (Breslau, Davis, Andreski, & Peterson,

1991; Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). Furthermore, research clearly shows that the majority of persons exposed to such experiences does not develop significant symptoms of psychological distress or impairments in their everyday functioning. Clearly, the DSM-III/III-R conceptualization of trauma as an unusual rare event that would elicit extreme distress in most people begged reconsideration.

Current Diagnostic Criteria for Posttraumatic Stress Disorder

With the publication of the 4th edition of the DSM (DSM-IV; APA, 1994), the concept of trauma evolved from focusing on uncommon, highly adverse, external events to describing the specific characteristics of a traumatic event, including the individual’s psychological response to the event regardless of whether the event is rare or common. Specifically, the DSM-IV definition of a traumatic event has two criteria: the first is that a person “experienced, witnessed or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others,” and the second is that “the person’s response involved intense fear, helplessness, or horror” (APA, 1994, pp. 427–428).

Although exposure to a stressful event is an indispensable condition, exposure alone is insufficient for determining whether the experience is traumatic. In DSM-IV, the critical determinant is the person’s cognitive and affective reactivity to an event. Therefore, if an event, such as a motor

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

vehicle accident, involves “actual or threatened death or serious injury ... to self or others” (APA, 1994, p. 427) and also elicits severe and incapacitating psychological distress such as “intense fear, helplessness, or horror” (APA, 1994, p. 428), the experience is traumatic. Studies of extreme situations have shown that in some individuals exposed to the most severe events, serious psychopathology develops, including but not limited to posttraumatic stress disorder (PTSD) (Dohrenwend, 1998). Indeed, traumatic experiences can lead to the development of several different disorders, including major depression, specific phobias, panic disorder, disorders of extreme stress not otherwise specified (DESNOS), personality disorders such as borderline personality disorder, and a range of physical symptoms, as well as PTSD (Foa, Keane, & Friedman, *in press*; Hyams, Wignall, & Roswell, 1996). Although it is important to understand the range of potential syndromes and disorders associated with traumatic experiences, the focus of this chapter is to review and synthesize the epidemiologic and clinical research that examines the nature, assessment, and treatment of PTSD, specifically.

The symptoms that characterize PTSD include distressing thoughts, feelings, and images that recapitulate the traumatic event, avoidance of stimuli associated with the event, emotional numbing of responsiveness, and a collection of symptoms that represent a persistent increase in stress and arousal (Keane, Weathers, & Foa, *in press*). The duration of the disturbance is longer than one month and “causes clinically significant distress or impairment in occupational, social, and other areas of functioning” (APA, 1994).

Specifically, PTSD is characterized by reexperiencing symptoms that include (1) recurrent and intrusive distressing recollections of the event, (2) recurrent distressing dreams of the event, (3) acting or feeling as if the event were recurring, (4) intense psychological distress at exposure to cues that symbolize the event, and (5) physiological reactivity to reminders of the experience. PTSD also involves persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness. Symptoms of avoidance and emotional numbing can include (1) efforts to avoid thoughts, feelings, or conversations about the event; (2) efforts to avoid activities, places or people associated with the trauma; (3) an inability to recall important details of the trauma; (4) a

markedly diminished interest in formerly important activities; (5) a feeling of detachment or estrangement from other people; (6) a restricted range of affect; and (7) a sense of a shortened future. Symptoms of arousal that were not present before the traumatic event are also a component of the PTSD symptom profile. PTSD arousal symptoms can include (1) insomnia, (2) irritability or anger outbursts, (3) difficulty concentrating, (4) hypervigilance, and (5) an exaggerated and distressing startle response.

Epidemiology

Epidemiology is the study of patterns and correlates of disease onset and course in human populations. Psychiatric epidemiology includes studies of the prevalence of psychiatric disorders (i.e., how many people have specific disorders), the distribution of disorders among subgroups of populations, the relationship of a particular disorder to other disorders, and factors that affect the onset and course of a disorder. In the following sections, we review findings addressing (1) the frequency of exposure to potentially traumatic events, (2) the prevalence of PTSD, (3) putative risk factors for PTSD, and (4) the comorbidity of PTSD with other mental and physical health problems.

Exposure to Traumatic Events

Posttraumatic stress disorder is unusual in the psychiatric nosology in that it ascribes etiological significance to a particular type of life experience—exposure to a traumatic event. Although such experiences were once considered rare (i.e., “outside the range of normal human experience;” see DSM III-R, APA, 1987), epidemiologic studies conducted in the United States suggest that the majority of Americans will experience a potentially traumatic event at least once in their lives. In the National Comorbidity Study (NCS; Kessler et al., 1995), a survey interview of psychiatric disorder administered to a probability sample of persons aged 15 to 54 years in the noninstitutionalized civilian population living in the 48 contiguous United States and the first nationally representative general population survey to assess traumatic stressor exposure and PTSD, 60.7% of men and 51.2% of women reported exposure to a potentially traumatic event. Moreover, most NCS par-

ticipants who indicated that they had experienced one potential trauma reported experiencing two or more types of trauma. In the NCS, which used DSM-III-R criteria for trauma exposure and PTSD, the most frequently identified types of trauma were witnessing someone being badly injured or killed (35.6% of men and 14.5% of women); involvement in a fire, flood, or natural disaster (18.9% of men and 15.2% of women); and involvement in a life-threatening accident (25% of men and 13.8% of women). Using a DSM-IV definition of traumatic events, a recent survey found that the unexpected death of a loved one was the most frequently reported trauma in a random sample of 18- to 45-year-old Detroit residents (Breslau et al., 1998).

Research suggests that the types of potentially traumatic events men and women experience may differ. For example, in the NCS (Kessler et al., 1995), men were more likely than women to report witnessing injury or death, involvement in a natural disaster or life-threatening accident, involvement in a physical attack, and combat exposure. Women were more likely to report having experienced rape, sexual molestation, and childhood physical abuse. Consistent with these results, findings from a national survey of adult women in the United States, the National Women's Study (NWS; Resnick, Kilpatrick, Dansky, Saunders, & Best, 1993), indicated that 12.7% of participants had experienced a completed rape, 14.3% had experienced molestation or attempted sexual assault, and 10.3% had been physically assaulted. Nearly 30% of rapes reported in the NWS occurred before age 11, and approximately two-thirds occurred before age 18.

Epidemiologic studies have identified various risk factors for exposure to potentially traumatic events. As suggested by findings from the NCS (Kessler et al., 1995) and substantiated by a sizable body of research (e.g., Breslau et al., 1998; Kilpatrick, Resnick, Saunders, & Best, 1998), past exposure to potentially traumatic events confers increased risk of future exposure to such events. In a prospective epidemiologic study of 21- to 30-year-old members of a health maintenance organization, persons who had a history of traumatic stressor exposure at baseline were nearly twice as likely to report an additional trauma during the 3-year follow-up (Breslau, Davis, & Andreski, 1995). Exposure to traumatic stressors also varies with age, socioeconomic status, psychiatric his-

tory, substance use, personality characteristics, family history of psychiatric disorder and substance use problems, and geographic location (Adler et al., 1994; Breslau et al., 1991; Breslau et al., 1995; Breslau et al., 1998; Bromet, Sonnega, & Kessler, 1998; Norris, 1992). For example, a 1993 report by the International Federation of Red Cross and Red Crescent Societies found that in the period from 1967 to 1991, disasters affected people in developing countries as compared with developed countries at a ratio of more than 150 to 1 (International Federation of Red Cross and Red Crescent Societies, 1993).

Epidemiologic studies also have examined the prevalence of exposure to potentially traumatic events among children and adolescents; the majority of these studies assessed physical victimization, sexual victimization, or exposure to community violence. A telephone survey of a nationally representative sample of 2000 10- to 16-year-old children found that more than 40% reported at least one experience that could be categorized as violent victimization (Boney-McCoy & Finkelhor, 1995). Consistent with these findings, Kilpatrick, Saunders, and Resnick (1998) estimated the lifetime prevalence of exposure to sexual assault, physical assault, and witnessing violence as 8%, 17%, and 39%, respectively, in a national sample of 12- to 17-year-old adolescents. In addition, a number of school surveys evaluated rates of exposure to community violence. In one sample of more than 500 Black elementary and middle school students in Chicago, 30% said they had witnessed a stabbing, and 26% reported that they had seen someone being shot (Bell & Jenkins, 1993). Another survey of 2248 students in the sixth to eighth and tenth grades in an urban public school system found that 41% reported witnessing a stabbing or shooting in the past year (Schwab-Stone et al., 1995). Another survey of 3735 high school students in six schools in Ohio and Colorado found relatively high rates of exposure to violence within the past year that varied by size and location of the school (Singer, Anglin, Song, & Lunghofer, 1995). Among male adolescents, 3% to 22% reported being beaten or mugged in their own neighborhoods, 3% to 33% reported being shot at or shot, and 6% to 16% reported being attacked with a knife. Reported rates of most types of victimization were lower for adolescent females than males; however, more females reported sexual abuse or assault. Although a number

of studies reported PTSD prevalence estimates among youths exposed to specific types of traumatic events, we were unable to identify any general population studies of PTSD prevalence among children and adolescents in the scientific literature. Thus, the remainder of this review of the epidemiology of PTSD focuses on PTSD in adults.

Prevalence of PTSD

Epidemiologic studies conducted over the past two decades provided empirical information about the prevalence of PTSD in the general population and among individuals who have been exposed to specific types of potentially traumatic events. This research indicates that most individuals who are exposed to a potential trauma do not develop PTSD. However, this research also suggests that the likelihood of developing PTSD following traumatic stressor exposure varies with the type of trauma experienced. Additional factors that affect people's risk of developing PTSD following traumatic stressor exposure are discussed in a subsequent section.

Estimates of the lifetime prevalence of PTSD from surveys of the general adult population in the United States have ranged from 1.0% to 12.3%. The two earliest community studies of the prevalence of PTSD were carried out as part of the Epidemiologic Catchment Area (ECA) program. Using DSM-III criteria as operationalized in the Diagnostic Interview Schedule (DIS; Robins, Helzer, Cottler, & Golding, 1988), these studies reported lifetime prevalence estimates for PTSD of 1.0% in metropolitan St. Louis (Helzer, Robins, & McEvoy, 1987) and 1.3% in the Piedmont region of North Carolina (Davidson, Hughes, Blazer, & George, 1991). More recent surveys have found substantially higher rates of PTSD in the general population. The NCS, which also used a version of the DIS to assess PTSD, estimated a lifetime prevalence of DSM-III-R PTSD of 7.8% among persons ages 15 to 54 in the United States (Kessler et al., 1995); the estimated current (30-day) prevalence of PTSD in the NCS was 2.8%. Using the DIS-IV (Robins, Cottler, Bucholz, & Compton, 1995), Breslau et al. (1998) estimated the conditional risk of PTSD following exposure to any traumatic stressor at 9.2% in their Detroit sample. It has been postulated that a number of factors account for variations in PTSD prevalence estimates in these and other studies, including differ-

ences in (1) diagnostic criteria, (2) the measurement approach used to ascertain exposure and assess PTSD, and (3) the demographic characteristics and representativeness of the study populations (e.g., Acierno, Kilpatrick, & Resnick, 1999; Kessler et al., 1995).

The risk of developing PTSD following exposure to a potentially traumatic event also varies with the nature of the exposure. In the NCS, the trauma most likely to be associated with PTSD was rape; 65% of men and 45.9% of women who identified rape as their most upsetting trauma developed PTSD. In contrast, among NCS respondents who identified a natural disaster or fire as their most upsetting trauma, only 3.7% of men and 5.4% of women met lifetime diagnostic criteria for PTSD. In addition to rape, other most upsetting traumas associated with a comparatively high risk of PTSD in the NCS were combat exposure, childhood neglect, and childhood physical abuse among men (probabilities of lifetime PTSD were 38.8%, 23.9%, and 22.3%, respectively) and sexual molestation, physical attack, being threatened with a weapon, and childhood physical abuse among women (probabilities of lifetime PTSD of 26.5%, 21.3%, 32.6%, and 48.5%, respectively). Consistent with these findings, in the NWS (Resnick et al., 1993), women who had experienced interpersonal violence (i.e., physical assault, sexual assault, or the homicide of a close friend or relative) were more than twice as likely to meet criteria for lifetime (25.8%) and current (9.4%) PTSD than women who reported noncrime stressors only. (PTSD rates in this subgroup were 9.7% lifetime and 3.4% current). Similarly, Breslau et al. (1998) found that among the men and women in their sample who reported exposure to a potential trauma, the highest conditional risk of PTSD (21.9%) was associated with the experience of assaultive violence.

Epidemiologic studies of PTSD often have assessed at-risk groups of individuals who have experienced a specific type of trauma, such as veterans of armed conflicts (Goldberg, True, Eisen, & Henderson, 1990; Kulka et al., 1990; Solomon, Weisenberg, Schwarzwald, & Mikulciner, 1987; Sutker, Uddo, Brailey, & Allain, 1993), internally displaced persons and refugees (Sack et al., 1995; Steel, Silove, Bird, McGorry, & Mohan, 1999), and victims of a range of criminal acts, including sexual assault (Saunders, Kilpatrick, Hanson, Resnick, & Walker, 1999), terrorist attacks (Aben-

haim, Dab, & Salmi, 1999; North et al., 1999), and torture (Basoglu et al., 1997). Although it was largely through observing the postwar experiences of soldiers engaged in combat that the syndrome known as PTSD was recognized, PTSD was not broadly or systematically studied among war veterans until the Vietnam War. Study of PTSD among Vietnam veterans was facilitated by publication of DSM-III (APA, 1980) that included PTSD as a diagnostic category defined by specific behavioral criteria. To date, the most comprehensive examination of the prevalence of PTSD among Vietnam veterans comes from the 1989 National Vietnam Veterans Readjustment Study (NVVRS; Kulka et al., 1990), a congressionally mandated, community epidemiologic study of the prevalence of PTSD and other postwar psychological problems among veterans who served in the Vietnam theater of operations. Findings from the NVVRS indicated that 15.2% of men and 8.5% of women who served in Vietnam had "current" PTSD (i.e., met DSM-III-R criteria for PTSD during the 6 months before the study interview). By contrast, the current PTSD prevalence among a matched (for age and race/ethnicity) sample of military veterans who did not serve in Vietnam was 2.5% among men and 1.1% among women; for non-veterans, current PTSD prevalence was 1.2% among men and 0.3% among women. The NVVRS reported lifetime PTSD prevalence rates among Vietnam veterans of 30.9% for men and 26.9% for women. Findings from other major epidemiologic studies of the prevalence of PTSD among Vietnam veterans are generally consistent with these results. Estimates of current PTSD prevalence from the majority of these studies lie within the 95% confidence interval of the NVVRS estimates (13.0–17.4%). More recent studies evaluated PTSD prevalence among military personnel who served in the Persian Gulf War (Operation Desert Shield/Storm; ODS). Estimates of current PTSD prevalence rates among ODS veterans varied across studies and ranged from 4 to 19%; however, studies generally found higher rates of PTSD among ODS veterans than among military personnel who served during the same time period but were not deployed to the Persian Gulf (Perconte, Wilson, Pontius, Dietrick, & Spiro, 1993; Southwick et al., 1993, 1995; Sutker et al., 1993; Wolfe, Brown, & Kelley, 1993).

During the past decade, the prevalence of PTSD associated with forms of interpersonal violence

other than combat also has been evaluated. In the NCS (Kessler et al., 1995), sexual assault (i.e., rape) was associated with comparatively high rates of PTSD, as found in other studies (Kilpatrick, Saunders, Vernon, Best, & Von, 1987; Resnick et al., 1993; Rothbaum, Foa, Riggs, Murdock, & Walsh, 1992). Whereas sexual assaults were strongly associated with PTSD for both men and women in the NCS, only 1.8% of men who reported a physical attack as their most upsetting trauma developed PTSD, compared with 21.3% of women. Research indicates that, in general, rates of PTSD in women following physical assault are relatively high and in many cases comparable to those observed among women sexual assault survivors (Kilpatrick et al., 1987; Norris, 1992; Resnick et al., 1993). Sexual victimization in childhood is also associated with PTSD in *adult* women. For example, in the NWS, women who were raped before age 18 were four times more likely to meet criteria for PTSD at the time of the study interview than women who were not raped as children or adolescents (Saunders et al., 1999).

McFarlane and Potts (1999) noted that the field of traumatic stress research largely evolved from the study of victims of three types of potentially traumatic events: war, interpersonal violence and related crimes, and disasters. Studies of the prevalence of PTSD among survivors of a variety of natural and technological disasters have been conducted in the United States and other countries, including several developing countries. Not surprisingly, research suggests that rates of PTSD among disaster survivors vary with the population and the type of disaster. The 1972 Buffalo Creek dam collapse and flood is one of the most widely studied natural disasters in the United States (Grace, Green, Lindy, & Leonard, 1993; Green, Lindy, Grace, & Leonard, 1992; Green & Lindy, 1994). Green and colleagues found that, as long as 14 years after this disaster, 25% of a sample of survivors followed longitudinally met criteria for a current diagnosis of PTSD. Although high, this estimate represents a decrease from the 44% current PTSD prevalence estimated 2 years after the flood. Comparatively high rates of PTSD were also reported among survivors of other natural and technological disasters, including a tornado (59%; Madakasira & O'Brien, 1987) and an industrial accident (71–80%; Weisaeth, 1989) both in the U.S., a cyclone in Fiji (Fairley, Langeluddecke, & Tennant, 1986), and earthquakes in Armenia (67%;

Goenjian et al., 1994) and Mexico (32%; Conyer, Sepulveda, Medina, Caraveo, & De La Fuente, 1987). However, other investigators reported considerably lower rates of PTSD among disaster survivors. For example, Canino, Bravo, Rubio-Stipec, and Woodberry (1990) reported PTSD prevalence rates of approximately 5% among survivors of a mud slide and flood in Puerto Rico that killed 800 people. Similarly, Shore, Vollmer, and Tatum (1989) reported PTSD prevalence rates of 4.5% for men and 3% for women in a large sample of survivors of the Mt. St. Helens volcanic eruption. Consistent with these findings, Norris (1992), in an epidemiological study of 1000 residents of four southeastern cities in the U.S., estimated that the rate of PTSD in disaster-exposed individuals was between 5 and 6%. The variability in PTSD prevalence rates among studies of disaster survivors suggests consideration of the dimensions of exposure (e.g., whether the individual was seriously injured or perceived a significant threat to personal safety) within classes of potentially traumatic stressors, an issue further addressed in the next section on risk factors for PTSD.

Risk Factors for PTSD

Epidemiologic studies are empirical sources of information about risk factors for PTSD—pre-exposure factors, exposure characteristics, and postexposure factors that are believed to be related to the probability of an individual developing PTSD following exposure to a potentially traumatic event. A small number of general population studies have examined risk factors for PTSD. General population studies have focused primarily on the role of preexposure factors in the development of PTSD. Studies also examined risk factors for PTSD among individuals exposed to specific types of stressors. The most consistently reported preexposure risk factors for PTSD among individuals who experienced a potential trauma include female gender, preexisting psychiatric disorder, family history of psychopathology, and prior exposure to trauma including abuse in childhood (Breslau et al., 1991, 1998; Bromet et al., 1998; Kilpatrick et al., 1998). Within classes of potentially traumatic stressors, characteristics of the stressor exposure also influence risk for developing PTSD (e.g., Kilpatrick et al., 1989; Winfield, George, Swartz, & Blazer, 1990; Shore, Tatum, & Vollmer, 1986). Postexposure factors, including

postexposure social support and exposure to other potentially traumatic events, also affect the risk for PTSD.

Epidemiologic studies in the United States have generally found higher rates of PTSD in women than in men (Breslau et al., 1991, 1998; Kessler et al., 1995). These findings for PTSD are consistent with gender differences reported for other anxiety disorders and major depression. This gender difference is not due to higher overall rates of exposure to potentially traumatic events among women. Data from community surveys indicate that men are more likely than women to be exposed to potential traumas (Breslau et al., 1991; Kessler et al., 1995). At the same time, the types of potential traumas that men and women experience may differ. For example, studies consistently find that women are more likely than men to experience sexual victimization (Breslau et al., 1991; Kessler et al., 1995; Norris, 1992). Differences in the types of traumas to which men and women are exposed may partially account for gender differences in the rates of PTSD. However, in both the Detroit Area Survey of Trauma (Breslau et al., 1998) and the NCS (Kessler et al., 1995), the probability of PTSD among respondents reporting exposure to a potential trauma was two to four times higher in women than men, even after statistically adjusting for gender differences in the distribution of trauma types. Note that these findings do not rule out the possibility that gender differences in the characteristics of stressors experienced within broad categories of trauma types may contribute to the higher rates of PTSD observed among women. (See Saxe & Wolfe, 1999, for a detailed discussion of gender and PTSD.)

Among both men and women, preexisting psychiatric disorder and a family history of psychiatric disorder are associated with increased risk for PTSD following exposure to a potentially traumatic event (Breslau et al., 1991; Bromet et al., 1998; King, King, Foy, & Gudanowski, 1996; Sack et al., 1994). In the NCS, preexisting anxiety disorder and preexisting affective disorder were associated with PTSD in men and women, respectively, even after statistically adjusting for the nature of the index trauma (Bromet et al., 1998). Consistent with these findings, in Breslau et al.'s (1991) sample of urban young adults, the probability of developing PTSD among individuals reporting exposure to a potential trauma was more than twofold for those with a preexisting anxiety

disorder or preexisting major depression. With respect to family history, Breslau et al. found that the risk of developing PTSD from exposure to a potential trauma was significantly higher among individuals who reported a family history of anxiety, depression, psychosis, or antisocial behavior. (A family history of substance abuse did not increase vulnerability to PTSD in this sample.)

In addition to conferring increased risk for future exposure on such events, past exposure to potentially traumatic events elevates the risk of developing PTSD upon exposure to a subsequent trauma. In the NWS, for example, women who reported exposure to multiple potentially traumatic events were more likely to receive a PTSD diagnosis than women who reported only a single exposure (Kilpatrick et al., 1998). Findings from several studies conducted with military veterans suggest that prior physical or sexual abuse, including abuse in childhood, is a risk factor for developing PTSD following military service in a war zone (Engel et al., 1993; Fontana, Schwartz, & Rosenheck, 1997; King et al., 1996).

Research indicates that the number and type of stressor exposures and also the specific characteristics of the exposure can influence the risk of developing PTSD. Subjective characteristics of stressor exposures (e.g., perceived life threat) as well as objective characteristics of the stressor (e.g., experienced injury) have been considered, and both influence the development of PTSD. Studies conducted with Vietnam veterans were among the first to consider multiple aspects of exposure to a particular type of stressor rather than simply measuring exposure as a dichotomous variable. Indeed, these studies have repeatedly found associations between risk of PTSD and the degree and nature of war zone stressor exposure (King, King, Foy, Keane, & Fairbank, 1999; Kulka et al., 1990). Evidence for an association between stressor characteristics and PTSD prevalence rates are not limited, however, to studies of war zone stressor exposure. In the NWS (Resnick et al., 1993), for example, the rate of lifetime PTSD among the women who reported assaults that involved both perceived life threat and injury (45.2%) was more than double that observed among assault survivors who reported neither perceived life threat nor injury (19%). In studying individuals exposed to the Mount St. Helens volcano eruption, Shore et al. (1986) found a strong association between proximity to the mountain and the effects

of exposure. Among males, first-year postdisaster onset rates for the three stress-related disorders evaluated (of which PTSD was one) were 0.9% in nonexposed controls, 2.5% in the low exposure group, and 11.1% in the high exposure group. Onset rates for females in these groups were 1.9, 5.6, and 20.9%, respectively.

Compared with research on preexposure factors and exposure characteristics, relatively few studies examined the role of postexposure factors in the development of PTSD. In one study L. King, D. King, Fairbank, & Adams (1998) used structural equation modeling to assess the contribution of postexposure factors to the development of PTSD in Vietnam veterans. Among the postexposure factors examined, postwar functional social support and stressful life events had direct effects on PTSD in both genders, as did structural social support for men. In this study, functional support was operationalized in terms of veterans' perceptions of the availability of emotional and instrumental support. Structural support was operationalized by a measure of the size and complexity of the veterans's social network. The impact on current PTSD of what King et al. (1998) referred to as "resilience factors" (e.g., hardiness) was also evaluated in this study. Consistent with these results, Fontana & Rosenheck (1994) found that homecoming experiences along with war zone stressor exposures were key correlates of PTSD among Vietnam veterans. Findings from a small number of studies suggest that social reactions that followed exposure to interpersonal violence may also affect the development of posttraumatic symptoms in civilian populations (e.g., Astin, Lawrence, & Foy, 1993; Zoellner, Foa, & Brigidi, 1999).

Comorbidity

Another key component of the epidemiology of PTSD is its pattern of occurrence with other psychiatric and physical conditions, or *comorbidities*. Both general population studies and studies of individuals exposed to particular traumas indicate that the experience of other psychiatric disorders is common among individuals with PTSD. For example, in the St. Louis ECA study, almost 80% of persons with PTSD had a previous or concurrent psychiatric disorder, compared to about one-third of persons with no posttraumatic symptoms (Helzer et al., 1987). Similarly, in Breslau et al.'s

(1991) urban young adult sample, 83% of participants with lifetime PTSD had at least one other lifetime psychiatric disorder. In interpreting these and other findings addressing the psychiatric comorbidity of PTSD, however, it is worth noting that such results may in part be an artifact that reflects similarities in the diagnostic criteria for PTSD and other anxiety or depressive disorders. Further, as suggested by Acierno et al. (1999, p. 62) in reviewing research on crime-related PTSD, "large relative risk estimates may be a function of exposure to traumatic events, rather than PTSD *per se*" and thus may indicate of the potentially broad-reaching effects of traumatic life experiences.

In the NCS, the most extensive study of psychiatric comorbidities conducted to date, lifetime comorbidity between PTSD and the other DSM-III-R disorders was 88% for men and 79% for women (Kessler et al., 1995). In contrast, 46% of women and 55% of men with disorders other than PTSD had lifetime histories of another psychiatric disorder. The disorders most prevalent among men with lifetime histories of PTSD were alcohol abuse or dependence (51.9%), major depression (47.9%), conduct disorder (43.3%), and drug abuse or dependence (34.5%). The disorders most prevalent among women with lifetime PTSD were major depression (48.5%), simple phobia (29.0%), social phobia (28.4%), and alcohol abuse/dependence (27.9%). In Breslau et al.'s (1991) young adult sample, the two most prevalent disorders among individuals with lifetime PTSD were major depression (36.6%) and alcohol abuse or dependence (31.2%). Note, however, that comorbidity rates in both of these studies refer to lifetime disorder rather than current disorder and therefore do not necessarily imply the simultaneous occurrence of PTSD with other psychiatric disorders.

High rates of psychiatric comorbidity have been also found in studies of PTSD among individuals who experienced specific types of trauma. In the NVVRS, Kulka et al. (1990) found that virtually all Vietnam veterans with PTSD had met the criteria for one or more other psychiatric disorders at some time during their lives (three-quarters if alcohol disorders are excluded). Moreover, half of the veterans with PTSD met criteria for another current psychiatric disorder. In men with PTSD, the most frequent diagnostic comorbid disorders were alcohol abuse or dependence (75% lifetime, 20% current), generalized anxiety disorder (44%

lifetime, 20% current), and major depression (20% lifetime, 16% current). Among women veterans with PTSD, the most frequent disorders were major depression (42% lifetime, 23% current), generalized anxiety disorder (38% lifetime, 20% current), and dysthymic disorder (33% lifetime). Consistent with these findings for women military veterans, a study of criminal victimization among women community residents (Boudreaux, Kilpatrick, Resnick, Best, & Saunders, 1998) also found that women with current PTSD were more likely than women without PTSD to meet criteria for the following disorders: major depression (32% vs. 4%), obsessive-compulsive disorder (27% vs. 3%), agoraphobia (18% vs. 1%), and social phobia (18% vs. 4%).

Epidemiologic studies also examined the temporal order of PTSD in relation to other psychiatric disorders that are highly comorbid with PTSD. In the NCS (Kessler et al., 1995), the absence of a PTSD assessment for all traumas experienced precluded an unequivocal determination of how often comorbid PTSD was a primary disorder (in the sense of having an earlier onset than other psychiatric disorders). By placing upper and lower bounds on this figure, however, Kessler et al. estimated that PTSD was primary with respect to all other disorders between 29% and 51% of the time among men and between 41% and 58% of the time among women. In a community sample of 801 women (Breslau, Davis, Peterson, & Schulz, 1997), PTSD was associated with an increased risk for first-episode onset of major depression and alcohol abuse or dependence (but not any anxiety disorder). Exposure to a potentially traumatic event also was associated with an increased risk of alcohol abuse or dependence in this sample. In Breslau et al.'s sample of young adults, PTSD was associated with an increased risk of subsequent drug abuse or dependence, whereas exposure to a potential trauma in the absence of PTSD did not increase risk for drug use disorders (Chilcoat & Breslau, 1998).

In addition to studies of psychiatric comorbidity, there is a growing body of research on the physical health comorbidities and life adjustment problems associated with PTSD. Correlates of PTSD identified in the empirical literature include more somatic complaints, poorer health status, increased use of health services, and higher rates of cardiovascular symptoms, neurological symptoms, gastrointestinal symptoms, and other physi-

cal symptoms of known and unknown etiology (Beckham et al., 1998; Boscarino & Chang, 1999; Holen, 1991; Kulka et al., 1990; Long, Chamberlain, & Vincent, 1992; McFarlane, Atchison, Rafalowicz, & Papay, 1994; Schnurr & Spiro, 1999; Shalev, Bleich, & Ursano, 1990). Research also has shown a greater frequency of adverse health practices (e.g., smoking, alcohol use) among persons with PTSD (Beckham, 1999; Beckham et al., 1997; Schnurr & Spiro, 1999). Although the impact of PTSD on functioning has not been well-studied, a few studies found evidence of impaired functioning (e.g., more physical limitations, a greater likelihood of not being employed) among individuals with PTSD (Fairbank, Ebert, Zarkin, & Johnson, 1999; Zatzick et al., 1997a,b).

Assessment

During the past decade, the literature devoted to the clinical assessment of PTSD advanced considerably. Of particular note is the increase in attention to the development of assessment tools for use with noncombatants and even more specifically with survivors of specific civilian traumas (e.g., tools developed specifically for use with rape survivors, crime victims, etc.), the increase in the number of tools available for use with children, as well as the progress that has been made toward understanding the neurobiological factors that may contribute to the development and maintenance of PTSD. However, because there is still no one absolute diagnostic measure of PTSD, state-of-the-art and comprehensive assessment of PTSD uses a multi-axial, multimodal approach (Caddell & Drabman, 1993; Keane, Wolfe, & Taylor, 1987; Litz et al., 1992; Newman, Kaloupek, & Keane, 1996; Schlenger, Fairbank, Jordan, & Caddell, 1997). The term *multi-axial* denotes that multiple sources of information are used in the assessment process (e.g., clinical interview, collateral report, self-report inventories). To capture the nature and extent of dysfunction more fully, a multimodal approach is used to access selected response modalities that have demonstrated utility in measuring the anxiety construct and specifically PTSD (e.g., overt behavioral responses, subjective responses, physiological responses, cognitive/neuropsychological status) (Barlow & Wolfe, 1981; Keane, Wolfe, & Taylor, 1987; King, Hamilton, & Ollendick, 1988; Lang, 1977; Newman, Kaloupek, & Keane, 1996). The ultimate goals of this compre-

hensive assessment of PTSD are to identify signs and symptoms of the disorder, as well as comorbid disorders; to determine factors that have contributed to the development of the disorder, as well as factors that maintain current symptoms; to gain an understanding of an individual's functional status; and to establish a baseline against which to gauge treatment gains. The use of a multi-axial, multimodal assessment protocol allows the determination of a DSM-IV diagnosis, as well as further functional analysis, to specify the behavioral, cognitive, and physiological excesses and deficits displayed by an individual who meets diagnostic criteria.

Generally, the multi-axial, multimodal assessment approach should be used to gather converging data to indicate the presence of clinically significant symptoms of PTSD. The possibility of monetary compensation for PTSD makes the issue of assessment validity a paramount concern for clinicians who conduct PTSD evaluations. Every effort should be made to ensure that multiple data corroborate the diagnostic impression. Additionally, when assessing for PTSD, it is most important to remember that symptoms of PTSD show considerable overlap with other diagnostic categories. Consequently, the diagnostician must strive to determine that symptoms are manifest in response to experiencing a traumatic event and that the current level of functioning represents a change, compared to functioning before the traumatic experience. Furthermore, the clinical evaluator should be aware that the symptom picture presented can vary as a function of the amount of time that elapsed since the trauma. The clinician should also be sensitive to the differences in the symptom picture and the response to trauma displayed by various racial and cultural groups, as well as those displayed in response to different types of traumas (e.g., repeated sexual abuse vs. a single automobile accident). Finally, when assessing children, the evaluator should make every effort to tailor the selection and use of assessment tools to the developmental level of the child being assessed (Caddell & Drabman, 1993; Ollendick & Hersen, 1984).

Practical considerations may dictate using a more streamlined approach to assessing PTSD. Likewise, a comprehensive assessment battery that uses the full array of available tools may not be required in all situations. Nonetheless, numerous components are available to choose from

in selecting an assessment protocol to meet the requirements of a specific context, and using the most comprehensive assessment battery possible is generally recommended in any given situation. It is beyond the scope of the current chapter to review in any detail the large number of relevant assessment tools that have been developed and refined in the last decade, but we present information to introduce the reader to the following types or categories of assessments that can be used in a PTSD assessment battery: structured clinical interviews, self-report psychometric rating scales, clinician rating scales, psychophysiological assessment, and neurobiological and neuropsychological assessments. For a more complete treatment of the broad range of issues surrounding the assessment of PTSD, we refer the reader to several other excellent sources that address these issues and describe specific assessment instruments in more detail (Friedman, 2000; Newman et al., 1996; Stamm, 1996; Weathers & Keane, 1999; Wilson & Keane, 1997).

Structured Clinical Interviews

There is no definitive diagnostic tool available for making any psychiatric diagnosis, but the clinical interview currently stands as the linchpin of a multiaxial, multimodal assessment protocol. With a goal of improving diagnostic validity and reliability, a number of structured and semistructured clinical interviews have been developed to assess psychological and psychiatric problems. The *Structured Clinical Interview for DSM-IV* (SCID; First, Spitzer, Williams, & Gibbon, 1996) was designed for use by trained clinicians to assess signs and symptoms of both Axis I and Axis II disorders. The interview is divided into modules that assess the presence of major categories of disorders and also assess specific diagnoses within each category. The format of the interview is such that the diagnostic criteria are presented concurrently with the stem questions to assess the presence of each DSM diagnostic criterion. However, the stem questions are not intended to be used in the absence of further probing by the clinician.

The original PTSD module of the SCID was developed for use in the National Vietnam Veterans Readjustment Study (NVVRS; Kulka et al., 1990); consequently, considerable data have been collected regarding the reliability and the validity of the PTSD module in a veteran population. In the

NVVRS, interrater reliability for the DSM-III version of the PTSD module was .933 (kappa coefficient). Additionally, the correspondence in PTSD diagnosis between the SCID and other measures of PTSD (e.g., Mississippi Scale for Combat-Related PTSD, the Keane et al. MMPI-PTSD subscale) was high. As the diagnostic criteria for PTSD (and other psychiatric disorders) have been revised, subsequent versions of the SCID have been revised to correspond to current nosological specifications.

As researchers and clinicians have gained a better understanding of the complexities of PTSD and its co-occurrence with other psychiatric disorders, recognition of the importance of the capacity to assess comorbid disorders has been commensurate. Instruments such as the SCID that assess the full spectrum of Axis I and Axis II diagnoses offer a decided advantage in this regard. However, the same concerns about ensuring reliable and valid diagnosis apply to assessing these comorbid conditions. Fortunately, the SCID has been fairly rigorously tested across the diagnostic spectrum. For example, the SCID has been shown reliable when distinguishing major depressive disorder from generalized anxiety disorder (Riskind, Beck, Berchick, Brown, & Steer, 1987).

In child and adolescent assessment, the Diagnostic Interview for Children and Adolescents—Revised (DICA-R; Nader, 1997) offers an approach similar to that of the SCID; that is, the instrument assesses several DSM-IV disorders, including PTSD. A four-point rating scale of symptom frequency is part of this assessment. Examination of the reliability of the PTSD module has indicated good interrater reliability; however, validity studies of the PTSD module of the DICA-R revealed variable sensitivity and specificity (Friedman, 2000).

Several interviews have been designed that are narrower in focus; that is, they were developed for assessing PTSD exclusively. One notable example of this type of interview is the Clinician Administered PTSD Scale (CAPS; Blake, Weathers, Nagy, Kaloupek, Gusman, Charney, & Keane, 1995; Blake, Weathers, Nagy, Kaloupek, Klauminzer, Charney, & Keane, 1990). The CAPS was designed to address the shortcomings of previously developed structured interviews for diagnosing PTSD. The CAPS is a comprehensive interview that (1) uses behavioral referents for symptoms when feasible; (2) assesses all DSM-IV criteria, as

well as a selected sample of relevant associated features; (3) provides separate intensity and frequency ratings of symptoms; (4) specifically establishes that the time frame for symptom occurrence is consistent with diagnostic criteria; and (5) determines both current and lifetime symptoms. Additionally, the CAPS provides ratings of global functioning and of the impact of PTSD symptoms on relevant areas of life functioning. Evaluations of reliability and validity indicate strong psychometric performance. Initial examinations of interrater reliability were quite good (at the symptom level, r ranges from .92 to .99, and there is perfect agreement at the diagnostic level), and subsequent examinations of test–retest reliability for PTSD were .89 (Weathers, Blake et al., 1997). Weathers, Blake et al. (1997) also found a coefficient alpha of .89, and compared to a SCID PTSD diagnosis, they obtained a sensitivity of .91, a specificity of .86, and a kappa of .77. Additionally, the CAPS has shown strong correlation with other psychometric measures of PTSD, including the Mississippi Scale and the PK Scale of the MMPI (Weathers and Keane, 1999). Recent additions to the CAPS include changes to accommodate DSM-IV symptom revisions, as well as additional questions to assess trauma exposure in more detail.

A version of the CAPS for use with children has also been developed—the CAPS-C (Nader, Kriegler, Blake, Pynoos, Newman, & Weathers, 1996). This instrument is based on DSM-IV diagnostic criteria but also includes the assessment of additional symptoms/features that have been documented in children. Assessment of academic and social functioning are also included in the CAPS-C. This relatively new instrument has not yet reached full psychometric maturity but shows promise, particularly given the full range of symptoms and functional variables that are assessed. There is some indication, however, that the length and the demand of completing the rating scales may be problematic for younger children (Nader, 1997).

In this section, we have provided only a brief introduction to the types of clinical interviews and approaches now available for assessing PTSD, as well as examples of some of the more notable of these interviews. Other choices of clinical interviews that are currently available are delineated and reviewed more extensively in other sources (Friedman, 2000; Newman et al., 1996; Stamm,

1996; Weathers & Keane, 1999; Wilson & Keane, 1996).

Assessments of Trauma History

Because the hallmark symptom of PTSD is exposure to a traumatic event, it is crucial that any assessment of PTSD determine that exposure has occurred. Researchers and clinicians have not yet reached a consensus regarding how best to identify and characterize events that meet the diagnostic criteria for traumatic event exposure as specified in DSM-IV. Approaches to developing instruments to assess the nature and level of exposure to trauma have focused variously on identifying the type of event, characterizing the degree or level of exposure, defining characteristics of the events that are purportedly related to poorer outcome, and determining the subjective response of an individual to an event. Currently, DSM specifies that a traumatic event is defined both by the objective characteristics of an event and the subjective response to that event. At present, however, there are few published instruments designed to assess trauma history that assess both the objective characteristics and the subjective reaction to the event. Additionally, it should be noted that more formalized and quantitative assessments of trauma histories are at times incorporated into clinical interviews (e.g., the CAPS). To provide a flavor of the type of instruments available for use as “stand-alone” trauma assessments, we review here two widely used instruments that represent different approaches to trauma assessment: (1) the Potential Stressful Events Interview that assesses exposure to a broad array of potentially traumatic events and is designed to provide an assessment that corresponds with the DSM-IV definition of a traumatic event and (2) the Combat Exposure Scale that is limited to assessing combat-related traumatic events and does not attempt to provide results that correspond to the current DSM conceptualization of traumatic events. For a more complete treatment of instruments that assess trauma history, we refer the reader to Friedman (2000), Newman et al. (1996), Stamm (1996), and Weathers & Keane (1999).

The Potential Stressful Events Interview (PSEI; Falsetti, Resnick, Kilpatrick & Freedy, 1994) was developed initially for use in the DSM-IV PTSD field trial. This interview gathers information on exposure to low magnitude stressors and high

magnitude stressors, as well as objective and subjective information on high magnitude stressors. The interview inquires about experiencing a broad array of potential traumatic events using well-crafted and direct language. This instrument is used quite widely, but currently there is no reliability or validity information published on it. Additionally, the detail obtained by using this instrument requires considerable time and effort that may prove prohibitive in some situations. In an effort to address the issue of burden, researchers have developed a brief self-report instrument that is based on the PSEI—the Trauma Assessment for Adults (TAA; Resnick, Best, Freedy, Kilpatrick, & Falsetti, 1993). Using the TAA may be more feasible when time availability for gathering information is a primary consideration—such as community epidemiologic studies (Schlenger, Fairbank, Jordan, & Caddell, 1996).

One of the most rigorously tested measures of combat exposure is the *Combat Exposure Scale* (CES; Keane, Fairbank, Caddell, Zimering, Taylor, & Mora, 1989). The CES was partly derived from Figley's (1978) combat scale, and additional items were constructed by PTSD content experts. Individuals who complete the scale rate items that describe various types of combat-related experiences on a Likert scale, and ratings are totaled to yield a range of possible scores between 0 and 41. Items are weighted in determining the total score based on the severity of the combat experience described by the item. This scale has demonstrated good internal consistency (coefficient alpha = .85), high test–retest reliability ($r = .97$), and some concurrence with measures of PTSD. Although this scale was developed initially for use with Vietnam veterans, item content is not exclusive to Vietnam combat experiences, and it has been adapted for use with veterans of the Persian Gulf War, as well as soldiers who served in Somalia and Bosnia (Friedman, 2000). Note that this measure does not have validity indicators, thus highlighting the importance of corroborating results obtained with other sources of information.

Self-Report Psychometric Rating Scales

Attention in the field of PTSD assessment has turned from developing purely descriptive measures to designing instruments that have sound psychometric properties and acceptable diagnostic accuracy (Litz et al., 1992). During the past

decade, researchers have worked to advance the psychometric maturity of self-report instruments, and particular advances have been made in assessing noncombat trauma and trauma in children. The sheer number of self-report instruments that were developed in the past decade is truly astounding. This proliferation of assessment tools is generally positive, but it does create some concern because assessment protocols used across clinical settings and research studies are rarely uniform, and many of the tools currently available are still in their infancy with regard to assessing their psychometric properties (Weathers & Keane, 1999). Because it is not possible to provide even a cursory overview of all these instruments within this chapter, a selected set of illustrative instruments that are widely used with adults and were developed with adherence to sound psychometric methods will be reviewed here. Other existing sources can be consulted for more exhaustive reviews of self-report instruments, including those designed for use with children and adolescents (Friedman, 2000; Stamm, 1996).

The instruments that assess PTSD symptoms and functioning can be classified according to whether they use a DSM framework. Additionally, there are a number of self-report measures available that are designed to assess associated features or other areas of functioning that are relevant for trauma survivors.

Measures Focusing on Assessing DSM PTSD Criteria. The PTSD Checklist (PCL) was developed at the National Center for PTSD as a tool for validating the CAPS (Weathers, Litz, Herman, Huska, & Keane, 1993). This seventeen-item scale uses a five-point Likert rating (1 = not at all, 5 = extremely) of DSM-IV PTSD symptoms. There is a generic civilian version and a generic military version for use when a specific traumatic event has not been identified. There also is a specific stressor version for which the respondent provides symptom ratings in relation to a specific event that has been identified by taking a trauma history. Examinations of the psychometric properties of the PCL indicated that it has performed very well in veteran populations (Weathers, Litz et al., 1997). Although the PCL was strongly correlated with other psychometric measures of PTSD (e.g., the MS Scale, the PK Scale), most impressive is its performance compared to the SCID. Using a cut score of 50, the PCL produced a sensitivity of .82, a specificity of .83, and a kappa of .64. The bulk of the research

that examined the utility of the PCL was with veteran populations, but it is important to note that the PCL has shown promise as a measure of PTSD symptoms in other traumatized populations (Blanchard, Jones-Alexander, Buckley, & Forneris, 1996; Cordova et al., 1995).

The Davidson Trauma Scale (DTS; Davidson, 1996) is another DSM-based self-report measure of PTSD. This scale also includes seventeen items, indicative of DSM symptoms, that are rated using a Likert scale in terms of frequency (0 = not at all, 4 = every day) and severity (0 = not at all distressing, 4 = extremely distressing) during the past week. The respondent must specifically identify a "most disturbing" traumatic event that then serves as the anchor event for symptom ratings. The DTS provides a continuous measure of PTSD symptoms, and in addition the DTS manual provides information for converting these scores to a PTSD diagnosis. The DTS has shown good correspondence with CAPS diagnosis and correlates strongly with the Impact of Event Scale (IES; Horowitz, Wilner, & Alvarez, 1979) and other measures of trauma symptoms. It also has shown good test-retest reliability—.86 at 1 week. Another potential advantage of the DTS is that it is sensitive to symptom improvement. However, note that limiting the symptom ratings to the past week does not permit assessment of the 1-month symptom duration criteria for diagnosing PTSD that is specified in DSM-IV.

Measures That Assess PTSD from a Non-DSM Framework. The *Minnesota Multiphasic Personality Inventory* (MMPI; Hathaway & McKinley, 1967) has long been a standard of personality assessment. Two subscales to assess PTSD in a veteran population were developed from the existing clinical scales of the MMPI: the Keane MMPI-PTSD subscale (PK; Keane, Malloy, & Fairbank, 1984), and the Schlenger and Kulka PTSD subscale (Kulka et al., 1990) derived from the MMPI-2. Both of these subscales were empirically derived and therefore are not as susceptible to problems related to the face validity of items as other instruments that will be reviewed. Additionally, the validity scales of the MMPI can be used to determine whether a biased response style was used in endorsing items on the subscale. Both subscales have performed well in diagnostic accuracy, but their utility has been established largely with a veteran population. Koretsky and Peck (1990), however, found that the PK subscale could

accurately identify cases of PTSD that result from nonmilitary trauma. Note, however, that the performance of the PK subscale varied across studies and consequently, establishing optimal cut scores for specific populations is recommended (Lyons & Keane, 1992; Newman et al., 1996). Differences in performance highlight the importance of using these MMPI scales primarily as corroborative measures within a more comprehensive assessment battery.

The Mississippi Scale for Combat-Related PTSD (MS Scale; Keane, Caddell, & Taylor, 1988) was developed to provide a psychometrically sound quantitative self-report measure of combat-related PTSD that can be administered easily. This scale includes thirty-five items that represent selected behavioral manifestations of some of the DSM-III PTSD diagnostic criteria, selected associated features of PTSD, and items describing functional deficits commonly observed in traumatized veterans. Subjects rate each item on a five-point Likert scale. Suggested cutoffs for total scores (sum of item ratings) were determined for both clinical and community-based non-help-seeking Vietnam veteran populations. Total scores possible range from 35 to 175, and higher scores indicate the endorsement of more PTSD symptomatology. To maximize diagnostic accuracy, sensitivity, and specificity, a cutoff of 107 was suggested to distinguish PTSD patients from non-PTSD patients in a hospital sample (Keane et al., 1988) and another score of 89 to distinguish patients from nonpatients in a community population (Kulka et al., 1990). However, note that subsequent analyses of the NVVRS data indicate that a cutoff score of 95 may be more appropriate for distinguishing cases from noncases in a community sample. The relatively high face validity of the MS Scale can be problematic in some situations, though, such as when secondary gain is an important issue.

Several versions of the Mississippi Scale were developed, including a version for civilians, various abbreviated versions, and a Spouse/Partner version. Although relatively little work has focused on instruments designed to systematically collect data from collateral sources to assist with patient diagnosis, the Spouse/Partner version of the Mississippi Scale is an attempt to address this need (MS Scale-S/P; Caddell, Fairbank, Schlenger, Jordan, & Weiss, 1991). This instrument was initially developed for use in the NVVRS. Al-

though further refinement and testing are required, initial tests of psychometric properties indicate adequate internal consistency ($\alpha = .937$ for S/Ps of male veterans and $.864$ for S/Ps of female veterans) and good correspondence between the MS Scale-S/P and other indicators of PTSD. This instrument clearly requires further validation, but it shows promise as a quantitative tool to corroborate patient self-reports.

The Impact of Event Scale (IES; Horowitz et al., 1979) is one of the most widely used self-report scales designed for assessing trauma-related symptoms. Two of the advantages of this instrument are that it is applicable to veteran and civilian populations and that considerable work has been done with standardization samples that include women. When completing the IES, individuals identify a stressful event and then rate items pertaining to intrusion and avoidance of that event. Although the IES is primarily focused on assessing avoidance and intrusive symptomatology, it has recently been revised to assess manifestations of other symptoms in the PTSD diagnostic construct—most specifically symptoms of hyperarousal (Weiss & Marmar, 1997). The IES has acceptable reliability but does not offer scores that indicate clinically significant symptoms of PTSD. Furthermore, the IES offers no guidelines for having the subject identify stressful events that would be classified as traumatic by DSM-IV standards. Still, this instrument can be quite useful as a research tool and as a clinical tool to help delineate the major response that an individual manifests to trauma (intrusion, avoidance, or a combination), thereby assisting in developing relevant treatment strategies.

Non-PTSD Self-Report Instruments Relevant to Trauma Populations. Other more generic self-report instruments have also been employed with PTSD populations to assess non-PTSD psychological constructs that may be of interest when attempting to characterize the functioning of trauma populations. Because trauma survivors often display deficits across multiple domains of life functioning as well as comorbid symptoms beyond classic PTSD symptoms, the astute clinician and researcher will consider using the variety of other well-established instruments available to further define patient/subject functioning.

For example, the State-Trait Anxiety Inventory (STAI; Spielberger, Gorsuch, & Lushene, 1970), the Beck Depression Inventory (BDI; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961), and the

State-Trait Anger Scale/T-Anger (Spielberger, 1988) have been used with PTSD patients (Chemtob, Hamadam, Roitblat, Muraoka, & Pelowski, 1991; Keane, Fairbank et al., 1985; Riley, Treiber, & Woods, 1989). In a comparison of Vietnam veterans with PTSD to well-adjusted Vietnam veteran and to noncombat veterans with other non-psychotic psychiatric disorders, veterans with PTSD scored consistently higher on the STAI and BDI than the comparison groups (Fairbank, Keane, & Malloy, 1983). Additionally, veterans with PTSD scored higher on the Trait scale of the State-Trait Anger Scales than relevant comparison groups (Chemtob et al., 1991; Riley et al., 1989). Therefore, these instruments may be useful for assessing generic symptoms of anger, anxiety, and depression that are often associated with PTSD.

The Dissociative Experiences Scale (DES; Carlson & Putnam, 1993) is an example of a measure that attempts to capture and characterize one particular associated feature often seen in trauma survivors—dissociation. Although understanding the level and phenomenology of dissociation is not necessary for making a diagnostic determination of PTSD, obtaining such information can be invaluable in treatment planning and in research studies. The DES is a twenty-eight-item measure of the frequency of experiences that represent differing levels of dissociation. A large body of research has been conducted on this scale, and it has shown excellent psychometric properties.

The few instruments described represent only a small subset of the large number of well-researched instruments that are available. Consequently, clinicians and researchers have the opportunity to tailor their selection of instruments to address the issues that are of the most interest or importance in any given context.

Psychophysiological Assessments

The psychophysiological measurement of anxiety is a particularly attractive assessment strategy in that it offers a potentially more objective measure of the anxiety construct and the symptomatology of anxiety disorders. As used in this context, the phrase “more objective measure” does not necessarily imply a more accurate or more fundamental measure, but rather a measure not solely dependent on the individual’s subjective perceptions and less easily subject to direct manipulation by the individual. Psychophysiological techniques have been used to assess a variety of anxiety dis-

orders, including PTSD. Typically, PTSD symptoms have been measured by presenting trauma-related stimuli and comparison stimuli while measuring the three modalities of response most relevant to anxiety: physiological response, behavioral avoidance, and subjective response. Physiological measures of PTSD have included heart rate, skin conductance, and electromyogram (EMG). Subjective response is usually measured by some self-report rating of arousal, such as the Subjective Units of Distress Scale (SUDS). Typically, the behavioral response is measured as a function of the subject terminating the assessment or avoiding the trauma-related stimuli.

Numerous studies using a variety of stimulus presentation methods (imaginal, auditory, visual) demonstrated that veterans with PTSD respond with increased arousal to combat-related stimuli, compared to control stimuli, and likewise respond with more arousal to combat-related stimuli than relevant control groups (Blanchard & Buckley, 1999; Blanchard, Kolb, Pallmeyer, & Gerardi, 1982; Malloy, Fairbank, & Keane, 1983; Pitman, Orr, Fogue, de Jong, & Claiborne, 1987). Indeed, the vast majority of physiological assessments of trauma survivors have been conducted with veterans. However, a burgeoning literature exists that examines psychophysiological response in other trauma populations, particularly motor vehicle accident victims and survivors of sexual assault. Overall, these studies indicate a pattern of response among nonveteran populations similar to that documented in veterans; that is, individuals with PTSD display more reactivity in response to trauma-relevant stimuli than control subjects, although this trend is not as clear or strong among sexual assault survivors (Blanchard & Buckley, 1999). Additionally, physiological measurement used as a within-subject measure of progress in treatment has shown promise with both veteran and nonveteran populations (Boudewyns and Hyer, 1990; Fairbank & Keane, 1982; Keane & Kaloupek, 1982; McCaffrey & Fairbank, 1985; Rychtarik, Silverman, van Lindingham, & Prue, 1984). Nonetheless, psychophysiological measures are still used primarily within a more comprehensive assessment battery as a corroborative measure for determining a PTSD diagnosis.

To refine and streamline physiological assessment procedures, Blanchard and Buckley (1999) recommend dropping EMG and temperature from most psychophysiological batteries, and generally believe that heart rate and electrodermal activity

provide the most significant results. Additionally, there is interest in using psychophysiological measures to better characterize treatment prognosis, although efforts in this area are relatively new and require considerably more research to refine (Blanchard & Buckley, 1999).

Neurobiological and Neuropsychological Assessment

Considerable progress has been made in the last decade in documenting and understanding the potential neurobiological underpinnings of PTSD. Although this approach may eventually provide more objective and biological tests for diagnosing PTSD, at this point that literature is still focused on elucidating the potential relationships of neurobiology to symptom development and presentation rather than on using neurobiological methods as diagnostic tools. Consequently, we will not review or present the findings from neurobiological research (see Bremner, Southwick, & Charney, 1999 for an overview of these findings to date). Likewise, research that focuses on the use of neuropsychological testing to characterize cognitive and behavioral deficits and excesses in trauma patients is also in its early phases compared with other areas of trauma research. Neuropsychology does not yet offer diagnostic tools to assist in making PTSD diagnosis, nor does it currently offer definitive assessment strategies to define the neurocognitive concomitants of PTSD. Still, neuropsychological assessment can be of considerable clinical utility now (Knight, 1997). As one example, standardized neuropsychological testing can shed light on aspects of a patient's cognitive functioning that could interfere with maximum treatment benefit (e.g., memory deficits or abstraction difficulties could prove problematic when using cognitive behavioral treatment strategies) (Knight, 1997). Gaining a fuller understanding of this type of functional factor through neuropsychological testing could be invaluable in treatment planning.

Approaches to Treating PTSD

Psychosocial and neurobiological models of PTSD have influenced the development of clinical interventions for this disorder (Fairbank, Friedman, & Basoglu, in press; Southwick & Friedman, in press). Among the main approaches to treating PTSD that are conceptually linked to these models

are cognitive behavioral therapy (CBT), psychodynamic therapy, pharmacotherapy, and eye movement desensitization and reprocessing (EMDR). Other approaches used to address the psychological sequelae of potentially traumatic experiences are family and marital therapy, supportive psychotherapy, inpatient and milieu therapy, professional and self-help group therapies, hypnotherapy, pastoral counseling, and interventions based on community psychology and public health models of prevention (e.g., education, debriefing, crisis counseling, early intervention).

This section provides a selective overview of interventions that have been used, separately and in combination, to treat people with PTSD. Emphasis is placed on summarizing the results of treatment outcome studies for those interventions that have been evaluated empirically.

Cognitive-Behavioral Therapy for PTSD

Early behavioral conceptual models of PTSD were largely based on the two-factor learning theory of psychopathology originally proposed by Mowrer (Keane, Zimering, & Caddell, 1985). As applied to PTSD, two-factor conditioning models posit that fear and other aversive emotions are learned through association via mechanisms of classical conditioning (Fairbank & Nicholson, 1987). Such fear conditioning is the first factor in the acquisition of aversive emotions characteristic of PTSD. The second factor involves principles of instrumental conditioning in that persons with PTSD will learn to escape from and to avoid cues that stimulate aversive emotions. Through the process of fear conditioning, neutral cues associated with a traumatic (or otherwise aversive) event acquire the capacity subsequently to evoke a conditioned emotional (fearful) response in the absence of the aversive stimulus. First described by Pavlov and associates, this psychological mechanism, it is posited, preserves information about exposure to previous threats to promote future survival.

More recent conceptual models have emphasized the role of cognitive factors in developing and maintaining PTSD symptoms (Brewin, Dalgleish, & Joseph, 1996; Chemtob, Roitblatt, Hamada, Carlson, & Twentyman, 1988; Foa, Steketee, & Rothbaum, 1989; Lang, 1977; Resick & Schnicke, 1993). Information processing theory has been proposed as an explanation of the ways in

which information associated with traumatic experiences is encoded and recalled in memory (Foa & Kozak, 1986; Foa, Rothbaum, & Molnar, 1995; Foa et al., 1989). Foa et al. (1989), for example, offered a model based upon the concept of a fear structure, which they describe as a network in memory that includes three types of information: (1) information about the feared stimulus situation; (2) information about verbal, physiological, and overt behavioral responses; and (3) interpretive information about the meaning of the stimulus and the response elements of the structure (Foa et al., 1989, p. 166). Foa and colleagues proposed that during periods of extreme distress, information processing is interrupted, and traumatic memories are consequently fragmented and disorganized. Nevertheless, persons with PTSD are assumed to have an attentional bias toward threat cues (Foa, Feske, Murdock, Kozak, & McCarthy, 1991) that is hypothesized to account for the reexperiencing phenomenon of PTSD. Foa and her colleagues (Foa et al., 1995) proposed that treatment should be based upon activating and correcting information in fear structures by prolonged exposure (PE) to traumatic stimuli and cognitive restructuring, respectively. According to Foa and colleagues, exposure within and across trials is an opportunity to integrate traumatic memories with the individual's existing conceptualization of safety versus danger. Foa and colleagues further hypothesize that this exposure can result in organizing trauma memory. The information processing model has yielded a productive, theoretically grounded approach to research into the clinical efficacy of cognitive-behavioral therapy (CBT) for PTSD.

CBT approaches to treating PTSD include exposure therapy, cognitive therapy, cognitive processing therapy, stress inoculation training, systematic desensitization, assertiveness training, and biofeedback and relaxation training (Friedman, 2000). To date, exposure therapy is the most rigorously evaluated intervention for PTSD (Friedman, 2000; Rothbaum, Meadows, Resick, & Foy, in press). Exposure treatment methods involve confronting fearful stimuli associated with the traumatic memories within the context of a stable therapeutic relationship (Fairbank & Nicholson, 1987). The process of exposure therapy for PTSD involves having the patient experience the arousal associated with the traumatic event through imagery or *in vivo* exposure exercises and intentionally maintaining the arousal until it diminishes.

Exposure therapy has been used to treat PTSD symptoms associated with combat, sexual assault, and motor vehicle accidents. Exposure therapy has been applied in treating adults, adolescents, and children who experienced traumatic events. For example, four controlled clinical trials of the efficacy of exposure therapy for combat-related PTSD in Vietnam veterans reported generally positive findings (Boudewyns & Hyer, 1990; Cooper & Clum, 1989; Glynn et al., 1999; Keane, Fairbank, & Zimering, 1989). Two randomly controlled studies of exposure therapy for female sexual assault survivors also found that exposure therapy is efficacious in reducing PTSD symptoms (Foa et al., 1991, in press).

Resick and Schnicke (1992) reported improvements in the PTSD symptoms of rape survivors using a particular form of CBT—cognitive processing therapy. The authors state that this treatment includes education about PTSD symptoms, exposure, and cognitive therapy. Instead of using *in vivo* imagery, the exposure component involved having participants write and read a detailed account of the rape. Safety, trust, power, esteem, and intimacy were beliefs addressed in cognitive therapy. Treatment was administered in a group format during 12 weekly sessions and was compared to a waiting-list control. Treatment subjects improved significantly from pretreatment to posttreatment in depression and PTSD measures and maintained these gains at the six-month follow-up. The waiting-list group did not significantly improve.

Another frequently reported behavioral approach to treating PTSD involves teaching patients specific coping skills for reducing or managing PTSD symptoms and/or alternative responses to fear and anxiety. Specific interventions applicable to PTSD include relaxation training, anger management training, thought stopping, assertiveness training, self-dialogue, problem-solving skills training, and relapse prevention (Friedman, 2000). An example of this approach is Kilpatrick and Veronen's (1983) stress inoculation training (SIT) procedure for treating rape victims. Directed at the acquisition and application of coping skills, the SIT package includes Jacobsonian relaxation, diaphragmatic breathing, role playing, cognitive modeling, thought stopping, and guided self-dialogue. Patients are given homework assignments that require them to practice each coping skill.

The effectiveness of SIT was examined in four

controlled studies (Foa et al., 1991, in press; Resick, Jordan, Girelli, Hutter, & Marhoefer-Dvorak, 1988). In one of these studies, Foa et al. (1991) reported findings of the comparative efficacy of SIT and PE for treating rape-related PTSD from a randomized trial. Specifically, these investigators compared the effectiveness of a wait-less control group and three interventions—prolonged exposure (PE), SIT, and supportive counseling (SC). PE consisted of both *in vivo* exposure exercises and imaginal exposure, SIT consisted of a modified version of Kilpatrick and Veronen's (1983) multi-intervention package, and SC consisted of a form of problem-oriented counseling where the counselors played a supportive role in the patients' recovery; no instructions for exposure or stress management were included in the SC regimen. Wait-list clients were randomly assigned to one of the three treatments following a 5-week period. Treatment consisted of nine twice-weekly individual sessions conducted by a female therapist. Indicators of general psychological distress and PTSD reexperiencing, avoidance, and arousal symptoms were collected at intake, at completion of treatment, and at follow-up (mean = 3.5 months post-treatment). Only SIT produced significantly more improvement than wait list in PTSD symptoms at termination, but PE produced superior outcome at follow-up. Patients in the SIT and supportive counseling conditions showed little improvement of symptoms between termination and follow-up, whereas patients in the PE group that received *in vivo* and imaginal exposure continued to improve. The authors interpreted these findings as suggesting that (1) SIT procedures produce immediate relief in PTSD symptoms because they are aimed at the acquisition of anxiety management skills but show decreased effectiveness over time as performance compliance erodes and (2) PE shows less of an effect than SIT in the short term (a function of temporary increased levels of arousal induced by repetitive exposure to traumatic memories) but greater effectiveness over the long term, because therapeutic exposure is thought to lead to permanent change in the rape memory, thus producing durable gains.

Psychodynamic Therapy

Horowitz et al. (1973, 1986; Horowitz & Kaltreider, 1980) present a psychodynamic formulation of stress response syndromes characterized by

two psychological states; one is typified by intrusive experiences, the other by denial and numbing. Psychodynamic interventions for PTSD tend to focus on tailoring treatment to symptoms and context and thus vary depending on whether the patient is experiencing intrusive or avoidance symptoms. When intrusive symptoms predominate, the immediate goal of treatment is to bring those symptoms under control. Mild intrusive symptoms may respond to social and informational "reassurances" in the form of relevant educational presentations and debriefing groups (DeWitt, 1990). As symptoms become more severe, more individual and intensive approaches are necessary, and "covering" techniques (i.e., reducing exposure) such as supportive measures and stress management approaches are appropriate.

When avoidance symptoms predominate, interventions are aimed at removing blocks to processing and encouraging encounter with the event. As noted by DeWitt (1990), an important aspect of brief dynamic therapy is the concept of *dosing*, in which the person is encouraged to approach ideas and feelings at tolerable levels for reasonable time periods, turning away and then returning to the traumatic memories until they become more manageable. At this stage, "uncovering" techniques (i.e., increasing exposure) such as psychodrama and imagery are recommended. Once intrusive and avoidance systems are within manageable limits, the full meaning of the event can be explored and worked through. Since its introduction more than two decades ago, Horowitz's brief phase-oriented approach to treating stress response syndromes has evolved into one of the most frequently employed clinical interventions for PTSD (Fairbank & Nicholson, 1987; Marmar & Freeman, 1988).

Two uncontrolled evaluations of this approach reported findings that provide modest support (Horowitz, Marmar, Weiss, DeWitt, & Rosenbaum, 1984; Lindy, Green, Grace, Titchener, 1983). A randomly controlled trial condition (Brom, Kleber, & Defares, 1989) found a significant reduction in PTSD symptoms among patients who completed a course of brief dynamic psychotherapy compared to patients assigned to a wait-list control. Brom et al. (1989) also reported that the efficacy of brief dynamic psychotherapy compared favorably with two behaviorally oriented exposure-based treatment conditions: trauma focused desensitization and exposure in imagination

via hypnotherapy. Interestingly, these investigators reported that patients in the two exposure interventions showed superior reductions at post-treatment and follow-up assessment on intrusive symptoms, whereas patients who received brief dynamic psychotherapy showed the best improvement in avoidance symptoms.

Pharmacological Approaches

A substantial body of research demonstrated abnormalities in psychobiological systems and function in persons with PTSD (Friedman, Charney, & Deutch, 1995). The strongest evidence shows alteration of adrenergic and hypothalamic-pituitary-adrenocortical (HPA) mechanisms, elevated physiological reactivity, and sleep disturbances (Bremner, Southwick, & Charney, 1999; Friedman, Davidson, Mellman, & Southwick, in press). Many medications have been used to treat specific PTSD symptoms, separately or in combination with psychotherapy. Pharmacological treatments for PTSD have included antidepressants, such as selective serotonin re-uptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs). Other drugs evaluated for their efficacy against specific PTSD symptoms are inhibitors of adrenergic activity, including propranolol and clonidine; benzodiazepines, such as alprazolam (though the patients must be thoroughly evaluated for the potential for substance abuse); and antimanic drugs, including carbamazepine and lithium carbonate (Silver, Sandberg, & Hales, 1990). Among drugs applied to the treatment of PTSD, the most widely studied and most widely prescribed are antidepressants. Antidepressants are the only drugs that have been tested for PTSD outcome efficacy under double-blind experimental conditions.

Several randomized clinical trials examined the efficacy of SSRIs (fluoxetine and sertraline) for reducing symptoms of PTSD (Brady et al., 1998; Davidson et al., 1997; van der Kolk et al., 1994). A majority of the studies found that SSRI treatments led to more improvement in PTSD symptoms than a placebo. Several studies of the PTSD efficacy of older antidepressants (MAOIs and TCAs) reported significant effects (e.g., Davidson et al., 1990; Frank et al., 1988), whereas other double-blind comparisons of antidepressants and placebo have reported no differences in PTSD treatment efficacy (Reist et al. 1989; Shestatsky et al., 1988).

Although findings on the outcome efficacy of TCA and MAOI antidepressant medications for PTSD are mixed, evidence from clinical trials indicates that the SSRI antidepressants are currently the most efficacious drug treatment for PTSD (Friedman et al., in press).

Eye Movement Desensitization and Reprocessing (EMDR)

Eye movement desensitization and reprocessing (EMDR) is a relatively new treatment for PTSD in which patients are asked to focus attention on certain distressing aspects of the relevant traumatic memory while simultaneously following the movements of the clinicians' finger in front of their visual fields (Chemtob, Tolin, van der Kolk, & Pitman, in press; Shapiro, 1995). More specifically, the patient is instructed to select (1) a disturbing image associated with the memory, (2) a negative cognition associated with the memory, and (3) associated bodily sensations, and to try to keep these in mind during the eye movement procedure. The procedure is then repeated until the distress surrounding the memory decreases and until more adaptive cognitions develop regarding the experience. In addition, the eye movement procedure is used for installing new adaptive behaviors, coping strategies, and alternative positive cognitions.

In randomly controlled trials, EMDR has been shown to have greater efficacy for treating PTSD than no treatment (wait-list control), standard care, and some active treatments. However, such empirical support for the efficacy of the overall process does not necessarily imply support for the idea that the eye movement component is critical to the clinical effects. In fact, randomized dismantling studies to date have provided little support for the postulated role of the eye movements. More specific identification of the beneficial components of EMDR will require additional dismantling studies of sufficiently rigorous design (Chemtob et al., in press).

Crisis Counseling

Crisis counseling is a supportive intervention that provides traumatized individuals with a forum to express feelings about the event within a non-judgmental environment. Crisis counseling is frequently provided to victims of violent crimes,

such as rape or sexual assault, as well as to survivors of natural and manmade disasters (Kilpatrick & Veronen, 1983; Sowder, 1985). General characteristics of crisis counseling are (1) it is time limited and issues oriented, (2) the counselor responds to the crisis request of the victim, (3) the counselor responds to the crisis-related problems and not to other problems, and (4) the counselor takes an active role in initiating follow-up contacts (Burgess & Holmstrom, 1974; Kilpatrick & Veronen, 1983). This approach is often carried out by peer counselors who offer support, information, and empathy to the victim. Hartsough and Myers (1985) emphasized that providing crisis counseling to victims can be stressful for the provider, and they outlined a training program for providers to minimize these effects.

Family Considerations

In addition to the effects of PTSD on those who have the disorder, PTSD also affects family members and others (Danieli, 1998). For example, studies of the families of Holocaust survivors (Bergman & Jucovy, 1982; Danieli, 1985; Solomon, 1998; Yehuda et al., 1998), survivors of the atomic bombing of Japan during World War II (Tatara, 1998), refugees and internally displaced persons (Kinzie, Boehnlein, & Sack, 1998; Rousseau & Drapeau, 1998), and veterans of armed conflicts (Rosenheck & Nathan, 1985; Rosenheck & Fontana, 1998) demonstrated transgenerational effects on the children of survivors. Rosenheck and colleagues (Rosenheck & Nathan, 1985; Rosenheck & Fontana, 1998) similarly described a process they called "secondary traumatization" among some children of combat veterans, in which the child develops symptoms that mirror those of the veteran father. Davidson, Smith, and Kudler (1989) found that children of veterans with PTSD were at increased risk of developing psychiatric or behavioral problems, particularly hyperactivity/attention-deficit problems.

Findings with clinical studies of veterans with PTSD suggest important impacts on family relationships. Solomon, Mikulincer, Fried, and Wosner (1987) showed that levels of family cohesion and expressiveness were inversely related to the severity of PTSD symptomatology among Israeli veterans who suffered combat stress reactions. Verbosky and Ryan (1988) found increased levels of stress among wives of veterans with PTSD.

Roberts, Penk, Gearing, Robinowitz, Dolan, and Patterson (1982) found more difficulties in the areas of intimacy and sociability among Vietnam veterans with PTSD, whereas Carroll, Rueger, Foy, and Donahoe (1985) reported that Vietnam veterans with PTSD admitted more global relationship problems, problems with self-disclosure and expressiveness, and physical aggression toward their partners than non-PTSD help-seeking Vietnam veterans.

Findings from the NVVRS community sample confirm many of these clinical and research observations. Reporting on findings from interviews with the spouses/partners of a national sample of Vietnam veterans, Jordan et al. (in press) described markedly elevated levels of problems in marital and family adjustment, parenting skills, violent behaviors, and child behavior in families of male Vietnam veterans with PTSD.

Results of these early investigations reveal the need for a comprehensive treatment plan to take account of the individual patient's family situation and the needs of the patient's family members. For example, Figley (1988) outlined a five-phased approach to the treatment of PTSD in families that emphasized developing a shared understanding of the problem and the joint development and acceptance by the family of a "healing theory" (see Figley, 1983).

Community-Level Interventions

Clinical or therapeutic interventions for PTSD focus on the cure or care of the individual patient. Community psychology and public health interventions for PTSD focus on preventing and controlling exposure to traumatic stress and ultimately on the psychological sequelae of such exposures in the community. Integrated clinical and community strategies are needed to address the complex matrix of issues involved in providing appropriate and potentially effective PTSD prevention and treatment services to populations that have been exposed to traumatic events or are at risk of such exposures. The area of youth violence prevention is a good example of an evolving comprehensive approach based on community and clinical treatment models. Currently a repertoire of violence prevention strategies exists that operate at different levels of intervention (community programs, school programs, peer training programs, family interventions, individual treatment).

Summary and Conclusions

PTSD is an anxiety disorder that occurs in some individuals who were exposed to traumatic events. Traumatic events are defined in the DSM-IV as experiences that (1) "involve actual or threatened death or serious injury, or a threat to the physical integrity of oneself or others" and (2) produce feelings of "intense fear, helplessness, or horror" (American Psychiatric Association, 1994, pp. 427–428). PTSD is characterized by three kinds of symptoms: reexperiencing symptoms, avoidance and numbing symptoms, and symptoms of increased arousal. The best available estimates suggest a lifetime prevalence of PTSD in the general adult population of the United States between 7 and 12% (Breslau et al., 1991, 1998; Kessler et al., 1995). At the same time, epidemiologic studies in the United States indicate that more than half of the population is likely to be exposed to potentially traumatic events at some time in their lives. Taken together these findings suggest that most people exposed to potentially traumatic events will not develop PTSD. Thus, researchers have attempted to identify risk factors that affect the likelihood of developing PTSD following exposure to such events.

The bulk of the research evidence to date is consistent with an etiologic model of PTSD that posits a role for preexposure factors (potentially including biological, psychological, and socio-cultural factors), a role for characteristics of the stressor, and a role for postexposure variables. The most frequently identified preexposure risk factors for PTSD include female gender, preexisting psychiatric disorder, prior exposure to trauma, and a family history of psychopathology. The nature and characteristics of the stressor exposure are another important determinant of the likelihood of developing PTSD, and some stressors such as rape or those that involve both perceived life threat and injury are associated with comparatively high rates of PTSD. The role of postexposure factors in the development of PTSD has not been as well studied; however, postexposure social support and conflict are potential moderators. Although epidemiologic studies have provided valuable information about risk factors for PTSD and trauma exposure, additional research is required to improve our understanding of the relationships among these variables and the processes through which they affect the development and *course* of PTSD.

Studies consistently find that the experience of other psychiatric disorders is common among individuals with PTSD. The most frequent comorbid disorders are major depression, substance abuse disorders, and other anxiety disorders. However, data from general population studies typically pertain to lifetime disorder rather than current comorbidity. Additional research is needed to determine the extent to which psychiatric comorbidities among individuals with PTSD are (1) artifactual, reflecting overlapping diagnostic criteria; (2) exacerbations of preexisting pathology; (3) part of an overall syndrome of response to traumatic events, including reactions to PTSD symptoms; or (4) independent disorders.

The PTSD assessment literature has burgeoned considerably during the past decade. Of particular note are the advances in the development of (1) measures for nonveteran populations and children and (2) instruments designed to obtain a comprehensive trauma history. Additionally, the utility of psychophysiological measures to assess PTSD has been demonstrated with some nonveteran populations, and researchers have refined their understanding of the response channels that are most beneficial to include in psychophysiological batteries. Although the literature on neuropsychological testing is not as mature, such testing can serve as a useful adjunct for treatment planning in PTSD. Despite these considerable advances, state-of-the-art assessment of PTSD should continue to use multiple assessment strategies and sources of data to confirm or rule out a diagnosis of PTSD as well as to assess for other comorbidities and other indicators of functional status. Future efforts focusing on further elucidating the neurobiological underpinnings of PTSD have the potential to produce more objective and biological diagnostic measures of PTSD.

Findings from randomly controlled trials provide strong evidence that cognitive behavioral therapy (CBT), antidepressant pharmacological agents, and EMDR are efficacious treatments for PTSD. Much more research is needed, however, to clarify the active components of treatment for PTSD. At present, the science of PTSD treatment and trauma prevention has yet to determine which types and levels of treatment are most effective for which populations of trauma survivors. We still lack essential information on the relative effectiveness of the various approaches to PTSD treatment in different communities, cultures, and

political, economic and religious traditions, and systems.

CHAPTER 9

Somatoform and Factitious Disorders

**Tony Iezzi, Melanie P. Duckworth,
and Henry E. Adams**

Introduction

Although somatoform and factitious disorders have been recognized throughout the years and have received considerably more empirical attention during the last 10 years, these disorders continue to represent categories of psychiatric disturbances that are highly misunderstood. This is not surprising for a number of reasons. The empirical database for these disorders continues to be inadequate and largely dated. This group of disorders still relies heavily on an either/or (e.g., organic versus psychogenic) conceptualization of psychopathology. The diagnosis of some of these disorders is largely by exclusion and based more on a collection of symptoms rather than signs. The symptom cutoffs or thresholds that indicate the presence or absence of a disorder are somewhat arbitrary. The etiology and symptomatology are sometimes treated as the same. Still, despite these problems, these disorders continue to fascinate researchers, clinicians, and laypersons alike.

According to the 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; American Psychiatric Association [APA], 1994), somatoform disorders are characterized by physical symptoms that suggest a general medical condition but are not fully explained by a general medical condition, by the direct effects of a substance, or by another mental disorder. To be considered a somatoform disorder, these physical symptoms need to cause significant emotional distress and impairment in social, occupational, or other areas of functioning. The somatoform disorders section of the DSM-IV include somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, body dysmorphic disorder, and somatoform disorder not otherwise specified.

Unlike somatoform disorders, where physical symptoms, it is believed, occur unintentionally, factitious disorders are characterized by physical or psychological symptoms that are intentionally induced or feigned. In contrast to malingering, where the presumed goal is to accomplish an externally recognizable objective (e.g., obtaining financial compensation or avoiding unpleasant tasks), the presumed goal of factitious behavior is to assume the "sick role." Factitious disorders in DSM-IV (APA, 1994) are subcategorized as factitious disorder with predominantly psychological signs and symptoms, factitious disorder with predominantly physical signs and symptoms, and factitious disorder with combined psychological and

physical signs and symptoms. Clinical descriptions, diagnostic requirements, theoretical issues, and relevant research pertaining to the identification and management of individual somatoform and factitious disorders are reviewed in the following sections.

Somatoform Disorders

Somatization Disorder

Broadly defined, somatization is a term that covers a broad range of physical symptoms that occur in the absence of organic pathology or the amplification of bodily sensations that accompany physical conditions beyond those that can be explained by organic pathology (Barsky & Klerman, 1983; Ford, 1986; Katon, 1982; Kellner, 1985; Lipowski, 1988). Somatization has also been defined as a bodily or somatic expression of psychic distress (Barsky & Klerman, 1983; Ford, 1986; Katon, 1982; Kellner, 1985; Lipowski, 1988). In other words, patients who ought to be complaining of problems in daily living often focus on bodily sensations and seek a medical cure for these problems. For example, it is easier for these patients to say to a physician "my back hurts" than it is to say "I want to die because my life has no meaning."

The history of somatization disorder is intimately tied to the history of hysteria. Although the origins of somatization can be attributed to Sydenham in 1682 and Sims in 1799 (Lipowski, 1988), it was not until 1856 that Paul Briquet published his oft-quoted classical study on hysteria that somatization was more firmly established (Lipowski, 1988; Mai & Merskey, 1980, 1981; Nemiah, 1985). Briquet's work is contained in a 700-page compendium that describes and categorizes symptoms of 430 patients seen during a 10-year period. Except for a handful of patients, most of the cases he studied were women. According to Briquet's conceptualization, hysteria resulted from stress or stimuli that affect the central nervous system of susceptible individuals, causing a plethora of physical symptoms. He conceptualized this syndrome as a form of hysteria, but it is clear from some of his descriptions that he also captured elements of conversion reactions.

In 1909, Briquet's work was followed by Thomas Saville's study of 500 hysterical patients (Nemiah, 1985). Adopting Briquet's methodology and con-

ceptualization, Saville came to similar conclusions about hysteria. The term somatization was first used by Steckel (1943), who defined somatization as a bodily disorder that arises out of a deep-seated neurosis and as a disease of the conscious. Purtell, Robins, and Cohen (1951) later rediscovered the ideas of Briquet and Saville, but their study also emphasized the dramatic, vague, and exaggerated manner in which these patients described their symptoms.

The study of somatization culminated in extensive phenomenological studies conducted by Guze and his colleagues at Washington University in St. Louis (Arkonac & Guze, 1963; Cloninger & Guze, 1970; Gatfield & Guze, 1962; Guze, 1983; Guze, Kloninger, Martin, & Clayton, 1986; Guze, Tuason, Gatfield, Stewart, & Picken, 1962; Guze, Wolfgram, McKinney, & Cantwell, 1967; Guze, Woodruff, & Clayton, 1971a,b; Perley & Guze, 1962; Woerner & Guze, 1968). These studies were aimed at defining relatively distinct psychiatric disturbances in terms of characteristics, phenomenology, natural history, prognosis, treatment response, and family history. The emergence of somatization disorder was primarily out of a controversy in the mid-1960s between Samuel Guze and Elliot Slater, then the editor of the *British Journal of Psychiatry*. Guze's work on hysteria was seriously questioned by Slater and Glithero's (1965) classical study. As Guze (1983) stated, it was because of Slater's influence and in an attempt to reduce confusion surrounding hysteria, that he renamed hysteria after Briquet. In 1971, hysteria became known as Briquet's syndrome (Guze et al., 1971a). Over the years, Guze and his associates and others were able to demonstrate that Briquet's syndrome had excellent diagnostic stability (Perley & Guze, 1962), a high degree of reliability (Spitzer, Endicott, & Robins, 1978), and good validity (Guze, 1975). Briquet's syndrome was conceived as a polysymptomatic syndrome that begins early in life, occurs primarily in women, and is associated with marital problems, poor work history, teenage delinquency, alcohol problems, and sociopathy in first-degree relatives (Guze, 1983).

Diagnosis. As a diagnostic entity, somatization disorder is a fairly recent addition to the DSM nomenclature and was intended as a simplified version of Briquet's syndrome. Somatization disorder was officially recognized in DSM-III (APA, 1980) and was also included in DSM-III-R (APA,

1987) with some minor changes. Before DSM-III, the criteria for Briquet's syndrome required at least twenty-five of sixty physical symptoms without clear organic explanation from at least nine out of ten symptom groups (Perley & Guze, 1962). It should be emphasized that the number of symptoms required for somatization disorder had been established arbitrarily rather than empirically. In an attempt to be nonsexist, DSM-III-R required the presence of at least thirteen physical symptoms for both men and women; in DSM-III, the diagnosis of somatization disorder required twelve physical symptoms for men and fourteen physical symptoms for women. The DSM-IV (APA, 1994) requires eight physical symptoms to diagnose somatization disorder. The current diagnostic criteria for somatization disorder are listed in Table 1.

The criteria for somatization disorder proposed in DSM-IV have fared well in DSM field trials. Yutzy et al. (1995) examined the concordance between the proposed diagnostic criteria for DSM-IV somatization disorder and DSM-III-R, DSM-III, Perley-Guze, and the International Classification of Diseases-10 (ICD-10) criteria in 353 female patients recruited from five sites; recruitment procedures were designed to maximize sociocultural, ethnic, and geographic diversity. The ICD-10 criteria agreed poorly with all other diagnostic sets including DSM-IV, which is consistent with other work (Rief & Hiller, 1998). Yutzy et al. (1995) found that the DSM-IV criteria were an accurate and simpler method for diagnosing somatization disorder and had excellent concordance with DSM-III-R criteria. The authors reported that the DSM-IV criteria did not require special expertise in administration. Of note, no racial differences were observed as a result of any of the criteria sets used. However, the determination of which criteria are best in diagnosing somatization disorder depends on the specificity and sensitivity of the criteria (Bucholz, Dinwiddle, Reich, Shayka, & Cloninger, 1993). Sensitivity is defined by the proportion of true cases correctly classified, and specificity is defined by the proportion of true noncases classified. Bucholz et al. (1993) compared the sensitivity, specificity, and positive predictive value (proportion of test positives who are truly positive) of DSM-IV criteria, a DSM-III-R seven-item symptom screen, and Swartz, Blazer, George, and Landerman's (1986) eleven-item screen. The authors found that no one set of criteria was clearly superior and that selection criteria should be based

Table 1. DSM-IV Criteria for Somatization Disorder

-
- A. A history of many physical complaints beginning before age 30 years that occur over a period of several years and result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning.
- B. Each of the following criteria must have been met, with individual symptoms occurring at any time during the course of the disturbance:
- (1) *four pain symptoms*: a history of pain related to at least four extremities, chest, rectum, during menstruation, during sexual intercourse, or during urination)
 - (2) *two gastrointestinal symptoms*: a history of at least two gastrointestinal symptoms other than pain (e.g., nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance of several different foods)
 - (3) *one sexual symptom*: a history of at least one sexual or reproductive symptom other than pain (e.g., sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy)
 - (4) *one pseudoneurological symptom*: a history of at least one symptom or deficit suggesting a neurological condition not limited to balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, urinary retention, hallucinations, loss of touch or pain sensation, double vision, blindness, deafness, seizures; dissociative symptoms such as amnesia; or loss of consciousness other than fainting)
- C. Either (1) or (2)
- (1) after appropriate investigation, each of the symptoms in Criterion B cannot be fully explained by a known general medical condition or the direct effects of a substance (e.g., a drug of abuse, a medication)
 - (2) when there is a related general medical condition, the physical complaints or resulting social or occupational impairment are in excess of what would be expected from the history, physical examination, or laboratory findings
- D. The symptoms are not intentionally produced or feigned (as in Factitious Disorder or Malingering)
-

on the intended application. For example, the results indicated that DSM-IV criteria for somatization disorder had almost perfect specificity and the highest predictive value of all screening sets, but sensitivity calculations yielded 33 to 50% missed cases.

Clinical Description. A somatizing patient may present with many symptoms referred to any body part or organ system, and these symptoms may indicate any type of disease entity, but none of the physical symptoms of somatization disorder are pathognomonic. The clinician working with somatizers needs to be aware that multiple physical symptoms, in and of themselves, do not imply psychopathology. Furthermore, the diagnosis of somatization does not preclude the patient from experiencing true pathological conditions. For example, the co-occurrence of somatization and a medical disorder has been noted in the following conditions: cardiovascular disease (Bass & Wade, 1984), chronic fatigue syndrome (Manu, Lane, & Matthews, 1989), and fibromyalgia (Walker, Keegan, Gardner, Sullivan, Katon, & Bernstein, 1997).

Pain is by far the most common complaint of somatizers, especially pain involving the back, neck, head, pelvis, abdomen, and diffuse muscle aches (Ford, 1986; Iezzi, Stokes, Adams, Pilon, & Ault, 1994; Katon, Ries, & Kleinman, 1984a; Lipowski, 1988). Complaints of fatigue, shortness of breath, dizziness, and palpitations are also common. The presentation of symptoms is often elaborate, involving obsessively detailed symptom descriptions, but the chronology itself can be very vague.

Nemiah (1985) presents a thorough description of behaviors observed in the somatizer. He noted that somatizers are often exhibitionistic, particularly in terms of overly made-up or overdressed women. These individuals tend to be more revealing of their bodies in session and during physical examinations than necessary. Somatizers display an excessive preoccupation with themselves at the expense of others and, though this is not apparent at first, are highly dependent individuals. They demonstrate a wide range of affect that at times can be bewildering to the clinician. These patients are often perceived as flirtatious and seductive, but evaluation of sexual functioning frequently finds that they are tolerant at best, if not indifferent, toward sex. Somatizers are especially skilled at manipulating family, friends, and the health care system to meet their needs. They are prone to

suicide attempts but rarely follow through successfully.

Somatizers frequently have a history of multiple hospitalizations and surgeries. These patients represent a major source of health care utilization (Miranda, Perez-Stable, Munoz, Hargreaves, & Henke, 1991). An estimated 50% of ambulatory health care costs in the United States has been attributed to somatizers (Barsky & Klerman, 1983; Kellner, 1985). In 1980, the per capita expenditure of health care costs for hospital services was \$543 for the average consumer, whereas it was \$4,700 for somatizing patients (Smith, Monson, & Ray, 1986a). Interestingly enough, despite the multiple symptom presentation of somatizers, somatization disorder is not associated with increased mortality (Coryell, 1981).

In addition to multiple somatic symptoms, somatizers also present with a diversity of psychological and psychosocial complaints. Depression and anxiety are prominent features in somatizers. Although patients with somatization disorder appear heterogeneous, they all share one essential feature: a predominant pattern of somatic, rather than cognitive, response to emotional arousal (Lipowski, 1988). Barsky, Wyshak, and Klerman (1986) went even further in stating that somatic symptoms represent a final common pathway through which emotional disturbances, psychiatric disorders, and pathophysiological processes all express themselves and cause the patient to seek medical care.

Psychosocially, somatizers come from inconsistent, unreliable, and emotionally unsupportive family environments (Mai & Merskey, 1980). Physical and sexual trauma are common among somatizers (Kinzl, Traweger, & Biebl, 1995; Leserman, Zhiming, Drossman, Toomey, Nachman, & Glogau, 1997; McCauley et al., 1997; Walker, Keegan, Gardner, Sullivan, Bernstein, & Katon, 1997). Marital discord, separation, and divorce are also frequently observed. Because of their incapacitating symptomatology, somatizers often have poor occupational histories. Interpersonally, relationships with somatizers tend to be shallow and chaotic.

Epidemiology and Demographics. The estimated prevalence of somatization ranges from relatively uncommon (Fabrega, Mezzich, Jacob, & Ulrich, 1988; Swartz et al., 1986) to very common (Barsky & Klerman, 1983; Kellner, 1985). It has been estimated that 20 to 84% of patients seen

by primary care physicians suffer from idiopathic somatic complaints (Barsky & Klerman, 1983; Kellner, 1985). The prevalence of somatization tends to be higher in primary care facilities (Barsky & Klerman, 1983; Kellner, 1985; Kirmayer & Robbins, 1991, 1996) than in psychiatric facilities (Fabrega et al., 1988). Several studies have examined prevalence rates of somatization disorder in the community at large. Prevalence estimates of somatization disorder in the community ranged from 0.06 to 0.6% (Blazer et al., 1985; Escobar, Burnam, Karno, Forsythe, & Golding, 1987; Robins et al., 1984; Swartz et al., 1986).

DSM-IV (APA, 1994) states that the prevalence of somatization disorder is 0.2 to 2% among women and less than 0.2% in men. In the Epidemiological Catchment Area Study (Robins & Regier, 1991), somatization disorder was most prevalent among African-American women (0.8%) followed by African-American men (0.4%); however, race is not a mediating variable in somatization disorder (Swartz, Landerman, Blazer, & George, 1989; Yutzy et al., 1995). Using DSM-III-R criteria for somatization disorder, Kroenke and Spitzer (1998) examined gender differences in the reporting of physical symptoms. One thousand patients from four primary care sites were evaluated with the Primary Care Evaluation of Mental Disorders Interview. After controlling for depressive and anxiety disorders, age, race, education, and medical comorbidity, results revealed that twelve out of thirteen physical symptoms were more commonly reported by women (odds ratio ranged from 1.5 to 2.5), and the reporting differences were statistically significant for ten of the thirteen physical symptoms. The authors concluded that increased symptom reporting in women may be a generic phenomenon rather than about specific symptoms, that medically unexplained symptoms are more common in women, and that the effect of gender on symptom reporting is independent of psychiatric comorbidity.

The notion used to be generally held that somatization was more common in non-Western cultures, but this view is no longer held (Kirmayer & Young, 1998). Although the prevalence and specific features of somatization may vary across cultures, the presentation of somatic symptoms as an expression of emotional distress is worldwide. In a cross-cultural study of somatization disorder, consecutive primary care patients (N = 25, 916) were screened using the General Health Question-

naire, and a stratified sample of 5438 patients was interviewed with the Composite International Diagnostic Interview (Gureje, Simon, Ustun, & Goldberg, 1997). Patients were recruited from fourteen countries: Turkey, Greece, India, Germany, Netherlands, Nigeria, United Kingdom, Japan, France, Brazil, Chile, United States, China, and Italy. Across all cultures, somatization was a common problem in primary care settings and was associated with significant health problems and functional disability. Thus, the prevalence of somatization disorder depends much on the clinical setting, patient sample, and definition of somatization used.

Somatization disorder is reportedly more common in individuals from lower socioeconomic status, lower educational level, and rural background (Barsky & Klerman, 1983; Escobar, Rubio-Stipec, Canino, & Karno, 1989; Swartz et al., 1986). Although Swartz and his associates (1986) found an increased rate of somatization disorder in rural areas, in another study they found an increased prevalence of somatization disorder in urban areas (Swartz et al., 1989). Thus, the role of rural versus urban background in somatization disorder remains to be clarified. The age of onset of somatization disorder is usually in early childhood and adolescence (Campo & Fritsch, 1994; Garralda, 1996; Kriechman, 1987; Livingston & Martin-Cannici, 1985; Terre & Ghiselli, 1997). By definition, somatization disorder has to occur before the age of 30.

Etiological Formulations. Somatizers are a physically and psychiatrically heterogeneous group. The diversity in the clinical manifestations of somatizers suggests multifactorial etiology. Dominant etiological factors in one patient may be fleeting or minor in another patient. The predisposing factors in somatization disorder are likely to include genetic, neuropsychological, neurophysiological, and psychophysiological, developmental learning, personality trait, and sociocultural formulations.

Genetic. Guze and his associates have been instrumental in proposing a multifactorial model of disease transmission in somatization disorder (Cloninger, Reich, & Guze, 1975a,b; Guze, 1983; Reich, Cloninger, & Guze, 1975). According to their model, hysteria (i.e., somatization disorder) and sociopathy cluster in the same families. Hysteria in women is believed to be a more prevalent and less deviant form of the same process that

causes sociopathy in women. Based on their research, hysterics and sociopaths mate assortatively, thereby increasing the observed similarities among relatives, but this familial clustering does not completely depend on assortative mating. Other studies have noted an increased prevalence of 20% of somatization disorder in first-degree relatives of index cases (Cloninger & Guze, 1970; Guze, Cloninger, Martin, & Clayton, 1986; Woerner & Guze, 1968) and an increased rate of marital problems, poor occupational history, social dysfunction, teenage delinquencies, alcohol problems, and sociopathy in first-degree relatives of patients (Guze et al., 1971b). Adoption studies yielded similar findings (Bohman, Cloninger, Von Knorring, & Sigvardsson, 1984; Cloninger, Sigvardsson, Von Knorring, & Bohman, 1984; Sigvardsson, Von Knorring, Bohman, & Cloninger, 1984). Although the pattern of findings from these studies is very impressive, it is very unlikely that genetics alone accounts for somatization disorder.

Psychodynamic. Psychoanalysts view somatization as a form of symbolic communication, defense mechanism, and conflict resolution (Kellner, 1990). Somatization is a process whereby the body translates mental stress into physical expressions that have symbolic value (Steckel, 1943). The process of somatization also represents primitive defense mechanisms, like denial and repression, against undesirable wishes or urges. Finally, as a means to resolve conflict, somatizers blame their failures on their bodily symptoms or focus on their symptoms to avoid intolerable situations. As intuitive as the psychodynamic conceptualization of somatization is, it remains extremely difficult to test or validate.

Neuropsychological, Neurophysiological, and Psychophysiological. A number of studies propose a neuropsychological, neurophysiological, psychophysiological formulation of somatization disorder (Flor-Henry, Fromm-Auch, Tapper, & Schopflocher, 1981; Gordon, Kraihuhin, Meares, & Howson, 1986; James et al., 1987; Wickramasekera, 1989). Comprehensive neuropsychological examination, auditory evoked-response potentials, and cerebral blood flow studies of patients with somatization disorder demonstrated that these individuals display excessive distractibility, an inability to habituate to repetitive stimuli, and cognitive functioning characterized as concrete, partial, and circumstantial. These findings are associated with bilateral frontal and right hemisphere dysfunction. Another study examined the

laterality of symptoms in sixty-one patients with depressive, anxiety, and somatoform disorders (Min & Lee, 1997). The authors found that somatic complaints, especially pain, together with other somatic complaints, occurred more often on the left side of the body. They concluded that the right hemisphere of the brain is more involved in somatization symptom formation than the left hemisphere; however, causal statements about the relationship between symptom formation and brain hemisphere cannot be made. Most recently, Wickramasekera (1989) developed a high-risk model of threat perception that identifies three major risk factors for developing somatization. He found that patients who have high hypnotic ability, low hypnotic ability, or who are high on social desirability are most prone to developing somatization and other psychophysiological disorders. Chronic pain subjects high on one or more of these risk factors evidenced higher skin conductance in response to cognitive threat (mental arithmetic; Wickramasekera, Pope, & Kolm, 1996). These studies, however, need to be replicated with more sensitive designs and larger samples sizes to determine the stability of these results.

Personality Trait. Personality characteristics, like the tendency to amplify bodily sensations, to focus excessively on physical symptoms, and to misinterpret physical symptoms may predispose individuals to somatization (Barsky & Klerman, 1983). Somatization may also reflect a form of "neuroticism" (Lipowski, 1988). Somatizers score high on measures of neuroticism such as self-consciousness, vulnerability to stress, low self-esteem, anxiety, depression, and hostility. Somatization has also been associated with negative affectivity (Kirmayer, Robbins, & Paris, 1994; Rief & Hiller, 1998; Watson & Pennebaker, 1989). The tendency to misinterpret bodily sensations or to overreact to minor bodily sensations as disabling has been interpreted as an enduring personality trait. The term alexithymia (Sifneos, 1973) also describes a personality trait that is apparently common among individuals with psychosomatic disorders. Patients with alexithymia have difficulties expressing affect, their fantasies tend to be devoid of feelings and emotions, and their thinking is characterized primarily by concrete operations rather than abstract operations. Although Shipko (1982) reported a positive relationship between somatization and alexithymia, it is unclear whether alexithymia is really a manifestation of an emotional state, a cognitive style, or a form of repression and

denial (Kellner, 1990). More recent data suggests that somatization and alexithymia are independent of each other (Bach & Bach, 1995; Bach, Bach, & Zwann, 1996).

Developmental Learning. Childhood experiences that involve exposure to models with frequent complaints of pain play an instrumental role in childhood somatization (Kellner, 1990; Lipowski, 1988). Children who learn early that being ill or complaining of symptoms is likely to be rewarded with attention and sympathy or to lead to avoidance of conflict and responsibilities will be predisposed toward somatization as a coping style (Campo & Fritsch, 1994; Craig, Drake, Mills, & Boardman, 1994; Garralda, 1996). Later, as adults, these individuals maintain their behavior because of secondary gain and social reinforcement. The relationship between pain behavior and role models has received support in children with recurrent abdominal pain (Walker, Garber, & Zeman, 1991), headache (Deubner, 1977), and low back pain (Rickard, 1988). Family environment has also been implicated in the development of somatization. Sherry, McGuire, Mellins, Salmonson, Wallace, and Nepom (1991) found two predominant abnormal family milieus present in 100 children with musculoskeletal pain. One family environment could best be described as cohesive, stable, organized but intolerant of separation and individuation. The second predominant family milieu was characterized as chaotic, emotionally unsupportive, and highly conflictual. In a healthy sample of 933 subjects, ages ranging from 6–16, an examination of the relationship between family environment and physical health complaints indicated that disorganized and less cohesive family environments were associated with more health complaints (Terre & Ghiselli, 1997). In a two-year longitudinal study, parental lack of care was the best predictor of adult somatization (Craig, Boardman, Mills, Daly-Jones, & Drake, 1993). Finally, Livingston, Witt, and Smith (1995) found that parental somatization, substance abuse, and antisocial symptoms predicted children's somatization. In addition, children of adults with DSM-III-R somatization disorder had 11.7 times more emergency room visits and missed 8.8 times more school than children of adults with few unexplained somatic symptoms.

Sociocultural. Sociocultural aspects of somatization have received considerable attention (Brodsky, 1984; Goldberg & Bridges, 1988; Katon, Kleinman, & Rosen, 1982; Kirmayer & Young,

1998). As noted earlier, somatization is a worldwide phenomenon. Sociocultural aspects of somatization may really reflect differences in the way individuals somatize rather than psychologize their distress as a coping response (Goldberg & Bridges, 1988). In other cultures (e.g., Ayurveda or Chinese), the distinction between body and mind is usually not made (Kirmayer & Young, 1998). Especially within the Western culture, somatization and psychologization tend to be seen as mutually exclusive response styles. However, even Western societies are increasing their rates of somatization, despite the greater quality of medical care (Gureje, Simon, et al., 1997; Kirmayer & Young, 1998). It will be interesting to observe whether, with the advent of managed care in Western societies, the frequency and expression of somatization will change.

Somatization and Associated Psychopathology. Given the heterogeneous nature of somatization disorder, the process of somatization is associated with a spectrum of affective, personality, and thought disorders. In a large community study (N = 11,519), 24.6% of respondents experienced the co-occurrence of somatization disorder and depression (Boyd et al., 1984). From this same study, individuals with somatization disorder also had a 96.5% chance of having panic disorder and a 27.3% risk of having agoraphobia. In examining 100 consecutive somatizing patients, Katon, Ries, and Kleinman (1984b) noted that somatizers were more likely to suffer from depression (48%), personality disorder (37%), psychogenic pain disorder (11%), psychophysiological illness (9%), and panic disorder (4%) than a nonsomatizing group referred for psychiatric consultation. Sixty-one percent of females and 33% of males in a sample of fifty-five panic disorder cases displayed somatization (Katon, 1982).

The prevalence of somatization disorder in the presence of other DSM-IV Axis I and Axis II disorders has been documented in the context of epidemiological studies, as well as in studies of primary care facilities. Brown, Golding, and Smith (1990) calculated lifetime prevalence rates for comorbid disorders in 119 DSM-III-R somatization patients referred to primary care physicians. The most prevalent comorbid diagnoses were major depression (54.6%), generalized anxiety disorder (33.6%), phobic disorders (31.1%), panic disorder (26.0%), and alcohol abuse/dependence (21.0%).

In a study by Sheehan and Sheehan (1982), 71%

of patients with agoraphobia met the criteria for Briquet's syndrome. The results of Orenstein's (1989) examination of 188 consecutive female psychiatric patients indicated that Briquet's syndrome was associated with a lifetime history of major depression (81%) and a lifetime history of spontaneous panic attacks (69%). Orenstein commented that his results were consistent with a shared diathesis hypothesis underlying some cases of major depression, panic disorder, agoraphobia, and Briquet's syndrome. Moreover, Briquet's syndrome may represent the most extreme expression of a proclivity for physical and psychological syndromes to aggregate.

As part of a large epidemiological study of psychiatric disorders in a community sample of 3783 participants, 77.7% of the sixteen participants with somatization disorder met another concurrent psychiatric diagnosis, compared to 9.7% of patients with a dual diagnosis who did not have somatization disorder (Swartz et al., 1986). The most frequent concurrent diagnoses with somatization disorder included simple phobia (70%), major depression (65%), agoraphobia (64%), obsessive-compulsive disorder (52%), panic disorder (42%), schizophrenia (38%), atypical bipolar disorder (35%), social phobia (30%), alcohol abuse and dependence (17% each), and dysthymia (16%). Whether somatization disorder produces other psychiatric disorders is not known, but as Swartz et al. (1986) noted, by definition, individuals who endorse a plethora of symptoms to yield a diagnosis of somatization disorder are also more likely to endorse other physical and psychological symptoms at a high rate.

Liskow and his associates found a lifetime prevalence of depression in 87%, panic disorder in 45%, and phobic disorder in 39% of seventy-eight women diagnosed with somatization disorder (Liskow, Othmer, Penick, DeSouza, & Gabrielli, 1986). In addition, the prevalence of other psychiatric disturbances was considerable and included the following: obsessive-compulsive disorder (27%), schizophrenia (27%), drug dependence (23%) and drug abuse (17%), and antisocial personality disorder (17%). Using a genetic-epidemiological approach to examine the comorbidity of panic and somatization disorder, 159 outpatients with DSM-III-R panic disorder and seventy-six surgical controls were screened for the lifetime presence of DSM-III-R somatization (Battaglia, Bernadeschi, Politi, Bertella, & Bellodi, 1995).

The investigators found that 23% of women and 5% of men with panic disorder also had somatization disorder at one time. The authors also concluded that panic disorder and somatization disorder may coexist without sharing a common genetic diathesis and that the DSM-IV criteria for somatization disorder are simpler than the DSM-III-R criteria. Along similar lines, in a DSM-IV posttraumatic stress disorder field trial involving 395 traumatized subjects, a strong relationship was evidenced among reports of posttraumatic stress disorder, dissociation, and somatization (van der Kolk, Pelcovitz, Roth, Mandel, McFarlane, & Herman, 1996).

The relationship of histrionic personality disorder and antisocial personality disorder to somatization disorder (Lilienfeld, 1992; Lilienfeld, Van Valkenburg, Larntz, & Akiskal, 1986), as well as the relationship between hysteroid and obsessive features and Briquet's syndrome, has been similarly documented (Kaminsky & Slavney, 1983). Hudziak, Boffeli, Kriesman, Battaglia, Stanger, and Guze (1996) conducted a multisite study that examined the relationship of borderline personality to Briquet's syndrome (hysteria), somatization disorder, antisocial personality disorder, and substance abuse disorders in eighty-seven women (seventy-five from St. Louis and twelve from Milan) who met DSM-III-R borderline personality disorder. Patients were further examined with the DSM-III-R Checklist and the Perley-Guze Hysteria Checklist. Results indicated that every patient had at least one additional DSM diagnosis and patients from St. Louis and Milan averaged five and four additional diagnoses, respectively. Eighty-four percent of the St. Louis sample met criteria for somatization disorder, Briquet's syndrome, antisocial personality disorder, and substance abuse disorders. Patterns of comorbidity included major depression (87%), generalized anxiety disorder (55%), and panic disorder (51%). Two other studies looked at the prevalence of personality disorders and somatization disorder. Rost, Akins, Brown, and Smith (1992) evaluated thirteen personality disorders with the Structured Clinical Interview in ninety-four subjects with DSM-III-R somatization disorder from multiple primary care settings. The data indicated that 23.4% of somatization disorder cases had one personality disorder and 37.2% had two or more personality disorders. The four most common personality disorders included avoidance (26.7%),

paranoia (21.3%), self-defeating (19.1%), obsessive-compulsive (17.1%), and, interestingly enough, histrionic personality disorder (12.8%) and antisocial personality disorder (7.4%). In a small British sample, twenty-five women with somatization disorder were compared to a control group (clinical patients but without somatization disorder) of 25 women using the Personality Assessment Schedule (Stern, Murphy, & Bass, 1993). The prevalence of personality disorders among the somatization disorder group was 72%, compared to 36% in the control group.

In sum, physical and psychological symptoms are common and often co-occur in the same individual. Although considerable data support somatization disorder, there should be concerns when a clinical condition overlaps with many other DSM-IV disorders. Somatization disorder is associated with so many things that it runs the risk of having little discriminatory clinical value.

Prognosis and Treatment. Somatization disorder is a condition with a poor prognosis. The disorder runs a fluctuating course with periodic exacerbations during stressful episodes, but as noted earlier, somatization disorder is not associated with a higher mortality rate than that of the general population (Coryell, 1981). Briquet stated that hysteria was one of the most difficult illnesses to cure (Mai & Merskey, 1980). He reported that one-quarter of hysterics never recover. More dramatically, young girls with hysteria before the age of 12 or 13 were condemned to a lifetime of suffering; if the onset of hysteria occurred after 25 years of age, then the prognosis was more favorable. In another study, only 31% of patients with somatization disorder fully recovered in 15-year follow-up assessments (Coryell & Norton, 1981). Guze and his colleagues noted that 80 to 90% of their cases retained the diagnosis of hysteria 6 to 8 years later (Guze et al., 1986; Perley & Guze, 1962).

Unlike other psychiatric conditions, there is no definitive therapy for all somatizers. From a medical viewpoint, in many respects, the best treatment is no treatment at all. Medical management focuses on early diagnosis and conservative treatment to reduce iatrogenic effects from invasive diagnostics and surgical interventions. A study by Smith, Monson, and Ray (1986b) demonstrated the cost-effectiveness of noninvasive, supportive long-term care of somatization disorder patients by focusing largely on containing their health care utilization. Thirty-eight patients with somatiza-

tion disorder were randomly assigned either to a treatment group (i.e., instructing primary care physicians to see patients in a supportive manner, perform brief physical examinations, and avoid unnecessary hospitalizations) or to a no-treatment control group, and the two groups crossed over 8 months later. The investigators found a 40 to 53% decrease in health care charges for the treatment condition.

Much of the general discussion around treating somatization disorder is geared toward physicians in primary care, because they are most likely to see psychiatric disorders, somatizing or not (Lipowski, 1988). Unfortunately, general practitioners are not equipped to handle this type of patient on their own, and somatizers often refuse psychiatric referral. Reducing the physical distance between the physician's office and the mental health professional by relocating the mental health professional in the physician's office or right next door does much to increase the follow-through on psychological evaluation and possible treatment (Wickramasekera, 1989). The aim of treatment for somatizers is to help them cope with their symptoms, not to cure them. Given the chronic nature of somatization disorder, a rehabilitative approach that consists of comprehensive medical, psychiatric, and psychosocial evaluation and treatment with adequate follow-up to prevent relapses is well suited to somatization disorder.

Psychiatric and psychological management typically has consisted of ego-supportive techniques and has been beneficial in treating somatizers (Kellner, 1990). Several studies described the utility of inpatient and outpatient group therapy with somatization disorder (Abbey & Lipowski, 1987; Bass & Benjamin, 1993; Levine, Brooks, Irving, & Fishman, 1994). Group treatment has consisted of different combinations of therapeutic approaches with varying emphasis on support therapy, problem-solving skills, improving interpersonal relationships, occupational and vocational rehabilitation, physiotherapy, and cognitive-behavioral techniques. However, these studies are generally descriptive instead of evaluative, they are usually uncontrolled studies with poor methodology and small sample sizes, and they tend to lack objective outcome measures.

More recently, Kasher, Rost, Cohen, Anderson, and Smith (1995) conducted a randomized controlled clinical trial of group therapy for seventy somatization disorder patients. The patients as-

signed to the treatment condition were required to attend eight group meetings lasting 2 hours each; these group meetings were held every 2 weeks. Groups of four to six patients were involved in a number of exercises designed to increase peer support, increase communications about coping with physical problems, develop strategies to express emotions more openly, and increase personal risk-taking. The experimental group experienced better physical and mental health in the year following group treatment. The experimental condition also resulted in a 52% net saving in health charges. Employing Kellner's definition for somatization disorder rather than the stricter DSM-IV definition, Lidbeck (1997) assigned fifty somatization disordered subjects either to a treatment condition or to a waiting-list control condition. Using a cognitive-behavioral treatment approach (e.g., stress management, relaxation training, and cognitive restructuring), subjects met for eight, 3-hour meetings. At 6 months follow-up, the treatment group evidenced modest improvement with respect to physical illness, somatic preoccupation, hypochondriasis, and medication usage. Although these two studies of group treatment for somatization disorder (Kasher et al., 1995; Lidbeck, 1997) suffer from a number of threats to internal validity (e.g., small samples sizes, less restrictive definition of somatization disorder, and patients only from primary care facilities), the utility of group treatment for somatization disorder is still worth pursuing. Pharmacotherapy should be avoided whenever possible with somatizers, but judicious use of antidepressants and anxiolytics is helpful (Kellner, 1990; Lipowski, 1988).

Undifferentiated Somatoform Disorder

Undifferentiated somatoform disorder was apparently created to capture a sizable proportion of patients with multiple, chronic, physical symptomatology similar to somatization disorder, but do not meet the eight physical-symptom requirement. This diagnosis is given to persons with one or several medically unsupported physical complaints that are of at least 6-months duration and are not due to the effects of a substance (APA, 1994). The symptom or symptoms have to cause clinically significant distress in a number of functional domains. The diagnosis of undifferentiated somatoform disorder is precluded if physical symptoms occur in the course of another mental

disorder and if the symptom are intentionally produced or feigned (APA, 1994). Undifferentiated somatoform disorder, when compared to somatization disorder, is apparently less disabling and has a more variable course. Nonetheless, it is likely that undifferentiated somatoform disorder has a putative etiology similar to that of somatization disorder.

However, the utility of undifferentiated somatoform disorder as a diagnostic category is questionable. It is a relatively recent addition to the DSM (APA, 1987), difficult to use in a clinical setting, possibly overly inclusive (one unexplained symptom is enough for a diagnosis), and lacks validity data (Kroenke et al., 1997; Kroenke, Spitzer, deGruy, & Swindle, 1998). A number of investigators attempted a more systematic approach to somatic presentations that do not meet a formal diagnosis of somatization disorder. In two earlier studies, Escobar and his colleagues (Escobar et al., 1987, 1989) demonstrated the utility of the Somatic Symptom Index (SSI 4,6) as an abridged version of the somatization construct. The SSI consisted of four symptoms for men and six for women. Most recently, Escobar, Waitzkin, Silver, Gara, and Holman (1998) examined abridged somatization in primary care. Using the Composite International Diagnostic Interview (CIDI), 1456 patients were recruited from a university-affiliated outpatient clinic. The CIDI probed for symptoms of somatization, hypochondriasis, generalized anxiety, panic, agoraphobia, simple phobia, dysthymia, and major depression. The sample included four ethnic groups: U.S.-born non-Latinos (whites), U.S. born Latinos, Mexican immigrants, and Central American immigrants. The investigators found that one-fifth of the total sample met a diagnosis of abridged somatization and that somatizers had higher levels of psychiatric comorbidity and functional disability than non-somatizers. In addition, the authors found evidence for a new series of abridged somatization subtypes based upon the number of organ body systems involved ("simple" versus "polymorphous"), the type of body system involved (seven-organ system cluster, two distinct three-symptom clusters, and three single-organ system subtypes-genitourinary, cardiorespiratory, and headache), and discrete (one-third of the sample with abridged somatization did not meet criteria for any other psychiatric disorder) versus comorbid (two-thirds of the sample with abridged somatization met cri-

teria for other lifetime psychiatric disorders). Preliminary data on 108 psychiatric inpatients demonstrated that three unexplained symptoms for men and five for women out of thirty-three DSM-IV somatization symptoms were equivalent to Escobar SSI 4,6 (Rief, Heuser, Mayrhuber, Stelzer, Hiller, & Fichter, 1996).

Other ways of conceptualizing subthreshold somatization disorder have been put forward by other researchers. Robbins, Kirmayer, and Hemami (1997) used latent variable models to test "functional syndromes" in 686 primary care patients. Symptom items were derived from the National Institute of Mental Health Diagnostic Interview Schedule and were made to approximate diagnoses of fibromyalgia syndrome, chronic fatigue syndrome, and irritable bowel syndrome. Three models were tested for goodness of fit: the first model assumes that all forms of functional symptoms may be traced to a single underlying construct of somatic distress; the second model tests whether functional symptoms common to fibromyalgia, chronic fatigue, and irritable bowel can be subsumed under the physical symptoms for depression and anxiety; and the third model tests the convergent validity of these syndromes as discrete from one another and from depression and anxiety. The data indicated that patients with functional symptoms (multiple medically unexplained somatic symptoms) should be categorized in two groups: one group with distress across multiple-organ systems often associated with another psychiatric disorder; the second group with concerns limited to a single-organ system.

Finally, Kroenke and his colleagues (Kroenke et al., 1997, 1998) proposed multisomatoform disorder as an alternative to undifferentiated somatoform disorder. The authors defined multisomatoform disorder as three or more currently bothersome unexplained physical symptoms (from a fifteen-item symptom checklist) that are present more often than not for at least 2 years (Kroenke et al., 1997). Kroenke et al. (1998) then used data from the Primary Care Evaluation of Mental Disorders (PRIME-MD, N = 1000) and Somatization in Primary Care Studies (N = 258) to determine the optimal threshold of a fifteen-item checklist and to determine the concordance between multisomatoform disorder and somatization disorder. The optimal threshold for pursuing a diagnosis of multisomatoform disorder was seven or greater. The majority of multisomatoform disorder patients

(88%) met a diagnosis of either full somatization disorder or abridged somatization disorder. The authors also found that multisomatoform disorder was intermediate between abridged and full somatization disorder in functional impairment, psychiatric comorbidity, family dysfunction, and health care utilization and charges. The other advantage of the multisomatoform disorder diagnosis is that it takes less time to administer than Escobar's SSI 4,6 and Rief's SSI 3,5.

In sum, undifferentiated somatoform disorder is likely to continue being problematic in its application, but the number of persons subsumed under such a label necessitates continued efforts toward improving its diagnostic usefulness. Other subthreshold versions of somatization disorder have been developed, and their utility is more promising. Among them, multisomatoform disorder is most promising; this diagnostic category affords greater specificity in defining physical symptom requirements.

Conversion Disorder

Given the popularity of conversion disorder, it is surprising that little research work was done on this topic during the past 10 years. Conversion disorder remains an elusive entity, even though conversion phenomena have been described throughout the medical literature since antiquity. It has engendered much controversy as to its very existence (Chodoff, 1974; Engel, 1970; Ford & Folks, 1985; Lewis, 1974; Slater, 1965; Whitlock, 1967); a great deal of the confusion is due to changing diagnostic criteria and terminology and to the interchangeable use of diagnostic terms throughout the years. The ubiquitous term hysteria has often been used to refer to conversion hysteria, hysterical personality, somatization disorder, or some combination of all three (Chodoff, 1974; Chodoff & Lyons, 1958; Guze et al., 1971a; Kendall, 1972; Purtell et al., 1951). Note that on occasion these terms will be used interchangeably in this chapter so as to be consistent with the terminology in cited studies, although we do not feel that these terms are in fact interchangeable.

Although conversion phenomena were brought to the forefront by Freud (1956), the concept was originally put forward by the Egyptians. The term was derived from the Greek word *hustera*, meaning "uterus," because the ancient Egyptians and Greeks attributed a number of physical symptoms

in women to the “wandering of the uterus” (Jones, 1980). In the seventeenth century, the concept of conversion was further developed by Sydenham, who emphasized that hysterical phenomena could mimic almost all known physical diseases (Nemiah, 1985). In 1856, a French physician, Paul Briquet, published a comprehensive monograph on 430 clinical cases (Mai & Merskey, 1980, 1981). Although Briquet’s investigation attempted to provide a clearer and more systematic definition of hysteria than previously achieved, his work ultimately provided more support for somatization disorder than conversion disorder.

Around the same time, Jean Martin Charcot was credited with some of the seminal ideas regarding hysteria (Jones, 1980). Charcot’s contributions included the view that hysteria was a special type of consciousness, whereby individuals actually experienced the lack of physical functioning because they were highly suggestible. Charcot went on to postulate that conversion symptoms were attributable to an inherited degenerative process of the nervous system. He also became famous for his theatrical use of hypnosis, and, in fact, he indicated that hypnotizability was pathognomonic for the condition of hysteria. Pierre Janet, a student of Charcot, extended the theoretical formulations of hysteria to include a description of dissociative phenomena. A dissociated system represents a system of ideas and functions that, although no longer available to consciousness, could continue to be active and exert sensory and motor effects via unconscious mechanisms (Nemiah, 1985).

Sigmund Freud (1956), who was also a student of Charcot for a brief period, used hypnosis with conversion patients to demonstrate that the recollection of past memories and experiences could alleviate conversion symptoms. Freud developed the theory of conservation of psychophysical energy, which proposed that emotions not expressed or discharged lead to physical symptoms. Freud added that affect associated with a traumatic event that could not be expressed because of moral or ethical concerns would be repressed and converted to a somatic-hysterical symptom that was symbolic of the original trauma in some way. The repression of affect later became known as *la belle indifference*, one of the mainstays of hysterical conversion. Freud also noted that repressed ideas, affects, and conflicts were often sexual.

Diagnosis. Diagnostic considerations and terminology used to capture conversion disorder var-

ied over time. In the first edition of the DSM (DSM-I; APA, 1952), conversion reactions were defined as functional symptoms in organs or systems that were believed to be mainly under voluntary control and due to impulses that cause anxiety. Conversion reactions were distinguished from “dissociative reactions,” which referred to such phenomena as amnesias and fugue states. In the second edition of the DSM (DSM-II; APA, 1968), the term conversion reaction was changed to “hysterical neurosis,” returning the term hysteria to the nomenclature. The qualifying descriptors of conversion and dissociative were also retained by the DSM-II and the diagnostic subtypes were known as “hysterical neurosis of conversion type” and “hysterical neurosis of dissociative type.” *La belle indifference*, symbolism of symptoms, and secondary gain were considered essential features of hysterical neurosis of the conversion type.

In DSM-III (APA, 1980), hysterical neurosis of the conversion type became known as “conversion disorder” and was considered a subtype of the somatoform disorders; hysterical neurosis of the dissociative type was placed in a completely new category, the dissociative disorders. Much of the DSM-III description of conversion disorder was retained in DSM-III-R (APA, 1987) and DSM-IV (APA, 1994). DSM-IV criteria for conversion disorder are presented in Table 2. DSM-III-R diagnostic criteria for conversion disorder required that the clinician specify whether the conversion symptom represented a single episode or a recurrent phenomenon; this requirement has been dropped from the current edition of the DSM. Instead, now the DSM-IV requires the clinician to specify the type of symptom or deficit that characterizes the conversion (see Table 2).

Clinical Description. The manifestations of conversion are protean and may mimic many different known medical conditions. Conversion symptoms can be categorized according to four major subtypes (APA, 1994). Conversion disorder with motor symptom or deficit includes symptoms such as paralysis, paresis, impaired coordination, aphonia, difficulty in swallowing, or a lump in the throat (APA, 1994). *Astasia-abasia* is another classic example of a motor conversion (Nemiah, 1985). Individuals with *astasia-abasia* can be categorized by gross, irregular, pseudotaxic movements of the trunk, staggering and halting steps, and waving of the hands and arms. Like patients with pseudo-seizures, these individuals often do not hurt them-

Table 2. DSM-IV Criteria for Conversion Disorder

-
- A. One or more symptoms or deficits affecting voluntary motor or sensory function that suggest a neurological or other general medical condition.
- B. Psychological factors are judged to be associated with the symptom or deficit because the initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors.
- C. The symptom or deficit is not intentionally produced or feigned (as in Factitious Disorder or Malingering).
- D. The symptom or deficit cannot, after appropriate investigations, be fully explained by a medical condition, or by the direct effects of a substance, or as a culturally sanctioned behavior or experience.
- E. The symptom or deficit causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation.
- F. The symptom or deficit is not limited to pain or sexual dysfunction, does not occur exclusively during the course of Somatization Disorder, and is not better accounted for by another mental disorder.

Specify type of symptom or deficit:

With Motor Symptom or Deficit

With Sensory Symptom or Deficit

With Seizures or Convulsions

With Mixed Presentations

Source: American Psychiatric Association. (1994). *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (p. 457). Washington, DC: Author. Reprinted by permission.

selves when falling to the ground and may have complete control of the body while sitting. A second subtype of conversion disorder is characterized by some sensory symptom or deficit. Sensory disturbances usually come in the form of anesthetics and are experienced most frequently in the extremities. Glove anesthesia of the hands and sock anesthesia of the feet represent classic examples of sensory conversions. The sense organs for vision and audition can be used as sources of conversion. Seizures or convulsions with sensory or motor components represent a third subtype of conversion disorder. Pseudoseizures are characterized by wild, disorganized writhing of the body and arms and legs flailing with abandon. Unlike individuals with true seizures, this all occurs without the patients injuring themselves. In

addition, individuals with pseudoseizures do not void or soil themselves. The final subtype of conversion disorder tends to be characterized by a mixed presentation of more than one of the previous subtypes.

Epidemiology and Demographics. Because of the almost ephemeral nature of conversion and the differences in defining the term, the reported prevalence of conversion disorder fluctuates from rare (Lewis, 1974; Slater, 1965; Whitlock, 1967) to ubiquitous (Engel, 1970). Prevalence rates for conversion vary as a function of clinical setting. Guze et al. (1971a) found that 24% of 500 psychiatric outpatients had a history of conversion symptoms. Engel (1970) estimated that 20 to 25% of patients admitted to general medical services will experience a conversion symptom at one time or another; however, Engel's estimate was not empirically based. Empirical investigations resulted in more likely estimates of conversion that suggest that the prevalence is between 5 and 14% of all consultations in a general medical setting (Folks, Ford, & Regan, 1984; McKegney, 1967; Stefansson, Messina, & Meyerowitz, 1976; Ziegler, Imboden, & Meyer, 1960). DSM-IV notes the prevalence of conversion disorder at 1–3% of outpatient referrals. The use of such different diagnostic terms as conversion and hysteria have surely confounded efforts to determine accurate prevalence estimates across different samples.

The distribution of conversion in men and women is equivocal. It is generally believed that conversion symptoms occur more frequently in women (Folks et al., 1984; Gatfield & Guze, 1962; Guze & Perley, 1963; Perley & Guze, 1962; Purtell et al., 1951; Raskin, Talbott, & Meyerson, 1966; Whitlock, 1967). Engel (1970) reported that conversion symptoms occur two or three times more frequently in women than in men. The DSM-IV (APA, 1994) reports a 2:1 to 10:1 ratio in favor of women. The typical patient with conversion reaction has been described as a woman less than 40 years old from a rural and/or impoverished environment (Folks et al., 1984). On the other hand, Chodoff (1974) contended that conversion reactions occur as frequently in men as women. In fact, men experience conversion more frequently than women in such settings as industry (Allodi, 1974) and the military (Carden & Schramel, 1966). Ziegler, Imboden, and Rogers (1963) commented that women may use conversion symptoms more than men because the feminine role inherently

sanctions greater dependency and reliance on others, and more readily lends itself to a "sick role." Probably there is little sex difference in the prevalence of conversion. Differences reported in studies may reflect social and cultural influences on the expression and diagnosis of conversion instead of true sex differences.

The onset of conversion disorder is usually from late childhood to early adulthood (APA, 1994). The onset is typically acute and tends to resolve quickly, usually within 2 weeks. Factors associated with a good prognosis include acute onset, identifiable stress before hospitalization, and good premorbid functioning (Couprie, Wijdicks, Rooijmans, & van Gijn, 1995; Singh & Lee, 1997).

There has been considerable interest in examining conversion disorder in children and adolescents (Goodyer, 1981; Kriechman, 1987; Maloney, 1980; Siegel & Barthel, 1986; Spierings, Poels, Sijben, Gabreels, & Renier, 1990; Volkmar, Poll, & Lewis, 1984). The prevalence of conversion in children and adolescents has been estimated at approximately 5% (Maloney, 1980; Siegel & Barthel, 1986). However, an older study by Robins and O'Neal (1953) estimated that the prevalence of conversion reactions is as high as 17%. The presence of a family role model with similar physical symptoms, familial discord, early sexual trauma, and stress has been consistently found in children and adolescents with conversion symptoms (Goodyer, 1981; Kriechman, 1987; Volkmar et al., 1984). Spierings et al. (1990) conducted a 9-year retrospective study of eighty-four children between the ages of 6 and 17 who met DSM-III-R criteria for conversion disorder of various types (paresthesia, anesthesia, pseudoseizure, and loss of consciousness were the most common), and a number of noteworthy findings were revealed. They reported a 2.2:1 gender ratio for females, but below the age of 10 the ratio was even. Sixty-two percent of patients and 45% of family members had a history of significant organic disease. A personal model for the symptoms was observed in 29% of cases, suggesting a learning process. In general, studies of conversion in children and adolescents are particularly impressive and suggest possible genetic, environmental, and role-model influences in the expression of conversion disorder.

In 1896, Freud stated that conversion phenomena were rare in the lower class (Freud, 1956);

however, today the reverse is true (Guze & Perley, 1963; Stefansson et al., 1976). Conversion reactions are observed more frequently in individuals who reside in rural areas and in less psychologically sophisticated populations (Folks et al., 1984). Patients from rural and uneducated backgrounds also tend to present to clinicians with more primitive, bizarre, and dramatic clinical presentations of conversion, whereas more educated and sophisticated patients tend to present with symptoms that more closely simulate physical disease (Engel, 1970; Jones, 1980).

Etiological Formulations. Conversion disorder has proven difficult to define, partly because most of the conceptual formulation for conversion disorder has come from the psychoanalytic literature. Many of the ideas put forward by psychoanalysts are too vague and elusive to be properly and scientifically evaluated. Over time, the literature has incorporated behavioral, sociological, and neurophysiological conceptualizations of conversion disorder.

Psychoanalytic. Although psychoanalytic formulations have undergone considerable revision over the years (Chodoff, 1974; Lazare, 1981; Lewis, 1974; Nemiah, 1985; Viederman, 1995), a series of papers on an integrated theory of conversion written in the late nineteenth century by Freud (1956) continues to influence thinking about conversion disorder. He stated that a conversion symptom is usually associated with a passive sexual seduction that typically occurs during the oedipal period. Due to sexual feelings and situations that arise around puberty, the childhood seduction is then followed by a resensitization of the early childhood episode. At puberty, sexual urges recall frightening affects and memory traces of an earlier sexual trauma. In an attempt to cope with this, repression (as a defense) leads to the conversion of sexual arousal into a somatic symptom. Freud added that the actual early childhood sexual trauma did not have to be real and that sexual fantasy alone could produce a conversion reaction.

Lazare (1981) theorized that conversion reactions can result from impulses other than sexual, for example, aggression and dependency. Engel (1970) stated that conversion may develop for several reasons: (1) to permit expression of a forbidden wish or impulse, (2) as a form of punishment for a forbidden need, (3) to remove oneself from an overwhelming threatening life situation, and (4) to allow gratification of dependency needs

by assuming the sick role. In sum, a conversion symptom represents a compromise between the need to express ideas or feelings that are unconscious and the fear of expressing them (Viederman, 1995).

Behavioral. Conversion reactions can be conceptualized as behavioral excesses or deficits that follow a traumatic event or emotional state and are reinforced by particular outcomes (Mumford, 1978). A conversion symptom can be used to manipulate others, to get special attention, to receive special privileges, and to avoid unpleasant tasks or responsibilities. Use of a conversion symptom can also be reinforced and facilitated by a reduction in the intensity of a drive (Nemiah, 1985). For example, an initial episode of a conversion paralysis can result in a reduction of a painful emotional drive such as anxiety. This initial pairing of a stimulus and response can predispose an individual to using the same palliative response whenever anxiety occurs; consequently, responding to external stressors or pressures with a conversion reaction may represent a primary, although maladaptive, coping response. Others have conceptualized conversion symptoms as an adaptation to frustrating or stressful life experiences (Barr & Abernathy, 1977). The influence of role-modeling in the development of a conversion symptom in children and adolescents has been noted earlier (Spierings et al., 1990).

From a broader conceptual perspective, conversion reactions, it has been thought, result from cultural, social, and interpersonal influences (Cecani, 1976). Individuals with conversion disorder learn to use their symptoms to communicate helplessness, thereby fostering an environment that reinforces helplessness and inhibits aggressive impulses. Thus, a patient's conversion disorder can be reinforced by the reactions of caretakers or families and by the formation of a conversion symptom in times of stress or conflict. Strangely enough, much of the behavioral formulation of conversion disorder has come from psychiatrists. As behaviorally oriented clinicians get more involved in assessing and treating conversion disorder, our understanding of conversion should increase substantially.

Sociological. A different approach to understanding conversion phenomena comes from the field of medical sociology. Mechanic (1962) and Parsons (1951) have been most responsible for increasing our understanding of illness behavior and the sick

role. Illness behavior can be defined by the ways in which symptoms are perceived, evaluated, and acted upon (Mechanic, 1962). In other words, the context in which symptoms occur and the way that they are perceived by the individual are extremely important. Once illness has been recognized and legitimized by the physician, then individuals can be relieved of their duties or responsibilities, and others in the "system" may be required to be considerate and supportive of the sick individual (Parsons, 1951). In assuming the sick role, the patient is obliged to cooperate with treatment and to withdraw from activities, even those that are considered enjoyable. Variations of this model of conversion have been proposed by other investigators (Ziegler & Imboden, 1962).

Neurophysiological. Neurophysiological formulations of conversion reactions have received considerable attention. The neurophysiological formulation for conversion suggests that conversion symptoms result from some form of damage or malfunction of the brain (Ludwig, 1972; Whitlock, 1967). Whitlock (1967) proposed a neurophysiological conceptualization of conversion in which conversion disorder is considered primarily a disorder of attention and vigilance. The lack of attention and concern (i.e., la belle indifference) on the part of the conversion patient is due to a "selective depression of awareness of a bodily function" brought on by corticofugal inhibition of afferent stimulation (Whitlock, 1967). The corticofugal inhibition of sensory stimulation occurs at the level of the brain stem reticular formation. Ludwig (1972) added that memory impairments observed in patients with hysteria were due to the same mechanism proposed by Whitlock (1967).

In an attempt to examine neurophysiologically based assumptions pertaining to attention and memory dysfunction, Bendefeldt, Miller, and Ludwig (1976) had seventeen hospitalized conversion hysterics complete a series of tasks under nonstress (supportive behavior on the part of the experimenter) and stress (unsupportive behavior on the part of the experimenter) conditions. Their study also included a control group of nonpsychotic patients. Overall, the results indicated that the conversion group had heightened suggestibility, greater field dependency, and greater impairment of recent memory, vigilance, and attention. The authors then used stepwise discriminant function analysis and were able to classify correctly fourteen subjects out of seventeen in the

nonstress condition and sixteen subjects out of seventeen in the stress condition. However, the classification analysis should be questioned because the authors essentially had one subject per dependent variable. Despite this statistical weakness, their data does provide some interesting possibilities for a neurophysiological model of conversion disorder.

Studies that examined somatosensory average evoked responses substantiate the utility of a neurophysiological formulation of conversion disorder. In a study by Hernandez-Peon, Chavez-Ibarra, and Aguilar-Figueroa (1963), monitoring of somatosensory evoked responses from both the affected left upper extremity and the corresponding unaffected limb of a 15-year-old female patient with hysterical paralysis revealed an absence of evoked potentials during wakeful stimulation. However, during light central anesthesia (using a barbiturate), significant evoked potentials appeared following stimulation of the left upper extremity. Halliday (1968) found no appreciable differences between normal and anesthetic conditions in his analysis of somatosensory evoked potentials in a 40-year-old man with hysterical anesthesia of the left thumb and index finger. Levy and his associates confirmed the Hernandez-Peon et al. (1963) findings for low levels but not for high levels of sensory stimulation (Levy & Behrman, 1970; Levy & Mushin, 1973).

Another line of research supporting the neurophysiological formulation of conversion disorder came from studies that examined lateralization of symptoms in conversion hysterics. Bishop, Mobley, and Farr (1978), having conducted or in conducting a 10-year retrospective study of conversion reactions, reported that 70% of 430 patients with conversion neurosis, hysterical neurosis, hysterical personality, and psychophysiological CNS or musculoskeletal disorders had their symptoms on the left side of the body. Similar findings have been reported in other studies (Galín, Diamond, & Braff, 1977; Stern, 1977). These studies also suggest that the right cerebral hemisphere is particularly involved in modifying affective or motivational components of somatic symptoms.

Conversion Disorder and Associated Psychopathology. One reason that conversion disorder has questionable utility as a diagnostic entity is because this disorder often co-occurs with a variety of psychiatric disorders and personality styles. Although patients with conversion disorder

are generally considered more likely to have hysterical personality disorder, this relationship has fueled a great deal of controversy. Chodoff and Lyons (1958) stated that hysterical personality is a description of women by men and is basically a caricature of femininity. This stereotyping seemingly also holds for men. One group of authors suggested that hysterical personality disorder in men reflects a homosexual process, and if not a homosexual process, then these men are likely to have sexual problems and display "affectations" (Luisada, Peele, & Pittard, 1974). Kendell (1972) strongly stated that hysterical personality is a label used to describe a woman if the individual is perceived as difficult, demanding, and manipulative, whereas the same symptoms observed in a man will lead to the label of psychopathy.

The DSM-IV (APA, 1994) presentation of histrionic personality disorder includes the following traits: overly dramatic, incessant need for attention and reassurance, sensation seeking, reactions out of proportion to minor stimuli, irritability with outbursts of anger, shallowness, vanity, and proneness to manipulative suicidal gestures. Past studies have essentially used variations of the DSM-IV definition of histrionic personality disorder. A comprehensive review of studies of hysterical personality characteristics dating from 1949 to 1970 was conducted by Alacron (1973). Analysis of fourteen studies revealed a high degree of consensus for hysterical personality traits including emotional lability, dependency, excitability, egocentrism, and suggestibility. Alacron concluded that all patients with hysteria have some of the features of hysterical personality, whereas not all patients with hysterical personality will have typical features of hysteria.

The estimated percentage of the co-occurrence of conversion and hysterical personality has ranged from 5 to 50% (Lewis & Berman, 1965; Raskin et al., 1966; Stephens & Kamp, 1962). Ziegler et al. (1960) noted that less than half of their sample of 134 conversion patients had "hysterical character," which led the authors to conclude that the hysterical personality pattern was not a prerequisite for a conversion process. Barnert (1971) found that 7% of forty-six patients with conversion reactions exhibited a hysterical personality disorder. Of fifty patients with a DSM-III diagnosis of conversion disorder, only 6% of the cases had co-occurring histrionic personality disorder (Folks et al., 1984).

Given the difficulty in determining the validity of conversion disorder and the almost anecdotal definition of hysterical or histrionic personality, it is not surprising that determining the true co-occurrence of these two conditions is problematic. Although hysterical personality disorder may predispose individuals to conversion reactions, no single personality pattern characterizes individuals with conversion disorder.

Of greater interest is the relationship of depression and schizophrenia to conversion reactions. Ziegler et al. (1963) found rates of 29.9% for depression and 14.2% for schizophrenia in their conversion patient sample, and in another sample, prevalence rates of 17% for depression and 7% for schizophrenia were observed (Stephens & Kamp, 1962). Barnert (1971) reported overt depression in 33%, covert depression in 21%, and schizophrenia in 7% of patients diagnosed with conversion symptoms. Lewis and Berman (1965) observed that eight out of fifty-seven conversion patients evidenced schizophrenia or schizoid character. Roy (1980) found that 88% of fifty patients with hysterical conversion had depression and suggested that conversion symptoms may serve more as a "signal of distress" than anything else. Folks et al. (1984) indicated that 44% of their sample did not have any psychopathology other than conversion disorder but noted that 8% of their patients had depression and 29% had somatization disorder concurrent with conversion reactions.

Two studies by the same group of investigators (Kent, Tomasson, & Coryell, 1995; Tomasson, Kent, & Coryell, 1991) examined differences between conversion and somatization disorders. In the first study (Tomasson et al., 1991), the investigators reviewed charts of patients seen over a 2-year period at a large medical center. Cases were assessed for conversion disorder ($N = 51$) and somatization disorder ($N = 65$) using DSM-III criteria. Seventy-eight percent of the conversion disorder group and 95% of the somatization disorder group were women. Conversion disorder cases were overrepresented in the neurology services, whereas somatization patients tended to come from all units throughout the hospital. Age of onset occurred across the life span of the conversion group and tended to occur before 21 years of age in the somatization disorder group. The somatization disorder group tended to have a greater history of depression, attempted suicide, panic disorder, and divorce, suggesting that con-

version disorder was less pathological than somatization disorder. The investigators then went on to follow the course and outcome of these patients during a 4-year period (Kent et al., 1995). Still using DSM-III criteria, the conversion disorder group ($N = 32$) and the somatization disorder group ($N = 38$) were given follow-up interviews by a rater blind to the baseline diagnosis. Patients in the conversion disorder group were less likely to be given the same diagnosis at follow-up than patients in the somatization disorder group. Interestingly, six cases in the conversion disorder group were given a diagnosis of somatization disorder at follow-up and four other cases in the conversion disorder group were eventually diagnosed with an organic condition. Follow-up comparisons of overall distress and impairment were made using the Symptom Checklist-90 and the Short-Form General Health Survey. Again, the somatization disorder group displayed higher levels of emotional turmoil and functional impairment relative to the conversion disorder group. These two studies are compromised by the retrospective nature of the design, as well as diagnoses based on chart review.

In one of the more rigorous studies of conversion reactions, Binzer, Andersen, and Kullgen (1997) examined thirty consecutive patients with conversion disorder, motor symptom subtype, and compared them to a control group with corresponding motor symptoms due to an organic lesion. All patients were assessed with the DSM-III-R diagnostic system, the Hamilton Depression Rating Scale, and a special life events schedule. The results indicated that the conversion group had a higher degree of psychopathology. Thirty-three percent of the conversion group had an Axis I diagnosis, and 50% had an Axis II diagnosis, compared to 10 and 17% of control group patients, respectively. The conversion group also had higher depression scores and special life events before the onset of conversion symptoms. A logistic regression analysis indicated that low education, the presence of a personality disorder, and depression were associated with increased risk of conversion disorder.

Clearly, further research is needed to determine whether conversion disorder represents a unitary diagnosis or should be considered more as part of another psychiatric condition. Conservatively, conversion reactions can be thought of as the "tip of the iceberg," suggesting the presence of other

concurrent psychiatric disorders or serious medical disorders (Roy, 1980).

La Belle Indifference. The assumed sine qua non of conversion disorder is la belle indifference, or what is referred to as an indifference or lack of concern toward symptoms on the part of conversion patients. Chodoff (1974) noted that la belle indifference occurred as often as not in his sample of hysterics. He speculated that la belle indifference represented an example of the use of denial to defend against psychological stressors and not an indifference *per se*. Other studies reported la belle indifference in 30% (Stephens & Kamp, 1962), 41% (Raskin et al., 1966), and 54% (Barnert, 1971) of their respective samples.

One of the better studies that argued against the presence of la belle indifference in conversion hysteria was provided by Lader and Sartorius (1968). The authors compared a self-report of anxiety, psychiatrist ratings, and psychophysiology in a conversion hysteria group and an anxiety disorder group. The patients in the conversion hysteria group rated themselves as significantly more anxious than did the anxiety group, whereas the ratings of patients by examining psychiatrists were in the opposite direction, that is, psychiatrists rated conversion hysteria patients as less anxious than anxiety patients. As measured by galvanic skin response, patients in the conversion group (N = 10) displayed higher autonomic levels of arousal than the comparison anxiety group (N = 71) and a normal control group (N = 75). In another study, Meares and Horvath (1972) indicated that a group of seventeen patients who suffered from conversion could be separated on the basis of psychophysiological and biographical variables. One group, identified as "chronic hysterics," had more debilitating conversion symptoms, poor interpersonal and occupational coping skills, and longer histories of multiple medical complaints than a second group identified as "acute hysterics." In addition, the chronic hysterics displayed higher levels of heart rate, sweat gland, and muscle activity than the acute hysterics. On closer analysis of these two groups, the chronic hysterics label may be a misnomer; the profile obtained by chronic hysterics is more consistent with a somatization disorder profile.

Despite the long history, la belle indifference is not a reliable indicator or marker of conversion disorder. Conversion disorder patients are actually quite concerned about their symptoms, although

this concern may not be readily apparent (Lewis & Berman, 1965). A true indifference to symptomatology or disability is usually indicative of central nervous system damage (Gould, Miller, Goldberg, & Benson, 1986).

Organic Illness and Misdiagnosis. Because of the implications for both treatment and prognosis, a discussion of organic illness and misdiagnosis of conversion disorder before the review of treatments and prognosis for conversion disorder is appropriate. The diagnosis of conversion disorder is not as simple as might be expected. There are two salient aspects to the relationship between organic illness and conversion symptoms that are vitally important in understanding the complexities of clinical diagnosis in conversion disorder (Lazare, 1981). First, there are a substantial number of patients whose initial diagnosis of conversion symptoms is changed to organic illness. Second, there is a high incidence of patients with conversion reactions and concomitant organic illness. Clinicians who ignore these two basic tenets will experience many problems in understanding and managing this group of patients.

Conversion reactions can occur in isolation, as part of another psychiatric disorder, or as part of a neurological disorder. The following studies strongly challenge the diagnostic utility of conversion hysteria. In a seminal piece of research, Slater and Glithero (1965) performed a 7- to 10-year follow-up of ninety-nine patients discharged from the National Hospital in London. Four patients who had committed suicide and eight patients who died from an organic illness were not included at follow-up. Of the seventy-three patients contacted at follow-up, 30% of the cases initially diagnosed with conversion symptoms had organic illnesses that accounted for the presenting problem. Of the thirty-two patients who did not have organic illnesses, only thirteen patients could be truly said to have been without pathology, whereas the rest suffered from schizophrenia, depression, and severe disability. Because an organic illness may appear asymptomatic or atypical at one phase of an illness, clinicians may be predisposed to misdiagnose bona fide medical disorders as "conversions" (Slater & Glithero, 1965). Moreover, an organic illness may produce behavioral disturbances (e.g., emotional lability, attention seeking, constant need for reassurance, and aggressiveness) that mimic psychiatric presentations.

Gatfield and Guze (1962) performed a 2.5- to

10-year follow-up of twenty-four patients who were discharged from neurological and neurosurgical wards with a diagnosis of conversion reaction. Five of twenty-five patients had neurological disease. Raskin et al. (1966) examined fifty patients referred from an inpatient and outpatient neurological service of two teaching hospitals; follow-up periods ranged from 6 to 12 months. Organic illness was found in seven patients. Whitlock (1967) noted that almost 64% of his sample showed evidence of an accompanying or preceding organic brain disorder, compared to 5% for a control group of persons diagnosed with depression and/or anxiety. Merskey and Buhrich (1975) observed a prevalence of 50% for organic cerebral disorders in conversion patients ($N = 89$). In a 10-year follow-up of forty male patients with conversion, a 25% false positive rate was obtained (Watson & Buranen, 1979). Watson and Buranen reported that symptoms most characteristic of the false positives were degenerative diseases and structural damage that affected the spinal cord, peripheral nerves, bones, muscles, and connective tissue. Roy (1980) found that 40% of his sample had organic brain disease, whereas Folks et al. (1984) noted a 17.7% rate of organicity in their sample of patients with conversion disorder. In another study, a remarkable 80% of thirty patients originally diagnosed with conversion hysteria had, it was eventually found, diagnosable medical disorders as an underlying cause (Gould et al., 1986). Couprie et al. (1995) reviewed medical records of patients admitted with conversion disorders other than pseudoseizures over a seven-year span. A total of fifty-six patients were identified and interviewed in person ($N = 22$) or by phone ($N = 34$). The median interval from the onset of symptom to interview was 4.5 years. Contrary to findings from earlier studies, Couprie and colleagues found that only two of the fifty-six patients later developed neurological conditions. These data are consistent with other data presented by Kent et al. (1995) in which only four out of thirty-two conversion disorder cases followed 4 years later had organic conditions. The smaller number of cases of conversion disorder eventually diagnosed as organic conditions in more recent studies might suggest better psychiatric and medical assessments.

As it is currently conceptualized, conversion disorder will likely become more of a rarity in the clinical setting. Clearly, many patients are diagnosed with conversion disorder who then develop

significantly more serious medical or neurological disorders. Although no one has calculated the cost of the misdiagnosis of medical conditions, it is obvious that, if the error in diagnosis results in the deaths of patients (as some of the above studies suggest), then the price is extremely high. Consequently, it may be wise that the diagnosis of conversion disorder not be seen as an either-or decision between organic versus psychological symptomatology. However, if the diagnosis of conversion disorder is given, the clinician is well advised to carefully monitor ongoing symptomatology to ensure detection of an organic process.

Treatment and Prognosis. As Ford and Folks (1985) noted, a wide variety of treatment interventions have been suggested for conversion disorders. As they note, a plethora of therapies suggest that nothing is very effective and that most therapies help to some degree with conversion disorder. Treatment interventions have included psychoanalysis, supportive therapy, hypnosis, physical therapy, amobarbital interviewing, and behavior therapy. Concurrent mood or anxiety disorders associated with conversion disorder may also require pharmacological treatment. Direct confrontation of a patient's conversion symptom has no real benefit, and the interview should be carefully conducted so as to avoid a confrontational stance; otherwise, a confrontation is only likely to exacerbate the patient's defensiveness. A careful psychosocial evaluation and examination of possible precipitating life events and past history of psychological trauma should lead to an appropriate treatment intervention. Several case studies have demonstrated the utility of behavioral applications in treating conversion disorder (Barr & Abernathy, 1977; Fishbain et al., 1988).

It should be evident from the information in the prior section on organic illness and misdiagnosis of conversion disorder that the prognosis for conversion disorder is not encouraging. However, two studies reported favorable outcomes. Carter (1949) reported that 83% of ninety inpatients and outpatients were well or significantly improved at 4- to 6-year follow-up. Hafeiz (1980) found that there was an immediate favorable response to treatment in all of sixty-one psychiatric outpatients and only twelve patients had relapses at the end of 1 year. His treatment consisted of faradic stimulation, somlec (electro-sleeping machine), sodium amylobarbitone, and methylamphetamine. A good prognosis for conversion disorder is associated with an

acute or recent onset of symptomatology, a definite identification of a precipitant, good premorbid health, and the absence of concurrent organic illness or a major psychiatric condition (Couprie et al., 1995; Lazare, 1981; Singh & Lee, 1997).

Pain Disorder

Pain disorder was previously known as somatoform pain disorder in DSM-III-R and as psychogenic pain disorder in DSM-III. The essential feature of pain disorder in DSM-IV (APA, 1994) is a preoccupation with pain in one or more anatomical areas that is sufficiently severe to warrant clinical attention; that causes impairment in daily living; and psychological factors, it is judged, have a prominent role in the onset, exacerbation, and maintenance of pain. In addition, the pain is not intentionally produced or feigned and is not due to another affective or thought disorder or to dyspareunia. Unlike in the DSM-III-R, there is an attempt to identify subtypes of pain disorder in DSM-IV (APA, 1994) based on the predominant factors that characterize the etiology and maintenance of the pain: pain disorder associated with psychological factors, pain disorder associated with both a psychological and a general medical condition, and pain disorder associated with a general medical condition. In pain disorder associated with psychological factors, psychological factors, it is judged, have primary influence on the onset, exacerbation, and maintenance of the pain. A general medical condition plays little or no role in the etiology of pain in this subtype. In addition, this subtype cannot be diagnosed if the criteria for somatization disorder are met. As the name implies, both psychological factors and a general medical condition play an important role in the etiology of pain in the second subtype of pain disorder. The anatomical site or associated medical condition is coded on Axis III (e.g., diabetic neuropathy). In the third subtype of pain disorder, pain is due to a medical condition, is coded on Axis III, and is essentially not a mental disorder. In the first subtype of pain disorder, the duration of pain can be specified as acute if less than 6 months and chronic if longer than 6 months.

Nosologically, the history of pain disorder continues to be one of the least satisfactory of the somatoform disorders. Very few studies in the pain literature have ever used a DSM conceptualization. King and Strain (1992) noted that only five studies

had used somatoform pain disorder based on DSM-III-R criteria. The difficulty with this category is inherent in the complicated and experiential nature of pain. Pain is a multifaceted experience characterized by affective, sensory, and evaluative components. Although pain can be simultaneously pathogenic and psychogenic, the correlation between the subjective report of pain and the physiological evidence of pain is relatively low. Other problems include the fact that the majority of chronic pain patients have pain in one or more areas, so that the majority of chronic pain patients would meet this first criterion (Fishbain, 1996). The remaining criteria for pain disorder are equally overinclusive, and most chronic pain patients report that pain interferes with social, occupational, and other domains of functioning and that psychological factors play a role in the etiology of pain. Chronic pain patients are bound to be affected physically and psychologically; however, they do not necessarily have to be psychiatrically disturbed (Iezzi, Adams, Stokes, Pilon, & Ault, 1992).

Hypochondriasis

As early as 350 B.C., hypochondriasis sparked the imagination of the medical community and laypersons alike. Similar to conversion disorder, hypochondriasis has been described in the writings of the Hippocratic era (Nemiah, 1985). The word hypochondriasis is of Greek origin and is literally translated as "below the cartilage" (Kenyon, 1976). Hypochondriasis, it was speculated, was attributable to disturbances in bodily function, and mental changes were particularly associated with changes in the organs below the xiphoid process. Hypochondriasis was characterized by sharp belching, abdominal pains, flatulence, cold sweat, and sour eructations. Galen stated that hypochondriasis was a special form of melancholia and was the result of "black bile" (Nemiah, 1985). Galen's viewpoint was consistent with Greek humoral theories of disease and illness.

It was not until the seventeenth and eighteenth centuries that hypochondriasis became associated with a morbid preoccupation with one's body or state of health (Kenyon, 1965; Nemiah, 1985). During this era, hypochondriasis was variously described as a species of melancholy, "the spleen," "the vapors," and "the English malady" (Kenyon, 1965). Hypochondriasis was then thought of especially as a complaint of the English, and in

1733, Cheyne's treatise called "The English Malady" reviewed hypochondriasis within a cultural context (Kenyon, 1965; Nemiah, 1985). Moreover, Cheyne's treatise was also known for a detailed account of the author's own suffering.

Paradoxically, it was a layperson named Burton who wrote "The Anatomy of Melancholy" in 1651, which inspired the medical conceptualization of hypochondriasis (Kenyon, 1965; Nemiah, 1985). In addition, a theatrical representation performed and written in 1673 by Moliere in *Le Malade Imaginaire* captured the imagination of the public (Kenyon, 1965; Nemiah, 1985). In 1877, seventy essays outlining many references to personal experiences with hypochondriasis were written by Boswell during a 6-year period (Kenyon, 1965). During the next 150 years, because of Sydenham's influence, hypochondriasis was viewed as a male version of hysteria in women, and not surprisingly, the diagnostic terms were often used interchangeably (Fischer-Homberger, 1972).

By the early twentieth century, in a classic paper by Gillespie (1928), a strict definition of hypochondriasis was stated. Based on the review of thirteen cases, hypochondriasis was characterized by a variety of paresthesias, a thorough observation of bodily function, a firm conviction of illness or sickness, an inability to be reassured, and finally, a failure to respond to psychotherapy. It was not until the mid-1920s that hypochondriasis was listed as a diagnostic category in the American Psychiatric Association classification system (Nemiah, 1985).

Diagnosis. It is not presently clear whether hypochondriasis is a true independent, discrete, and cohesive diagnostic category. The scientific examination of hypochondriasis has been problematic for several reasons (Barsky & Klerman, 1983). First, hypochondriacal patients often present themselves to general medical settings rather than to psychiatric settings. Second, hypochondriasis tends to be a condition that falls between medicine and psychiatry. Third, the lack of clarity and knowledge about hypochondriasis reflects modern medicine's emphasis on disease rather than illness. On a positive note, there has been a significant increase in empirical attention to this topic in the last 10 years.

Despite their best intentions, internists and general practitioners are not equipped to handle these cases. Even among psychiatrists, who are more

interested in hypochondriasis than internists and general practitioners, there has been some degree of controversy. For example, hypochondriasis was not included in DSM-I (APA, 1952). Hypochondriasis was first included in DSM-II and has remained the same until DSM-IV, but hypochondriasis was moved from the neurosis section in DSM-II to the somatoform section in DSM-III where it has remained. DSM-III-R added a 6-month duration requirement before the diagnosis of hypochondriasis could be given. DSM-IV (APA, 1994) includes the specifier "poor insight" when the person does not recognize that the concern of serious illness for most of the duration of a hypochondriacal symptom is exaggerated or unreasonable. Table 3 presents the DSM-IV (APA, 1994) criteria for hypochondriasis.

Clinical Description. Although not data based, Nemiah (1985) presents an excellent description of the clinical aspects of hypochondriasis. Hypo-

Table 3. DSM-IV Criteria for Hypochondriasis Disorder

-
- A. Preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms.
 - B. The preoccupation persists despite appropriate medical evaluation and reassurance.
 - C. The belief in Criteria A is not of delusional intensity (as in Delusional Disorder, Somatic Type) and is not restricted to a circumscribed concern about appearance (as in Body Dysmorphic Disorder).
 - D. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
 - E. The duration of the disturbance is at least 6 months.
 - F. The preoccupation is not better accounted for by Generalized Anxiety Disorder, Obsessive-Compulsive Disorder, Panic Disorder, a Major Depressive Disorder, Separation Anxiety, or another Somatoform Disorder.

Specify if:

With Poor Insight: if, for most of the time during the current episode, the person does not recognize that the concern about having a serious illness is excessive or unreasonable

chondriacal symptoms are often diffuse and involve many areas of the body. As observed in Kenyon's (1964) study, the abdomen, viscera, chest, head, and neck are the areas most commonly affected. Patients commonly experience a general bodily sense of fatigue or malaise. A patient's symptoms typically arise from a heightened awareness of normal bodily functions (i.e., bowel movements or heartbeats). Patients with hypochondriacal concerns usually present their complaints at great length and may even exhibit what may look like pressured speech.

The clinical encounter with the hypochondriac can be characterized more as a monologue than as a dialogue. Hypochondriacal patients' thoughts and speech are entirely centered around their symptomatology, and any attempt by the clinician to discuss anything else is resisted. These patients are very well versed in medical terminology, which makes them more likely to try to manage their medical care instead of following the clinician's recommendations. Doctor-patient relationships tend to be difficult and rife with tension and hostility on both sides. Unlike patients with conversion disorder, who may show a lack of concern, hypochondriacal patients are very worried and anxious about their symptoms. Frequently, hypochondriacal patients present symptomatology that is out of proportion to the medical findings.

Epidemiology and Demographics. Although there are no prevalence figures for hypochondriasis in the general population, its prevalence in a medical practice, it has been estimated, ranges from 4 to 9% (APA, 1994). It has been estimated that from 60 to 80% of the normal population will experience, on average, at least one physical symptom in a given week (Kellner, 1985). Using a more restrictive definition, hypochondriasis, it has been noted, occurs in 3 to 14% of patients seen in medical settings (Kenyon, 1976). Using DSM-III-R diagnostic criteria, Barsky, Wyshak, Klerman, and Latham (1990) found that the 6-month prevalence rate of hypochondriasis falls between 4.2 and 6.3% in a tertiary academic medical setting. Based on a screening scale, the prevalence of hypochondriasis was 14% in a general medical clinic (Noyes, Kathol, Fisher, Phillips, Suelzer, & Holt, 1993). Hypochondriasis occurs equally among men and women (APA, 1994; Gureje, Ustun, & Simon, 1997). With respect to course, hypochondriacal symptoms tend to wax and wane over a long period of time.

Until recently, much of what was known about hypochondriasis was based on Kenyon's classic study of 1964. Kenyon reviewed case records of all patients who attended Bethlem Royal and Maudsley hospitals during a 10-year period from 1951 to 1960. A total of 512 patients was identified and characterized as either primary (hypochondriasis was the only complaint) or secondary (hypochondriasis was secondary to a preexisting disorder) hypochondriacs. He classified somatic complaints according to the distribution of symptoms in different parts of the body, physiological systems affected, and whether symptoms were unilateral or bilateral. The areas most commonly reported to be of hypochondriacal focus were the head, neck, abdomen, and chest, in that order. Musculoskeletal, gastrointestinal, and central nervous system areas were the bodily systems most involved. Pain (e.g., headache, chest pain, backache, and abdominal pain), the most common symptom reported, occurred in approximately 70% of the entire sample. Seventy-three percent of the whole sample reported symptoms primarily on the left side of the body. No striking differences in age, sex, religion, social class, marital status or relevant clinical variables were found between primary hypochondriacs ($N = 301$) and secondary hypochondriacs ($N = 211$). Among 295 patients subsequently admitted for inpatient hospitalization, Kenyon found an absence of significant physical abnormality in 47% of these cases, and in approximately one-half of these cases, no precipitating factors were noted.

The onset of hypochondriasis, it is believed, occurs as early as childhood (Nemiah, 1985) or as late as senescence (Brink, Janakes, & Martinez, 1981), but more commonly by early adulthood (APA, 1994). Kenyon (1964) found that the overall peak age of incidence for hypochondriasis was 30 to 39 years of age; the peak for males was in the 30 to 39 age group, and the peak for females was in the 40 to 49 age group.

Etiological Formulations. A number of theories have been presented to explain hypochondriacal behavior. For years, the psychoanalytic formulation of hypochondriasis has been the predominant conceptual framework. More recently, the psychoanalytic conceptualization of hypochondriasis has been replaced with models that emphasize the influences of learning, cognition, and attitudes. *Psychoanalytic.* Freud was the earliest proponent of the theory that hypochondriasis was the result

of sexual drives (Nemiah, 1985). He originally stated that the sexual libido, when withdrawn from external objects, would be redirected to the self in the form of narcissistic libido. Eventually, the narcissistic libido "overflows," and the resulting energy is transformed into physical symptoms. Brown and Vaillant (1981) conceptualized hypochondriasis as repressed hostility. These authors felt that the disorder arose from anger over having been disappointed, hurt, abandoned, or unloved; rather than openly complain, the individual displaces these thoughts and feelings onto the body. Other analysts thought that hypochondriasis occurred in individuals defending against very low self-esteem and against the experience of the self as worthless, inadequate, and defective (McCranie, 1979). According to this view, it is easier and more tolerable to feel that something is wrong with one's body than with oneself. In addition, pain and physical suffering in the hypochondriacal patient can be seen as an atonement, expiation, and deserved punishment for past wrongdoing and the sense that one is evil and sinful (Engel, 1959).

Learning, Conditioning, and Cognitive-Behavioral. It is well known that autonomic responses can be acquired by classical and operant conditioning (Kellner, 1985). Because of the fear of disease, repeated attention to and selective focus on parts of one's body may be enhanced. The resulting anxiety and concomitant physiological changes that lead to somatic symptoms (e.g., tachycardia or irritable bowel) can be conditioned via cues in the external environment, internal cues, and even thoughts about disease. Hypochondriasis can then be characterized by a vicious cycle of anxiety and somatic sensations leading to more anxiety, and with more frequent repetitions of this cycle, an overlearned pattern of behavior occurs in a rapid and predictable sequence (Kellner, 1985). Modeling influences have also been implicated in the development of hypochondriasis (Kreitman, Sainsbury, Pearce, & Costain, 1965). As a result of observing an illness model and assuming the sick role, the individual learns that sympathy, attention, and support for the patient can be received and unpleasant duties and obligations can be avoided.

More recently, a cognitive-behavioral formulation of hypochondriasis has been developed (Salkovskis & Warwick, 1986; Warwick, 1995; Warwick & Salkovskis, 1990). Salkovskis and Warwick proposed that the central feature of hypochon-

driasis is the occurrence of negative automatic thoughts resulting from the misinterpretation of innocuous physical symptoms and signs. These symptoms tend to be misinterpreted as indicators of illness. The typical reaction to this misinterpretation is anxiety that leads to cognitive changes that maintain the physical symptom. Information is consistently selected and attended to in ways that confirm a hypochondriacal concern. Bodily checking, avoidance, and reassurance seeking are examples of this selective attention. This model has yet to be empirically tested by other investigators.

Perceptual and Cognitive Abnormalities. A very interesting etiological formulation of hypochondriasis comes from the work of Barsky and Klerman (1983). They proposed that hypochondriasis results from perceptual and cognitive abnormalities. There are three major components to their formulation: that hypochondriacal patients amplify normal bodily sensory input, that these patients incorrectly assess and misinterpret somatic symptoms, and that they are innately predisposed to thinking and perceiving concretely rather than in emotional and subjective terms. Within this model, sensory input is magnified or altered by the degree of attention and arousal experienced. Anxiety that is paired with sensory input is misinterpreted, and negative meanings are attached to benign bodily sensations. The authors have provided considerable empirical work to support their model (Barsky & Wyshak, 1989, 1990; Barsky, Wyshak, & Klerman, 1990, 1991).

Various aspects of Barsky and Klerman's (1983) model have also been verified by other investigators. DSM-III-R-defined hypochondriasis patients, it was demonstrated, report more bodily sensations when not given instruction to attend to bodily sensations and consider themselves more sensitive to benign bodily sensations without being better able to discriminate two tactual bodily signals (Haenen, Schmidt, Schoemakers, & van den Hout, 1997). Gramling, Clawson, and McDonald (1996) assessed pain perception and stress reactivity in fifteen hypochondriacal female subjects versus fifteen control subjects. The hypochondriacal group displayed significant increases in heart rate during a cold pressor test, as well as a significant hand temperature drop and slower return to baseline for hand temperature during the recovery period, compared to the control group. Hypochondriacal patients also terminated the cold pressor

task more frequently, left their foot in the cold bath water for a shorter period of time, and rated the cold pressor task as more unpleasant. MaCleod, Haynes, and Sensky (1998) compared three groups (anxious hypochondriacal, generally anxious, and nonanxious general practice attenders) on their propensity to give somatic, psychological, or normalizing attributions for common bodily sensations as measured by the Symptom Interpretation Questionnaire. The anxious hypochondriacal group gave more somatic attributions, whereas the generally anxious group tended to give more psychological and fewer normalizing attributions.

Ludwig's (1972) neurophysiological model of hysteria and hypochondriasis can also be invoked as support for Barsky and Klerman's etiological conceptualization of hypochondriasis. As noted earlier, Ludwig indicated that hypochondriasis was the flip side of hysteria. He noted that, whereas patients with hysteria have a separation or dissociation of attention from their symptoms, patients with hypochondriasis have their attention focused and locked onto their symptoms. He noted that hysterics tend to show a lack of concern about their symptoms, whereas hypochondriacs show an exaggerated sense of concern regarding their symptoms. In addition, he remarked that although hysterics did not appear to be motivated to obtain symptom relief, hypochondriacs spent most of their time looking for relief. Ludwig hypothesized that hypochondriasis results from reduced corticoreticular inhibition, which causes an increase in attention that is directed and locked onto a source of afferent stimulation. It is still early to tell, but Barsky and Klerman's (1983) etiological formulation of hypochondriasis appears promising.

Hypochondriasis as a Constellation of Illness Attitudes and Behaviors. Considerable interest in the overt attitudes, fears, and beliefs of the hypochondriacal patient has emerged (Barsky & Wyshak, 1989; Bianchi, 1971, 1973; Kellner, Abbott, Winslow, & Pathak, 1987; Pilowsky, 1967). Pilowsky (1967) administered a yes/no questionnaire to a group of hypochondriacs and to a group of psychiatric patients without hypochondriasis. He found that seventeen out of twenty questions significantly discriminated the two groups: four questions related to worry or fear of disease, two questions related to the experience of somatic symptoms, two questions related to the amount of attention paid to symptoms, two questions related to hypo-

chondriacal beliefs, and seven questions pertained to attitudes other than fears and beliefs about disease. The hypochondriacal group displayed more anxiety, fear of disease, and greater attention to symptoms than the comparison group.

In 1971, Bianchi used a structured general psychiatric and hypochondriasis interview with 235 psychiatric patients evaluated as part of a larger study that examined depression. Thirty subjects with disease phobia were found. This subgroup was compared to a nonhypochondriacal group composed of psychiatric inpatients. Cancer phobia (47%) and heart phobia (30%) were the most common conditions observed in the hypochondriacal group. This group was more prone to anxiety, obsessiveness, inhibition of anger, and lower self-esteem. In addition, this study was positive in demonstrating a relationship between hypochondriasis and a family history of disease; cancer and heart phobics tended to have more family members with histories of the respective disease.

In another study by Bianchi (1973), twenty-four historical, clinical, and experimental variables were examined in a principal-components analysis conducted on 118 psychiatric inpatients. Patients were included in the analysis if they had one or more physical symptoms, disease phobia, disease conviction, bodily preoccupation, and psychogenic pain. Bianchi identified eight factors; five factors reflected clinical aspects of hypochondriasis. Two patterns of disease phobia were particularly noted: one was identified as "programmed augmentation" that reflects the indirect influence of family illness on the patient's subsequent disease phobia; the second reflects current anxiety and depression associated with disease phobia and was identified as "current augmentation." The author also found evidence for another subgroup of patients who had marked paranoid feelings and delusions of disease. This last group's presentation is more consistent with a thought disorder than with a somatoform process.

Using DSM-III criteria of hypochondriasis, Kellner et al. (1987) administered illness attitude scales developed by Kellner to twenty-one patients with hypochondriasis matched with a group of patients from a family practice, a group of nonpatient employees, and a group of nonhypochondriacal psychiatric patients. Hypochondriacal patients reported significantly more fears of and false beliefs about disease, attended more to bodily sensations, had more fears about death, and

had more distrust of a physician's judgments than all of the other groups. Interestingly enough, hypochondriacal subjects sought more medical treatment than the other subjects, but they did not take better precautions about their health.

In another study (Barsky & Wyshak, 1989), 177 outpatients at a general medical clinic underwent a comprehensive evaluation including descriptive questionnaires, the Whitley Index (a thirteen-item questionnaire developed by Pilowsky that focuses on hypochondriacal attitudes and beliefs), the somatization subscale from the Hopkins Symptom Checklist-90, and the hypochondriasis subscale of the Minnesota Multiphasic Personality Inventory. A five-item self-report questionnaire that examines a patient's propensity for amplification of symptoms and questionnaires that examine health-related variables and health care utilization were also used. Hypochondriasis was positively related to amplification of symptoms fears of aging and death, importance placed on health, sense of body vulnerability to illness and injury, and greater value placed on physical appearance. The authors performed a cluster analysis and found three discrete clusters of patients. One group was characterized by evaluating health very highly, being more concerned with their bodies, and feeling more vulnerable to disease. This group was significantly more hypochondriacal than the other cluster groups. A second, more stoic group of individuals was relatively disinterested in their health and appearance, was less concerned about death, did not feel particularly vulnerable to disease, and did very little to look after themselves. The final cluster group was moderately interested in health, had moderate concerns about disease, and engaged in relatively high levels of self-treatment. The authors concluded that hypochondriacal patients have an amplifying style that has widespread repercussions on health-related attitudes and concerns about their body and disease. Although hypochondriasis is typically conceptualized as heterogeneous, it is reasonable to assume that there is a subgroup of hypochondriacal patients with a fear of and preoccupation with disease that can be readily identified.

Although considerable emphasis has been placed on hypochondriasis as a diagnostic entity, worrying about illness is common. It can range from rational concerns or intermittent short-lived worries about illness to persistent, incapacitating fears. Transient or "normal" hypochondriasis is a

common response to stressful life events (Idzorek, 1975). Patients who have recently experienced a real medical disease (e.g., cancer) may become very preoccupied and narrowly focused on normal aches and pains, which may lead to misinterpretation of these symptoms. The patient's anxiety in this situation is quite understandable and often can be alleviated with medical evaluation and reassurance. Hypochondriacal concerns also can be increased or triggered by intense study of disease. Transient hypochondriacal concerns are very common among medical students (Hunter, Lohrenz, & Schwartzman, 1964; Woods, Natterson, & Silverman, 1976). From 70% (Hunter et al., 1964) to 76% (Woods et al., 1976) of medical students in studies admitted to hypochondriacal concerns.

In another interesting study by Barsky and his associates, a group of transiently hypochondriacal patients was compared with a group of nonhypochondriacal medical patients and a group of DSM-III-R-diagnosed hypochondriacal patients (Barsky, Wyshak, & Klerman, 1990). All patients were recruited from a general medicine outpatient clinic. Patients who exceeded a predetermined cutoff score on a hypochondriasis self-report questionnaire but failed to meet a DSM-III-R diagnosis of hypochondriasis during a structured interview were included in the transient hypochondriacal group ($N = 22$). The transient hypochondriasis group was compared to a group of DSM-III-R-diagnosed hypochondriacs ($N = 41$) and a comparison group ($N = 75$) of patients who did not meet the hypochondriasis cutoff score nor met a diagnosis of hypochondriasis during the structured interview. All patients underwent structured interviews, self-report questionnaires, and cognitive and perceptual tests.

The results indicated that the transient hypochondriacal group evidenced significant decreases in hypochondriasis questionnaire scores during a 3-week period, had less psychiatric disorders, and had more medical morbidity than the DSM-III-R hypochondriacal group. In addition, the transient hypochondriacal group viewed their medical care more positively and were rated as less hypochondriacal by physician ratings. In contrast to the comparison group, the hypochondriacal group had more Axis I and Axis II disorders, reported higher levels of physical symptom amplification, and experienced more medical disorders. Using matching procedures and an analysis of covariance to control for medical morbidity, the differences in

psychiatric comorbidity and amplification style were still present. The authors concluded that patients with personality disorders and a predisposition to somatic sensations were more prone to develop transient hypochondriasis.

Finally, Gureje, Ustun, et al. (1997) examined the construct of abridged hypochondriasis. The triad of disease conviction, associated emotional distress, and medical help-seeking behavior defined abridged hypochondriasis. In a fourteen-country study of primary care facilities, the authors found that persons with abridged hypochondriasis were significantly more psychologically impaired (General Health Questionnaire) and more likely to receive a diagnosis of generalized anxiety disorder and major depression than nonhypochondriacal patients. Patients with abridged hypochondriasis were perceived by physicians as having poorer physical health. These patients also rated themselves as functionally more impaired.

Hypochondriasis and Associated Psychopathology. Hypochondriacs are a heterogeneous group and require thorough assessment (Warwick, 1995). The problems of classifying and defining hypochondriasis are largely due to the overlap of this disorder with a wide spectrum of psychiatric disorders. Hypochondriasis has been associated with characterological types, affective disorders, and thought disorders.

Psychoanalysts have typically viewed the hypochondriac as displaying obsessive-compulsive traits, especially those of orderliness, obstinacy, and parsimoniousness (Kenyon, 1976). Narcissism also has been considered a prominent feature of hypochondriasis (Kenyon, 1976). Consistent with narcissism, hypochondriacal patients are described as egocentric and excessively concerned with their bodies at the expense of regard for others or objects in their natural environment. Other patients with hypochondriasis may present with passive-aggressive, passive-dependent, borderline, or paranoid personality features. Although these personality descriptions are interesting, there are no consistent data that demonstrate a personality pattern characteristic of hypochondriacs (Kellner, 1985; Kenyon, 1976; Ladee, 1966).

Hypochondriasis is most commonly associated with an affective disorder. In his 1964 study, Kenyon found that 12% of primary hypochondriacs and 82% of secondary hypochondriacs had co-existing affective disorders. Dividing affective disorders into depressive disorders and anxiety

disorders, Kenyon determined that 44% of hospitalized primary hypochondriacs and 63% of the hospitalized secondary hypochondriacs experienced depression. Anxiety was present in 18% of patients in the primary hypochondriasis group and in 20% of patients in the secondary hypochondriasis group. These results led Kenyon to conclude that hypochondriasis is frequently part of another syndrome, usually an affective one. In an extensive review of 225 cases with hypochondriacal symptoms, Ladee (1966) determined that only three patients could not be included in a broader syndrome. Consequently, Ladee, like Kenyon, concluded that hypochondriasis does not exist as an entity in its own right. Other studies have also noted the relationship between hypochondriasis and depression and its associated morbidity (Kreitman et al., 1965; Lesse, 1968).

In contrast to Kenyon and Ladee's viewpoint, Pilowsky argued for the existence of both primary and secondary forms of hypochondriasis, distinguished by their associated features. By conducting psychiatric and physical evaluations of 147 patients, Pilowsky (1970) demonstrated that primary hypochondriacs had longer disease histories before referral for psychiatric treatment and reported more musculoskeletal and dermal symptoms, whereas patients with secondary hypochondriasis reported greater feelings of depersonalization, poor male sexual adjustment, and apprehensiveness of future disease. Pilowsky then concluded that the two groups could be differentiated in terms of variables other than the defining characteristics. However, as Kenyon (1976) noted, Pilowsky's results can be seriously questioned, because he performed all of the psychiatric and physical evaluations himself.

Barsky, Wyshak, and Klerman (1992) examined psychiatric comorbidity in forty-two DSM-III-R hypochondriacs. With a random sample of seventy-six outpatients as a comparison group, the authors noted that the hypochondriasis group had twice as many lifetime Axis I diagnoses, twice as many Diagnostic Interview Schedule symptoms, and three times as many personality disorders compared to the control group. Eighty-eight percent of the hypochondriasis group had one or more Axis I disorders (greatest for depressive and anxiety disorders). Of note, 20% of hypochondriacs had somatization disorder. The significant overlap between hypochondriasis and somatization disorder has been reported in other studies (Barsky, Wy-

shak, & Klerman, 1992; Kirmayer & Robbins, 1991; Noyes, Holt, Happel, Kathol, & Yagla, 1997; Noyes, Kathol, Fisher, Phillips, Suelzer, & Woodman, 1994a). Barsky, Barnett, and Cleary (1994) screened 1634 cases who attended a primary care clinic and identified 100 lifetime DSM-III-R panic disorder cases. Patients then completed a structured diagnostic interview and a battery of self-report measures. Physicians also completed a questionnaire about their respective patients. Twenty-five of the 100 panic disorder cases met a diagnosis of hypochondriasis. The comorbid group was compared to the remaining seventy-five "pure" panic disorder cases, a "pure" hypochondriac group (N = 51), and a fourth group of randomly selected medical outpatients without hypochondriasis or panic disorder (N = 96). Patients with pure panic disorder were less hypochondriacal, somatized less, were less disabled, were more satisfied with their medical care, and were rated by physicians as less help-rejecting and less demanding than the comorbid panic disorder and hypochondriasis group. Major depression and phobias were also more prevalent in the pure panic disorder group. Somatization disorder and generalized anxiety disorder were more prevalent in the comorbid group. The authors concluded that there is an overlap between panic disorder and hypochondriasis, but these two conditions are phenomenologically and functionally distinct and are viewed differently by physicians. Similar conclusions have been reported by other investigators (Bach, Nutzinger, & Hartl, 1996; Noyes et al., 1993). However, because of the significant overlap between hypochondriasis, somatization, and affective disorders (Barsky et al., 1992; Noyes et al., 1994a), the independence of hypochondriasis from other psychiatric conditions has to be questioned.

Hypochondriasis may present as part of a prodromal stage of a schizophrenic reaction (Kenyon, 1965). In a study by Lucas, Sainsbury, and Collins (1962), 71% of 405 unselected schizophrenic inpatients had delusions, and paranoid delusions were the most common type of delusion. Notably, 20% of 127 males and 21% of 161 females schizophrenic inpatients had hypochondriacal delusions. However, Kenyon (1976) suggested referring to these hypochondriacal delusions as somatic delusions to reduce confusion. Monosymptomatic hypochondriasis is a good example of this diagnostic confusion; it has been used to refer to delusions of parasitosis (the belief that one is being

infested), delusions of bromosis (the belief that one is emitting an offensive odor), and dysmorphophobia (the belief that one is physically malformed or unattractive; Bishop, 1980). Dysmorphophobia will be discussed in another section of this chapter. Delusions of parasitosis or bromosis, however, reflect a thought disorder more than a true somatoform process. Delusions of parasitosis and delusions of bromosis have been associated with manic-depressive illness, folie à deux, schizophrenia, and organic brain diseases (Hopkinson, 1973; Pryse-Phillips, 1971). Monosymptomatic hypochondriasis is clearly not a run-of-the-mill hypochondriasis.

Although the clinical lore of hypochondriasis has always been colorful, a critical review of this area reveals that this disorder has a number of diagnostic weaknesses (Schmidt, 1994). There is an unsatisfactory distinction between a hypochondriacal attitude (which is usually based on a continuum) versus actual hypochondriasis (having it or not). This has introduced a type of hypochondriasis that can be transitory or acute, which is really quite different from hypochondriasis as a psychiatric disorder. Hypochondriasis conceptualized as primary or secondary is not useful. Pure or primary hypochondriasis can best be thought of as disease phobia and would best go under simple phobia in the anxiety disorders section of the DSM. Hypochondriasis, conceptualized in generic form, is so associated with other psychiatric conditions that it may be of little clinical use. Thus, it should be stricken from the somatoform disorders section.

Treatment and Prognosis. There are only a handful of treatment studies of hypochondriasis. The treatment outcome depends very much on the type of hypochondriasis. Treatment for a disease phobia can be easily implemented with a behavioral package (e.g., flooding, implosion, and thought stopping), but a strict behavioral approach will be less successful with monosymptomatic hypochondriasis. Kellner (1982) reported improvement in hypochondriacal patients at 2-year follow-up with techniques that included reassurance and explanations, multiple physical examinations, and suggestions. If depression or anxiety is present, then treatment of these conditions may lead to a resolution of hypochondriasis. Electroconvulsive therapy and leucotomy as options of last resort have been used to treat hypochondriasis but without much success (Kenyon, 1976).

In a test of the effectiveness of cognitive-behavioral intervention, Avia et al. (1996) assigned patients with hypochondriasis to either a cognitive-behavioral treatment condition ($N = 9$) or a waiting-list control condition ($N = 8$). The treatment, based on Barsky, Geringer, and Wool's (1988) treatment model, consisted of six 1½ hour sessions that largely covered discussions of inadequate and selective attention, muscle tension and bad breathing habits, environmental factors, stress and dysphoric mood, and explanations of somatic signals. Improvements were noted in decreasing fears, reducing dysphoric mood, as well-treated subjects noted an improvement in being more warm, open, and extroverted. Five subjects in the waiting group were also treated, and similar improvements were noted. However, the small sample size severely limits the strength of the conclusions in this study. In a better controlled study, Warwick, Clark, Cobb, and Salkovskis (1996) randomly assigned thirty-two hypochondriacs either to a cognitive-behavioral treatment group or to a waiting-list control group. Treatment consisted of sixteen individual sessions conducted during a 4-month period, followed by a 3-month reassessment. Treatment emphasized identifying and challenging misinterpretations of symptoms and signs, restructuring images, modifying dysfunctional assumptions, deliberate body focusing, response prevention for body checking, graded exposure to previously avoided illness-related situations, and prevention of reassurance seeking. Treatment was provided by the first author, who is also a psychiatrist. The waiting-list group waited for 4 months and then were given sixteen individual treatment sessions. The treatment group showed improvement in a number of dependent variables including, among others, disease conviction, need for reassurance, time spent worrying about health, health anxiety, and Beck Depression and Anxiety. The treatment group also showed significant improvements in therapist and assessor ratings of subjects. More recently, in a systematic, three-case analysis (Papageorgiou & Wells, 1998), attention training (Wells, 1990) was used to treat hypochondriasis, and early results appear very promising. This type of treatment consists of regular practice of selective attention, attention switching, and divided attention. The treatment is designed to teach patients how to "switch off" preservative self-focused processing. Clinical improvements were noted in self-report measures of anxiety, mood,

health, worry, and illness-related beliefs and behaviors. Most impressive was the finding that none of the three subjects met the criteria for DSM-III-R hypochondriasis at the end of treatment. Obviously, controlled outcome studies are required before embracing this technique to treat hypochondriasis.

The advent of specific serotonin re-uptake inhibitors has also been instrumental in improving hypochondriasis (Escobar, 1996; Fallon et al., 1996). Preliminary data suggest that fluoxetine may be beneficial in treating hypochondriasis. Future studies that integrate cognitive-behavioral treatment and pharmacotherapy will aid in managing hypochondriasis.

Hypochondriacal patients are generally best managed in medical rather than psychiatric settings (Barsky, 1996). In terms of prognosis, hypochondriasis is generally believed to be chronic with periodic remissions and exacerbations (Noyes, Kathol, Fisher, Phillips, Suelzer, & Woodman, 1994b). A better prognosis for hypochondriasis is reportedly associated with the concurrent presence of anxiety or depression, less serious personality disorder, acute onset of symptomatology, younger age, less secondary gain, absence of an organic process, shorter duration of illness, and less severe hypochondriasis at the time of assessment (Barsky, 1996; Noyes et al., 1994b).

Body Dysmorphic Disorder.

Dysmorphophobia, originally conceptualized by Morselli in 1886, refers to a subjective feeling of ugliness or physical defect in a person of normal appearance (Andreasen & Bardach, 1977; De Leon, Bott, & Simpson, 1989; Thomas, 1984). It also includes individuals with a minimal physical defect who react out of proportion to this defect (Andreasen & Bardach, 1977; Thomas, 1984). Dysmorphophobia is a label that has largely been used in Europe (Hay, 1970a) but ignored in the United States (Nakdimen, 1977); it was originally introduced in the United States by Finkelstein (1963) and was neglected until Andreasen and Bardach (1977) brought it back into the psychiatric nomenclature.

Historically, dysmorphophobia was thought of as part of monosymptomatic hypochondriasis (Bishop, 1980). As discussed earlier, dysmorphophobia is not a hypochondriacal process. Hypochondriacs draw attention to themselves by saying

they are not normal, whereas dysmorphophobics wish to appear normal but feel that other people notice that they are not normal (Hay, 1970a).

Diagnosis. In DSM-III (APA, 1980), dysmorphophobia was categorized as an atypical somatoform disorder in the somatoform disorders section. Dysmorphophobia as a term was replaced by "body dysmorphic disorder" in DSM-III-R. Because the disturbance did not involve true phobic avoidance, the term was considered a misnomer. Table 4 presents the DSM-IV (APA, 1994) diagnostic criteria for body dysmorphic disorder. DSM-III-R classified body dysmorphic disorder as delusional in the delusional disorders (somatic subtype) section. However, in DSM-IV, a diagnosis of delusional disorder, somatic type, can be added to body dysmorphic disorder if the individual's preoccupation with an imagined defect has delusional intensity. Even with this addition to DSM-IV, it is not clear whether body dysmorphic disorder and delusional disorder, somatic subtype, are really variants of the same disorder or are two different disorders.

Clinical Description. Although much of the early information on dysmorphic disorder was based on case studies, there has been a significant increase in systematic studies of body dysmorphic disorder. Research with these patients is difficult, because they are usually seen by cosmetic or plastic surgeons and dermatologists instead of mental health professionals. These patients also avoid reporting their concerns to others because of shame and embarrassment. Individuals with body dysmorphic disorder typically focus their attention on the face, ears, nose, hair, breasts, or geni-

talia (Andreasen & Bardach, 1977; De Leon et al., 1989; Thomas, 1984). Frequent complaints also include skin blemishes and facial wrinkles. Men tend to focus on genitals, height, excessive body hair, body build, and hair thinning, and women tend to focus on breasts, legs, hips, and weight (Perugi, Akiskal, Giannotti, Frare, Di Vaio, & Cassano, 1997; Phillips & Diaz, 1997). Individuals may focus on one body part or simultaneously focus on several body parts.

The current fad of patients who seek liposuction for excess cellulite in the thighs, buttocks, and abdomen, breast enhancement and reduction, rhinoplasty, lip enhancement, and hair growth treatments is a good example of how difficult it is to separate body dysmorphic disorder from normal body image concerns about physical appearance (Sarwer, Wadden, Pertschuk, & Whitaker, 1998). DSM-IV includes the clause "normal concerns about appearance" in the differential diagnosis section without defining what "normal" represents.

At its worst, body dysmorphic disorder is the belief that one is truly ugly, and at its best, that one is unattractive but could be made attractive if surgery is performed (Andreasen & Bardach, 1977). Little is known about the psychological status of patients who pursue cosmetic surgery (Sarwer et al., 1998), given the psychological profile of body dysmorphic disorder, but surgical patients who evidence body dysmorphic disorder are likely to be very dissatisfied following surgery and to engage in an adversarial relationship with surgeons (Phillips, McElroy, Keck, Hudson, & Pope, 1994). Alternatively, many individuals have accurate perceptions of their physical defect and will respond very favorably to corrective surgery (Hay & Heather, 1973). No relationship between the degree of deformity and the presence of psychological disturbances has been found (Hay, 1970b; Lacey & Birtchnell, 1984), but dysmorphophobics do tend to be less satisfied with their body images than others (Hardy, 1982).

Body dysmorphic disorder usually begins in adolescence and early adulthood (De Leon et al., 1989; Phillips, 1996; Rosen, 1995). At times, body dysmorphic disorder can occur spontaneously or can be precipitated by innocuous remarks (Hay, 1970a). Examples of seemingly innocuous remarks include, "You have such dark eyebrows" or "Your nose looks so much like daddy's." Other triggers include sexual and physical abuse, sexual

Table 4. DSM-IV Criteria for Body Dysmorphic Disorder

-
- A. Preoccupation with an imagined defect in appearance. If a slight physical anomaly is present, the person's concern is markedly excessive.
 - B. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
 - C. The preoccupation is not better accounted for by another mental disorder (e.g., dissatisfaction with body shape and size in Anorexia Nervosa).
-

harassment, and physical injury and illness (Rosen, Reiter, & Orosan, 1995). Men will tend to camouflage with hats (Perugi et al., 1997), and women will tend to camouflage with makeup (Phillips & Diaz, 1997). These patients will often brood for many years before consulting a physician or plastic surgeon. Patients with body dysmorphic disorder tend to perceive their preoccupations as distressing, time-consuming, and difficult to resist. Often, these preoccupations become repetitive and ritualistic. Because feelings of ugliness are common but usually temporary in adolescence, it is not surprising that this disorder usually begins during this period. Typically by the third decade, these patients come into contact with physicians (Hay, 1970a). The course for body dysmorphic disorder is chronic and has a mean duration of illness of 16 years in one study (Phillips et al., 1994). In a subgroup of body dysmorphic disorder cases, patients can be highly avoidant of social situations and ultimately become housebound. Consistent with this, 75% of one sample of body dysmorphics was unmarried (Phillips et al., 1994).

Epidemiology and Demographics. The prevalence of body dysmorphic disorder continues to be uncertain. Estimates have varied from rare to 2% in clinical samples (Andreasen & Bardach, 1977; De Leon et al., 1989; Thomas, 1984). There is some controversy regarding the gender distribution for body dysmorphic disorder. Three studies reported that body dysmorphic disorder was more common in men (62% of fifty subjects, 62% of thirteen subjects, 58.6% of fifty-eight subjects, respectively; Hollender, Cohen, & Simeon, 1993; Neziroglu & Yaryura-Tobias, 1993; Perugi et al., 1997). Two other studies noted that body dysmorphic disorder was more common in women (72% of eighty-two subjects and 76% of fifty subjects, respectively; Rosen & Reiter, 1996; Veale, Boocock, et al., 1996). In the largest studied sample of persons with body dysmorphic disorder ($N = 188$), the gender ratio was essentially 1:1 (Phillips & Diaz, 1997). In the same study, men were as likely to seek nonpsychiatric medical and surgical care as women, but women were more likely to receive such care.

Body dysmorphic patients typically come from middle class environments (Andreasen & Bardach, 1977). Their intelligence is in the average or above average range, and insight into their preoccupations ranges from good to delusional (Hollender, Neville, Frenkel, Josephson, & Liebowitz,

1992; Phillips, Kim, & Hudson, 1995). Unlike many of those with other somatoform disorders, their health tends to be normal except for concern about their apparent physical defect (Andreasen & Bardach, 1977). Due to the increased importance that society places on physical appearance, the prevalence of body dysmorphic disorder is likely to increase.

Body Dysmorphic Disorder and Associated Psychopathology. It is often assumed that body dysmorphic disorder arises from another, more pervasive affective disorder (e.g. depression or anxiety), personality disorder (e.g., schizoid), or psychotic disorder (e.g., schizophrenia). Many of the earlier studies that examined dysmorphophobia and associated psychopathology came from the plastic surgery literature. Through a series of investigations, Edgerton, Jacobson, Meyer and their colleagues determined that the prevalence of psychiatric disturbances in women undergoing facelifts was 74%; enlargement of breasts, 80%; and rhinoplasty, 53% (Edgerton, Meyer, & Jacobson, 1961; Edgerton, Webb, Slaughter, & Meyer, 1964; Meyer, Jacobson, Edgerton, & Canter, 1960). All 100 men seeking cosmetic surgery were regarded as suffering from psychiatric disorders (Jacobson, Edgerton, Meyer, Canter, & Slaughter, 1960).

One of the most widely cited papers on dysmorphophobia (Andreasen & Bardach, 1977) was based largely on anecdotal impressions and two case studies. Hay's work (1970a,b) is among the few attempts to obtain a larger sample of dysmorphophobics and to include a comparison group. In one study, Hay (1970a) compared seventeen dysmorphophobic patients to an age- and gender-matched control group. All subjects completed a structured psychiatric interview and psychological test battery (Hysteroid-Obsessoid Questionnaire, Personal Illness Scales, punitive scale, vocabulary scale, and Eysenck's Personality Inventory). The clinical group complained of various physical defects concerning the penis, mouth, breasts, eyes, arms, and other miscellaneous body parts. Eleven patients with dysmorphophobia had personality disorders, five patients were schizophrenic, and one patient was depressed. Dysmorphophobics tended to be more obsessoid, introverted, intro-punitive, sensitive, and insecure than the comparison group. In a second study, Hay (1970b) examined a total of forty-five dysmorphophobics with complaints about their noses. Using a similar con-

trol group and protocol as in his earlier investigation, Hay found less psychopathology in this second sample of dysmorphophobics. Still, he found that eighteen of the forty-five dysmorphophobics were diagnosed with a personality disorder, and one evidenced psychosis. The personality disorders noted in this study were similar to the prior study.

Connolly and Gibson (1978) performed a controlled follow-up study of eighty-six patients who underwent cosmetic rhinoplasty, compared to 101 patients who received reparative rhinoplasty for disease or injury. At 15-year follow-up assessment, 37% of the cosmetic surgery cases (as opposed to 9% of reparative cases) had "severe neurotic disorders." The authors also found that 7% of the cosmetic cases were schizophrenic, compared to 1% of the reparative cases. In a later study, twelve dysmorphophobic patients with dermatological symptoms were compared to eleven matched psoriatic patients and twelve matched controls (Hardy & Cotterill, 1982). Based on the Beck Depression Inventory and the Leyton Obsessional Inventory, the dysmorphophobics were more depressed than and as obsessional as the psoriatics. Both clinical groups were more depressed and obsessional than the control group. These authors concluded that dysmorphophobia was associated more with a depressed state than with an obsessional state.

More recent studies have found a strong association between body dysmorphic disorder and affective disorders. The prevalence of depression in body dysmorphic patients ranges from 68% (Hollender et al., 1993) to 80% (Phillips et al., 1994). Other studies have examined the prevalence of body dysmorphic disorder in patients with affective disorders. Brawman-Mintzer et al. (1995) compared rates of body dysmorphic disorder among patients with social phobia (N = 54), obsessive-compulsive disorder (N = 53), generalized anxiety disorder (N = 32), panic disorder (N = 47), major depression (N = 42), and a normal comparison subjects (N = 33). Body dysmorphic disorder was most prevalent in social phobia (11%) and obsessive-compulsive disorder (8%). The authors concluded that body dysmorphic disorder may share etiologic elements with both social phobia and obsessive-compulsive disorder. A cross-sectional, interview-based survey of fifty patients who met the DSM-IV diagnosis of body dysmorphic disorder revealed that patients

were female (76%), primarily single or divorced (74%), and suffered from a mood disorder (26%), social phobia (16%), or obsessive-compulsive disorder (6%) (Veale, Boocock, et al., 1996). Personality disorders were present in 72% of cases; paranoid, avoidant, and obsessive-compulsive were the most common. Wilhelm, Otto, Zucker, and Pollack (1997) examined comorbidity rates among 165 outpatients who sought treatment for anxiety disorders. Following structured interviews, the authors identified eighty patients with panic disorder, forty patients with obsessive-compulsive disorder, twenty-five patients with social phobia, and twenty patients with generalized anxiety disorder. Overall, 6.7% of anxiety disordered patients met a diagnosis of body dysmorphic disorder, and the rate of body dysmorphic disorder was highest among patients with social phobia (12.0%). They also concluded that social phobia precedes the onset of body dysmorphic disorder.

The specific relationship between body dysmorphic disorder and obsessive-compulsive disorder has been examined in other reports (Phillips, McElroy, Hudson, & Pope, 1995; Simeon, Hollender, Stein, Cohen, & Aronowitz, 1995). In a DSM-IV field trial of 442 patients who met a diagnosis of obsessive-compulsive disorder, 12% met a comorbid diagnosis of body dysmorphic disorder (Simeon et al., 1995). This subsample had more anxious, impulsive, and schizotypal features than obsessive-compulsive disorder patients without body dysmorphic disorder. The comorbid group also had less insight into their condition, less insight associated with greater severity of illness, and more functional impairment. No differences between the two groups in demographic variables, obsessive-compulsive symptoms, or age of onset were noted. The authors concluded that, given the comorbidity between obsessive-compulsive disorder and body dysmorphic disorder and the similarities in age of onset, gender ratio, and clinical characteristics, the two disorders are strongly related and may be part of the same spectrum. In an excellent review article that examined the question whether body dysmorphic disorder is part of an obsessive-compulsive spectrum, affective spectrum, or both, Phillips et al. (1995) concluded that body dysmorphic disorder could be conceptualized more narrowly as an obsessive-compulsive spectrum disorder and more broadly as a form of affective spectrum disorder.

Phillips and colleagues have also been instrumental in trying to differentiate insight, overvalued ideation, and delusional thinking in body dysmorphic disorder (McElroy, Phillips, Keck, Hudson, & Pope, 1993). Fifty consecutive patients with possible or current histories of body dysmorphic disorder (DSM-III-R) underwent a Structured Clinical Interview and were divided into body dysmorphic disorder patients with somatic delusions ($N = 26$) and without somatic delusions ($N = 24$). Patients had a delusional preoccupation when they were, or ever had been, completely (100%) convinced that their supposed defect was real and that their perception of their defect was accurate and undistorted. Patients who stated that they might have a real defect or that their perception was probably accurate and who consistently retained some insight were thought to have overvalued ideas (twenty cases out of twenty-four body dysmorphic disorder without somatic delusions fit this description). As expected, patients with somatic delusions had a higher lifetime rate of DSM-III-R psychotic disorders than patients without somatic delusions. Interestingly, there were surprisingly few differences in other variables (e.g., demographics, comorbidity with other mood, anxiety, and substance use disorders, and selective response to serotonin re-uptake inhibitors). The authors concluded that a subgroup of patients with imagined physical defects may display a psychotic subtype of body dysmorphic disorder. In addition, the authors stated that insight into perceived body defects can range from overvalued ideation to delusional thinking and that within some cases, insight may fluctuate from one end of the continuum to the other (Phillips et al., 1993).

In sum, body dysmorphic disorder is associated with a number of other psychiatric conditions. However, the homogeneity of body dysmorphic disorder as a psychiatric condition remains equivocal, and much research will be needed before firm conclusions about body dysmorphic disorder can be drawn.

Treatment. Psychological treatment and pharmacological agents have been effective in treating body dysmorphic disorder. Earlier studies in the treatment of body dysmorphic disorder included psychodynamic approaches (Bloch & Glue, 1988; Philippopoulos, 1979) as well as behavioral approaches (Marks & Mishan, 1988; Neziroglu & Yaryura-Tobias, 1993), both of which appeared

promising. However, these are uncontrolled case studies that suffer from a number of methodological problems. Recent studies have yielded more impressive results. Rosen et al. (1995) randomly assigned fifty-four body dysmorphic disorder cases to a cognitive-behavior therapy group or a no-treatment control group. The treatment group received eight 2-hour sessions. Therapy focused on modifying intrusive thoughts of body dissatisfaction and overvalued thoughts about physical appearance, exposure to avoided body image situations, and eliminating body-checking. Symptoms of body dysmorphic disorder were significantly reduced in the treatment group, and the disorder was eliminated in 82% of cases at 2 weeks post-treatment and in 77% at the 18-week follow-up. Veale and associates (Veale, Gournay, et al., 1996) also evaluated cognitive-behavioral treatment of body dysmorphic disorder. Nineteen patients were randomly assigned to twelve sessions of cognitive-behavioral treatment ($N = 9$) or a waiting-list control condition ($N = 10$). The results indicated that subjects in the treatment condition experienced a 50% reduction in symptoms on the Yale-Brown Obsessive-Compulsive Scale at posttreatment. Follow-up data were not available.

MAO inhibitors (Jenike, 1984) and tricyclic antidepressants (Brotman & Jenike, 1984) were reportedly effective in treating body dysmorphic disorder. Consistent with the debate over dysmorphic phobia as an overvalued idea versus a delusion, Riding and Munro (1975) advocated the use of pimozide, an antipsychotic agent, to treat body dysmorphic disorder. According to these authors, a positive response to pimozide was indicative of a delusional process, and a negative response was indicative of a disturbance rooted in personality. More recent pharmacological studies of body dysmorphic disorder emphasized the utility of serotonin re-uptake inhibitors (e.g., fluoxetine, paroxetine, and fluvoxamine). One retrospective study of 316 treatment trials on 130 patients noted clinical improvement in 42% of sixty-five serotonin re-uptake inhibitor trials in contrast to 30% of twenty-three trials with MAO inhibitors, 15% of forty-eight trials with nonserotonin re-uptake inhibitor tricyclics, and 3% of trials with neuroleptics (Phillips, 1995). In a clinical series by Phillips (1995), 70% of sixty-one serotonin re-uptake inhibitor trials demonstrated significant clinical improvement. In a retrospective study by Hollender et al. (1993), fifty patients were re-

viewed, and thirty-five cases were deemed much improved in serotonin re-uptake inhibitor trials. Eighteen cases on nonserotonin re-uptake inhibitor tricyclics evidenced no improvement at all. The preferential response of body dysmorphic disorder to serotonin re-uptake inhibitors is similar to the response of obsessive-compulsive disorder to serotonin re-uptake inhibitors, and this has added to the speculation that body dysmorphic disorder is part of the obsessive-compulsive spectrum (Hollender et al. 1992; Phillips, 1995). There is also the potential to augment serotonin re-uptake inhibitor trials with other medications (e.g., buspirone and pimozone) to enhance the treatment outcome, but controlled trials are needed (Phillips, 1995).

Somatoform Disorder Not Otherwise Specified

Included in this wastebasket category of disorders are somatoform presentations that do not meet the criteria for any specific somatoform disorder. Table 5 presents DSM-IV (APA, 1994) ex-

**Table 5. Somatoform Disorder
Not Otherwise Specified**

This category includes disorders with somatoform symptoms that do not meet the criteria for any specific Somatoform Disorder. Examples include

1. Pseudocyesis: a false belief of being pregnant that is associated with objective signs of pregnancy, which may include abdominal enlargement (although the umbilicus does not become everted), reduced menstrual flow, amenorrhea, subjective sensation of fetal movement, nausea, breast engorgement and secretions, and labor pains by the expected date of delivery. Endocrine changes may be present, but the syndrome cannot be explained by a general medical condition that causes endocrine changes (e.g., a hormone-secreting tumor).
2. A disorder involving nonpsychotic hypochondriacal symptoms of less than 6 months' duration.
3. A disorder involving unexplained physical complaints (e.g, fatigue or body weakness) of less than 6 months' duration that are not due to another mental disorder.

amples of somatoform disorder not otherwise specified. No other information is presented about this category of disorders in the DSM-IV.

Factitious Disorders

If the somatoform disorders are replete with conceptual difficulties, diagnostic quandaries, and insufficient empirical data, these problems are even more prominent with factitious disorders. The existing literature is reviewed and diagnostic and clinical features are outlined along with information pertaining to etiology and treatment.

Diagnosis and Clinical Description. Factitious disorders are characterized by deliberate and apparently senseless simulation or feigning of psychological and/or physical illness. Unlike malingering, where there is recognized secondary gain, patients with factitious disorders undergo medical or psychiatric assessment and treatment for the primary purpose of assuming the sick role. Although their behavior is typically considered under voluntary control, these patients believe that it is in fact beyond their control and that their behavior feels quite compulsive. To support their claimed histories, these patients go to great lengths to produce symptomatology: engage in self-mutilating behaviors (e.g., picking away at a scab wound), self-inject bacteria to produce septicemia, contaminate urine samples with feces or blood, or manipulate thermometers (Feldman, Ford, & Reinhold, 1994). These patients are usually very colorful and dramatic in presentation; their self-reports tend to be extremely vague and inconsistent (bordering on pathological lying); they often are very knowledgeable about medical assessments and treatments; they are eager to undergo highly invasive, even life-threatening procedures; and they deny allegations and will eventually bolt out of the hospital against medical advice, only to start the whole process again at another hospital.

In DSM-IV (APA, 1994), there are two categories of factitious disorders presented: factitious disorder and factitious disorder not otherwise specified. Factitious disorder is also coded according to three subtypes: factitious disorder with predominantly psychological signs and symptoms, factitious disorder with predominantly physical signs and symptoms, and factitious disorder with combined psychological and physical signs and symp-

**Table 6. Factitious Disorder
Not Otherwise Specified**

This category includes disorders with factitious symptoms that do not meet the criteria for Factitious Disorder. An example is factitious by proxy: the intentional production or feigning of physical or psychological signs or symptoms in another person who is under the individual's care for the purpose of indirectly assuming the sick role (see. p. 725 for suggested research criteria).

Source: American Psychiatric Association. (1994). *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (p. 475). Washington, DC: Author. Reprinted by permission.

toms. Table 6 includes DSM-IV diagnostic criteria for factitious disorder. Compared to DSM-III-R criteria for factitious disorder, there is one change of note in the DSM-IV criteria. Factitious disorder with combined psychological and physical signs and symptoms was categorized under factitious disorder, not otherwise specified, in DSM-III-R (APA, 1987).

The essential feature of factitious disorder with psychological signs and symptoms is simulation and feigning of mental illness. The range of psychopathology simulated may include hallucinations, delusions, depression and suicidal ideations, anxiety, and other bizarre behavior. Associated with the representation of depression is factitious bereavement, which represents a false claim of a recent death of someone significant under very dramatic circumstances (Sussman, 1989). Other types of factitious presentations with psychological signs and symptoms include factitious post-traumatic stress disorder associated with combat experiences (Lacoursiere, 1993; Lynn & Belza, 1984), factitious multiple personality (Toth & Baggaley, 1991), and factitious AIDS (Songer, 1995).

The detection of mental illness is a difficult task, and diagnosis is usually made after prolonged observation. Simulation of mental illness is suspected when a patient's symptoms become worse upon being observed or when new symptoms arise whenever discharge attempts are made (Sussman, 1989). Patients who participate in clinical trials of a new drug should be carefully evaluated for this disorder (Sussman, 1989). The iatrogenic effects of psychiatric care are probably not as life-threatening as those of medical care, but these

patients are willing to take massive doses of potent psychotropics and undergo electroconvulsive therapy.

The term Munchausen's syndrome is perhaps the most enduring and widely used label for factitious disorder with physical signs and symptoms. The label was first used in a seminal paper by Richard Asher in 1951. The eponym was named after Baron Karl Friedrich Hieronymus Frieheß von Munchausen, an eighteenth-century figure renowned for his tall tales of adventure in foreign lands. This fictional character became popular through the writings of Rudolf Raspe (Sakula, 1978). Asher (1951) noticed that a group of patients encountered in his work at a large-scale British hospital were characterized by far-reaching travels and dramatic and colorful recounting of personal medical histories that were, nonetheless, contrived. These cases often came in as medical emergencies and were categorized as acute abdominal type, hemorrhagic type, and neurological type. A multitude of scars all over their bodies (especially the abdominal area), truculent and irritable behavior while hospitalized, and multiple hospitalizations were commonly observed by Asher. Other terms used to describe these patients or their disorder include "hospital hoboos," "hospital vagrants," "hospital addiction," "peregrinating patients," "polysurgical addiction," "artifactual illness," and "S-H-A-F-T syndrome" (Sussman, 1989).

Asher's paper was followed by two review studies of Munchausen's syndrome (Ireland, Sapira, & Templeton, 1967; Spiro, 1968). Spiro (1968), in particular, was instrumental in asserting that Munchausen's syndrome was a misnomer, and he suggested the term chronic factitious illness as a replacement, which eventually became incorporated in the DSM-III. Nadelson (1979) agreed that the earlier term was a misnomer, noting that Baron Munchausen was not known for multiple hospital stays, nor did he submit himself to multiple invasive procedures or engage in self-destructive acts. Despite the change in label to factitious disorder, the term Munchausen's syndrome continues to remain popular. There are many case examples of factitious disorder with physical signs and symptoms in the literature: cancer (Feldman et al., 1994), septic arthritis of the right knee (Guziec, Lazarus, & Harding, 1994), hermaphroditism (Warren, Sutherland, & Lenz, 1994), hypoglycemia (Roy & Roy, 1995), pene-

trating chest wound due to sewing needles (Dixon & Abbey, 1995), and factitious quadriplegia (Feldman & Duval, 1997).

Except for a handful of case studies (Linde, 1996; Parker, 1993; Powell & Boast, 1993), there is very little formal information on factitious disorder with mixed psychological and physical signs and symptoms. One particular case is worth reporting because of its significant morbidity and cost (Powell & Boast, 1993). During a 12-year period, a subnormal man spent 6 years in institutions, 1300 days in psychiatric units, 556 days in prison, 354 days in medical care, leading the authors to refer to their case as "the million dollar man." Interestingly enough, the authors refer to their case as an example of Munchausen's syndrome. This illustrates the main problem with factitious disorder with physical signs and symptoms. In all practicality, most, if not all, cases of factitious disorder with physical signs and symptoms have a psychological component. At present, factitious disorder with mixed features is likely to represent a wastebasket category, including cases that do not fit neatly into other diagnostic categories.

Few data are available on the age of onset, prevalence, or family pattern of factitious disorder. Although factitious disorder has resulted in death (Feldman et al., 1994), the morbidity and mortality rates for factitious disorder are not known. The course of factitious disorder may be episodic or last a lifetime, and symptom experiences may vary in severity, chronicity, and resulting level of functional impairment. The Munchausen's syndrome version of factitious disorder (i.e., factitious disorder with physical signs and symptoms) is considered the most severe form and occurs in approximately 10% of all cases with factitious disorder (Eisendrath, 1989). Thirty-two of 343 patients referred to the National Institute for Allergy and Infectious Disease had factitious disorder (Aduan, Fauci, Dale, Herzberg, & Wolff, 1979). Sutherland and Rodin (1990) retrospectively reviewed 1288 case files consecutively referred to a psychiatric consultation service in a tertiary care hospital. A diagnosis of factitious disorder was made in ten (0.8%) of these cases; seven of the ten cases were females. Five (0.3%) of 1538 cases referred to a neurological unit had DSM-III-R factitious disorder, feigning neurological syndromes (Bauer & Boegner, 1996). They also concluded that all factitious disorder patients

displayed the characteristic features of self-discharge, aggressive behavior, pathological lying, and hospital wandering.

Through retrospective review of cases seen during a 9-year period in the consultation and liaison service of a large-scale medical hospital, Freyberger, Nordmeyer, Freyberger, and Nordmeyer (1994) identified seventy patients with factitious disorder, the largest sample of factitious disorder cases from a single setting. General characteristics of the sample were that it was primarily female (57%), unmarried (69%), the age of onset was in the early to midthirties, less than half the sample had elementary school education, but a substantial proportion (24%) of the sample worked in academic and professional settings. Pankratz (1981) surveyed the medical literature from 1968 to 1980 and attempted to tabulate the characteristics of patients with Munchausen's syndrome. Pankratz was able to document 104 adult cases and eleven child cases of Munchausen's syndrome. He found that males were twice as likely as females to have Munchausen's syndrome. The mean age for males was 39.9, and the mean age for females was 30.9. The age range varied from early childhood to 64 years of age. As with the somatoform disorders, pain was the most common complaint and was mentioned in 75% of the cases. The next most common complaint was bleeding, mentioned in 31% of cases. About one-quarter of all cases reported difficulties with the genitourinary system, and another one-quarter of the cases had cardiac difficulties. Ninety-five percent of patients surveyed had multiple hospitalizations, 77% did some "hospital shopping," and 61% had multiple surgeries. Leaving against medical advice occurred in 42% of the patients. Twenty-two percent of the cases were related to the medical profession in one capacity or another, a finding noted by other investigators (Aduan et al., 1979; Nadelson, 1979).

In another interesting study, Carney (1980) examined 35 patients, seen during a 10-year period, whose behavior gained them admittance to hospitals. Carney's sample consisted of nine males and twenty-six females whose mean age was 32.2 years. He divided his sample into "wandering" (N = 15) and "nonwandering" (N = 20) groups; however, the criteria used in assigning patients to wandering or nonwandering groups were not forwarded. Still, with this wandering/nonwandering variable, he obtained some revealing findings. Wanderers were more likely to be male and unem-

ployed, changed employment more frequently, abused alcohol and drugs, were more motivated by external gains, had personal histories lasting more than 10 years, were socially more maladjusted, and achieved less than nonwanderers. Conversely, nonwanderers were more stable, had less dramatic and more subtle symptomatology, and were harder to detect as artifactual. These patients were also more likely to be socially conforming women who worked hard as nurses. Twenty-six of the thirty-five patients had sexual and marital problems. Carney's study demonstrates the extent of impairment that individuals with factitious disorder have across many areas of functioning. Furthermore, it shows that patients with factitious disorder are not homogeneous in presentation (Sutherland & Rodin, 1990).

Factitious Disorder and Associated Psychopathology. Persons diagnosed with factitious disorder with psychological signs and symptoms generally have concurrent diagnoses of borderline personality disorder (Sussman, 1989). Hay (1983) conducted a review of the literature on the simulation of psychosis and additionally provided a presentation of six cases for discussion purposes. He concluded that the simulation of schizophrenia is a prodromal phase of psychosis that occurs in deviant premorbid personalities. Pope, Jonas, and Jones (1982) were able to identify nine patients with factitious psychosis out of 219 patients admitted with a psychotic disorder. After conducting 4- to 7-year follow-ups, they concluded that these patients did not develop typical psychotic episodes. However, these persons had high psychiatric comorbidity and poor social outcomes due to the severity of underlying personality disorders. These investigators aptly stated that "acting crazy may bode more ill than being crazy."

The differential diagnosis of factitious disorder with psychological signs and symptoms typically involves organic mental syndromes (e.g., pseudodementia), personality disorders (e.g., antisocial personality disorder), and malingering. In organic mental syndromes, the behavior is usually consistent with medical evidence and neuropsychological findings that reflect an organic profile. Cases with factitious disorder have difficulty feigning corroborating organic findings or providing an organic neuropsychological profile. Unlike factitious disorder, true psychotic behavior does not change upon observation. Simulated mental illness by antisocial types is also likely to fluctuate

and to be noticed after prolonged observation in the hospital. In malingering, identifiable secondary gain is present, whereas in factitious disorder with psychological symptoms, assuming the role of a psychiatric patient is the main goal. However, this may be extremely difficult to identify in the clinical setting. Some investigators have argued that factitious disorder with psychological signs and symptoms should be considered under the provisional diagnosis section in future editions of the DSM, if not dropped altogether from the DSM due to subjectivity in interpreting criteria and poor reliability of this diagnostic subcategory (Rogers, Bagby, & Rector, 1989; Rogers, Bagby, & Vincent, 1994).

In diagnosing factitious disorder, any disorder in which physical symptoms are prominent should be considered part of the differential diagnosis (Sussman, 1989). As noted earlier, the possibility of factitious disorder in the presence of actual physical disease must always be explored. A good example of this was reported in a case whereby an organic brain disorder led to the development of Munchausen's (Lawrie, Goodwin, & Masterton, 1993). Factitious disorder with physical symptoms is differentiated from somatization disorder in that factitious patients are consciously producing physical symptomatology, are more willing to undergo multiple procedures, and display a more extreme course of hospitalizations than patients with somatization disorder. There is often a symbolic significance or temporal relationship between the symptoms displayed and the emotional conflicts experienced by persons with conversion disorder, which factitious disorder cases are not likely to exhibit. Hypochondriacs do not produce their symptoms voluntarily and are usually not willing to submit themselves to aggressive and invasive procedures.

Consideration of personality disorders is also essential in establishing a diagnosis of factitious disorder. Antisocial, borderline, histrionic, schizoid, and narcissistic personality disorders have been noted in factitious disorder with physical signs and symptoms (Bauer & Boegner, 1996; Freyberger et al., 1994; Sutherland & Rodin, 1990). Due to pathological lying, inability to form close relationships, hostile and aggressive behavior, and alcohol and drug abuse, factitious disorder cases can be mistaken for antisocial personality disorder. However, even when individuals with antisocial traits have physical symptomatology,

they do not admit themselves for invasive procedures, nor do they spend most of their time in hospitals. Though the recounting of symptomatology by factitious cases may be done in a dramatic and histrionic fashion, these patients are actually quite withdrawn and bland on closer inspection. The differential between factitious disorder and borderline personality disorder is very difficult because of the similarly chaotic lifestyles, interpersonal problems, self-destructive behaviors, and the sense of entitlement that both groups evidence. One psychiatrist stated that Munchausen's syndrome should be considered a subgroup of the borderline character (Nadelson, 1979). Sussman (1989) similarly states that patients with factitious disorder should carry a diagnosis of borderline disorder on Axis II. As bizarre as the behavior of factitious disorder cases with physical symptoms is, they do not display any evidence of the marked thought disorder or prominent delusions of the schizophrenic. Malingers can be differentiated from factitious disorder by the identification of secondary gain and their ability to terminate their symptomatology as soon as it is not profitable.

Etiological Formulations. Factitious disorder is multifactorially determined. Most of the discussion of the etiology of this disorder is based on psychodynamic theory (Folks, 1995; Nadelson, 1979; Pankratz, 1981; Spivak, Rodin, & Sutherland, 1994; Sussman, 1989). Common psychodynamic themes revolve around dependency, abandonment, masochism, and mastery. Many patients with Munchausen's syndrome have experienced some form of parental cruelty, neglect, or abandonment. Early experiences of this kind prevent the patient from developing an adequate sense of worth and independence. Often, the patients are hospitalized for a genuine medical concern in childhood or adolescence. Factitious disorder can be reflected in socially sanctioned behavior that allows a dependent person to receive care from a symbolic parental figure (e.g., a physician). The invitation of painful diagnostic procedures and medical interventions may reflect a need to suffer for past sins or to reduce guilt associated with unconscious sexual impulses or rage. Others have argued that patients with factitious disorder may have disturbances in the core self (Spivak et al., 1994), which would be consistent with the prominent association of factitious disorder with borderline personality disorder. Factitious disorder can be also used to gain mastery over parental figures

by fooling and frustrating them. In assuming the role of the patient and reliving the painful experience through multiple hospitalizations, the patient can seize control of the illness by terminating it voluntarily. A simpler explanation for factitious disorder is the powerful reward in the form of identity and recognition that the patient obtains in taking on the sick role.

A diathesis-stress model of factitious disorder has recently been presented (Trask & Sigmon, 1997). Early conditioning or traumatic experiences combined with biological predisposition lead the individual to develop factitious disorder. Trask and Sigmon (1997) reviewed fifty-six cases of Munchausen's syndrome from the literature and noted that 42% of cases had either traumatic events in childhood or prehospitalization stressors, and the majority of the remaining cases failed to provide enough information to determine the presence of early childhood traumas. However, there is very little data available to ascertain the value of this model. Regardless of theoretical orientation, the difficulty in understanding the etiology of factitious disorder is best captured in the following quote from Pankratz (1981):

It is difficult to construct one theory that can explain the self-destructiveness of injecting oneself with parrot feces, the grandiosity of claiming to be an oceanographic physicist working with Jacques Cousteau, the passivity of submitting to 48 lumbar punctures, the skill to stop breathing to unconsciousness, and the wanderlust for 423 admissions. (p. 74)

Treatment. Needless to say, there are no controlled comparative outcome studies of factitious disorder; consequently, most of what is known about treatment is based on anecdotal reports. Clearly, the most important facet in treating this disorder is early diagnosis. This allows prevention of harmful iatrogenic effects. Once the assessment is completed, the disposition consists of a referral for psychiatric care or confrontation by the medical team and support staff. Although psychiatric hospitalization is probably the first essential step with these patients, much of this depends on the way patients respond to confrontation. Some authors believe that confronting the patient with the "facts" in a noncondemning fashion is therapeutic (Nadelson, 1979; Reich & Gottfried, 1983), whereas others feel that confrontation can be harmful (Eisendrath, 1989). There is a general consensus that room searches and "unmasking ceremonies" should be avoided at all costs because this sets up an adversarial relationship and may provoke de-

parture against medical advice (Sussman, 1989). Given the complexity of factitious disorder, it is not surprising that multimodal approaches (combined medical and psychiatric interventions) work best in managing factitious disorder. Folks (1995) reported that successfully managed case of factitious disorder share three common therapeutic approaches. He noted that it is important to reinforce healthy behaviors, emphasize the role of a primary therapist, and maintain a consistent relationship with a primary physician, regardless of the clinical outcome.

Factitious Disorder Not Otherwise Specified.

In DSM-III-R, factitious disorder not otherwise specified was designed to capture factitious presentations that were not consistent with either factitious disorder with psychological symptoms or factitious disorder with physical symptoms. This is still the case. However, now DSM-IV suggests categorizing factitious disorder by proxy as factitious disorder not otherwise specified (APA, 1994). Factitious disorder by proxy is also listed in the DSM-IV section of criteria sets and axes provided for further studies. The research criteria for factitious disorder by proxy are listed in Table 7. The essential feature of this presentation is the deliberate production and simulation of psychological and physical signs or symptoms in another person who is under the perpetrator's care. Very often, the victim is a child, and a parent, usually the mother, intentionally fabricates or feigns symptoms in the child. The parent's aim is to have the child sub-

jected to a number of tests and invasive treatments; this behavior essentially constitutes a form of abuse.

Although there are a number of colorful case descriptions of factitious disorder by proxy (Feldman et al., 1994; Fisher, Mitchell, & Murdoch, 1993; Livingston, 1987; Sigal, Altmark, & Carmel, 1986), there is little actual data on factitious disorder by proxy. With a discussion of two cases, Meadow (1977) was first responsible for bringing attention to factitious disorder by proxy. Based on case reports and literature review, significant morbidity and mortality in factitious disorder by proxy have been noted (Jani, White, Rosenberg, & Miasami, 1992; Meadow, 1990; Ostfeld & Feldman, 1996; Rosenberg, 1987; Schreier & Libow, 1993; Taylor & Hylar, 1993). Multiple surgeries, impaired gastrointestinal functioning, joint and gait problems, brain damage, seizures, fevers, apnea, and bleeding, are common medical sequelae of factitious disorder by proxy. In her review of the literature, Rosenberg (1987) noted a 9% mortality rate. In a sample twenty-seven victims of repeated suffocations, Meadow (1990) noted that there was a 55% mortality rate in their siblings. Although there is little data on prevalence and gender breakdown of victims, perpetrators are usually mothers. Sometimes older siblings are coached into colluding with a parent in perpetrating factitious acts on younger children and sometimes victims, themselves, can play active roles in being victims of factitious acts (Sanders, 1995).

A number of explanations for the etiology of factitious disorder by proxy have been put forward. Psychodynamic theory suggests that the parental figure is using the child to act out transference issues against the physician (Feldman, Rosenquist, & Bond, 1997; Schreier & Libow, 1993). Schreier & Libow (1993) have come to view the mother as engaged in a sadomasochistic relationship with the physician, where the child serves as a way to control the symbolic parental figure, the physician or the hospital. Behaviorally, the perpetrator may be responding poorly to stress from parenting, marriage, social relationships, and other life demands, and factitious behavior may be a cry for help and attention (Rosenberg, 1987; Sanders, 1995; Schreier & Libow, 1993). From the perspective of family systems, factitious behavior may be due to enmeshment, marital dysfunction, and substance and sexual abuse (Feldman et al., 1994; Rosenberg, 1987).

**Table 7. DSM-IV Research Criteria
for Factitious Disorder by Proxy**

-
- A. Intentional production or feigning of physical or psychological signs or symptoms in another person who is under the individual's care.
 - B. The motivation for the perpetrator's behavior is to assume the sick role by proxy.
 - C. External incentives for the behavior (such as economic gain) are absent.
 - D. The behavior is not better accounted for by another mental disorder.

Source: American Psychiatric Association. (1994). *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (p. 727). Washington, DC: Author. Reprinted by permission.

There is little data on comorbidity in perpetrators of factitious disorder by proxy. Similar to the factitious disorder with psychological and physical signs and symptoms, the personality types of adults engaged in factitious behaviors by proxy tend to be borderline, histrionic, and narcissistic. In the only group study of factitious disorder by proxy (Bools, Neale, & Meadow, 1994), psychiatric histories were reported in forty-seven mothers with factitious disorder by proxy. Seventeen subjects were thought to have personality disorders, usually histrionic and borderline. Ten subjects had histories of substance abuse, twenty-six subjects had histories of self-harm, and nine subjects had criminal histories that were independent of convictions related to the children. Thirty-four subjects had histories of factitious disorder or somatoform disorder.

Although there is no specific effective treatment for factitious disorder by proxy, the ultimate goal of treatment is the safety of children (Folks, 1995). Meadows (1982) outlined a treatment plan that consists of separating the child from the parental figure; corroborating the details of the history and the temporal relationships among signs, symptoms, and the presence of the parental figure; thoroughly investigating the reliability of signs and symptoms; and psychiatric consultation. Video surveillance has been proposed to confirm factitious disorder by proxy (Foreman & Farsides, 1993), but this is controversial from ethical, medical, legal, and psychological perspectives (Feldman et al., 1994; Southall & Samuels, 1993). In the absence of consistent effective treatment of the perpetrator and a safe environment for the child, the separation of the child from the parental figure is the primary intervention (Feldman et al., 1997). When there is a high risk for reoffending, foster home placement needs to be considered (Feldman et al., 1997). Bools et al. (1994) reported that when children were returned to parental figures rated as having moderate to severe factitious disorder by proxy, illness was again fabricated 35% of the time. Some emphasis has been placed on education in early detection and management of potential cases of factitious disorder by proxy to reduce the overall cost to individuals, systems, and society (Jani et al., 1992; Ostfeld & Feldman, 1996).

An interesting variant of Munchausen by proxy syndrome is Munchausen by adult proxy syndrome, whereby the elicitation of symptomatology in an adult is produced by another adult (Sigal

et al., 1986). Sigal et al. (1986) presented a fascinating case of a 34-year-old man who killed his wife with injections of gasoline during several years. Three years later, he repeated the process with a girlfriend who was threatening to leave him. After drugging her with flunitrazepam, he resorted to injections of gasoline in the neck, breast, and backside of his girlfriend's body. She eventually became a paraplegic, and he spent most of his time looking after her. He was apparently more interested in attention from the medical staff than he was in his girlfriend's health. He is now serving 46 years in jail for murdering his wife.

Conclusion

This group of disorders is unquestionably one of the least understood of mental disorders. A great deal of research in some areas (e.g., somatization disorder, body dysmorphic disorder, and hypochondriasis disorder) has emerged. Yet, our understanding of this fascinating but complicated group of disorders has not improved much.

The database continues to be inadequate for many of the diagnostic entities present in this group. In part, this is related to the general observation that these patients are seen primarily by physicians and resist psychological evaluation and treatment. As more psychologists and other health care professionals find their way into medical settings, it is hoped that an increase in our understanding of these disorders will occur. In addition, the base rates of some of these disorders are so low that it may take many years before an adequate database can be established.

Though the database is not satisfactory, even more disturbing are the conceptual problems associated with these disorders. These conceptual problems are rampant in the DSM-IV section of somatoform and factitious disorders. The validity and reliability of the diagnostic entities are poor because these diagnostic categories overlap, are poorly defined, and are too simplistic. Many of these disorders do not have pathognomonic criteria. The diagnosis of these disorders is often based on exclusion; diagnosticians find themselves first establishing what the clinical presentation is not and then concluding what it might be. Such an approach is fertile ground for diagnostic inaccuracies. These disorders, as conceptualized, also require an organic versus psychogenic distinction.

This is an extremely difficult task to accomplish: What physical condition does not have a psychological component, and vice versa? Thus, inclusion criteria for these diagnostic categories should be conjunctive and should incorporate psychological criteria. Consistent with this approach, strict psychological versus organic etiological formulations do not take into full account the complexity of somatoform and factitious disorders. Integrated conceptual formulations are likely to lead to a better understanding of these interesting and frustrating disorders.

Dissociative Disorders

John F. Kihlstrom

Introduction

In current diagnostic nosology, the category of dissociative disorders includes a wide variety of syndromes whose common core is an alteration in consciousness that affects memory and identity (American Psychiatric Association [APA], 1994). In *dissociative amnesia* (formerly, psychogenic amnesia), the patient suffers a loss of autobiographical memory for certain past experiences; in *dissociative fugue* (psychogenic fugue), the amnesia is much more extensive and covers the whole of the individual's past life; and it is coupled with a loss of personal identity and, often, physical movement to another location; in *dissociative identity disorder* (multiple personality disorder), a single individual appears to manifest two or more distinct identities; each personality alternates in control over conscious experience, thought, and action and is separated by some degree of amnesia from the other(s); in *depersonalization disorder*, the person believes that he or she has changed in some way, or is somehow unreal (in *derealization* the same beliefs are held about one's surroundings).

Impairments of memory and consciousness are often observed in the organic brain syndromes, but dissociative disorders are functional: they are attributable to instigating events or processes that do not result in insult, injury, or disease to the brain, and produce more impairment than would normally occur in the absence of this instigating event or process (Kihlstrom & Schacter, 2000). Dissociative disorders are rather rare, but for more than 100 years, these and related phenomena have been objects of fascination for clinicians and experimentalists alike (for other recent reviews, see Bremner & Marmar, 1998; Kihlstrom, Tataryn, & Hoyt, 1993; Klein & Doane, 1994; Lynn & Rhue, 1994; Michaelson & Ray, 1996; Ross, 1997; Spiegel, 1991, 1994).

Once considered exotic, in the 1990s, dissociative disorders have become the syndromes of the moment. In March 1999, a search of the PsycINFO database revealed forty entries on psychogenic or dissociative amnesia; twenty-eight of them (70%) had appeared since the prior edition of this chapter was completed in 1990; there was also a total of eight entries on psychogenic or dissociative fugue, five of which (63%) had appeared in that same period. Multiple personality, or dissociative identity disorder, the crown jewel of dissociative disorders, yielded 868 entries: more than half of these (485, or 56%) appeared since 1990, and 708 (82%) had appeared since the first edition of this handbook was published in 1984. Remarkably, however, little of this literature consists of quantitative clinical studies, much less experimental research. Thus, the enormous amount of clinical and popular interest in dissociative disorders has not yet translated into a substantial body of research.

John F. Kihlstrom • Department of Psychology, University of California, Berkeley, California 94720-1650.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

The Evolution of a Concept

The term “dissociative disorder” is almost unique in the psychiatric nosology because the label also implies a specific mechanism, dissociation, to account for the disturbances observed. Other category labels, such as schizophrenia, anxiety disorders, and personality disorders carry no such surplus etiologic baggage. The origins of the idea of dissociation lie in a body of medical and scientific literature that emerged from 1775 to 1900 and represents what Ellenberger (1970) called the “First Dynamic Psychiatry.” The first dynamic psychiatrists were interested in a wide spectrum of phenomena, including hypnosis and other forms of suggestion; spiritism (automatic writing, crystal-gazing); the “magnetic diseases” of catalepsy, lethargy, and somnambulism (so named because of their resemblance to certain phenomena of animal magnetism, a precursor of hypnosis); ambulatory automatisms (fugue); multiple personality; and hysterical anesthetics and paralyses. Each of these phenomena reflected the power of ideas to engender action, as well as a change in consciousness in which experience, thought, and action occurred outside of phenomenal awareness and voluntary control. The pathological forms, such as hysteria and multiple personality, were “dynamic illnesses,” caused by a suggestion or idea whose origins lay in some psychological trauma whose nature was unknown to the victim. As a result of this trauma, certain experiences, thoughts, and actions become separated from the monitoring and controlling function of a central executive ego.

The dominant figure in the First Dynamic Psychiatry was Pierre Janet (1889, 1907), who identified the elementary structures of the mental system as “psychological automatisms.” Each automatism represented a complex act, finely tuned to external (environmental) and internal (intrapsychic) circumstances, preceded by an idea, and accompanied by an emotion. According to Janet, the normal person’s entire repertoire of elementary psychological automatisms was bound together into a single, united stream of consciousness, accessible to introspective phenomenal awareness and voluntary control. However, under certain circumstances, one or more automatisms could be split off from the rest, thus functioning outside of awareness, independent of voluntary control, or both—a condition which Janet labeled *desaggre-*

gation, translated into English as dissociation. The dissociation view of the unconscious, as distinct from the repression view elaborated by Freud and his followers, was endorsed by William James (1890/1980; Taylor, 1982, 1996), and promoted in America by Morton Prince and Boris Sidis, among others.

The dissociative conceptualization of consciousness was briefly popular, but the claims of the dissociation theorists were often overly broad, and their clinical and experimental studies often methodologically flawed. In the clinic, the Second Dynamic Psychiatry of Freud and his followers, with its emphasis on sex and aggression, dreams and repression, soon triumphed over the First. In the laboratory, the behaviorist revolution banished all reference to mental states, conscious or not, from the vocabulary of scientific discourse. After World War II, however, interest in consciousness—attention, primary memory, and imagery—was revived in the course of the cognitive revolution. The concept of dissociation and the dissociative disorders played a role in this revival, as indicated by Hilgard’s (1977; see also Kihlstrom, 1992, 1998) “neodissociation” theory of divided consciousness.

Neodissociation theory assumes that the mind is organized as a system of mental structures that monitor and control experience, thought, and action in different domains. In principle, each of the structures can process inputs and outputs independently of the others, although under ordinary circumstances each structure is in communication with the others, and several different structures might compete for a single input or output channel. At the center of the system, yet another structure exercises executive functions of monitoring and control and provides the mental basis for the experience of phenomenal awareness and voluntary control. According to Hilgard, the operations of the central executive can be constrained, and the integration and organization of the individual control structures can be disrupted, producing a state of divided consciousness. For example, the lines of communication between two subordinate structures might be cut. The operations of each would be represented in phenomenal awareness and perceived as under voluntary control, but they would not be integrated with each other. Alternatively, the links between a subordinate structure and the executive might be cut. Under these circumstances, the operations of the subordinate

would be isolated from phenomenal awareness and the experience of intentionality—a classic instance of dissociation.

Whereas both the classical dissociation theory of Janet (1889) and the neodissociation theory of Hilgard (1977; Kihlstrom, 1992) assume that the normal unity of consciousness is disrupted by an amnesia-like process, Woody and Bowers (1994) offered an alternative view that many mental and behavioral functions are performed unconsciously and automatically to begin with, by specialized cognitive modules. Thus, some degree of dissociation is the natural state. Rather than reflecting the imposition of an amnesic barrier, the phenomena of dissociation reflect the failure of these modules to be integrated at higher levels of the system (e.g., by executive control structures associated with the frontal lobes). Currently, the distinction between dissociated experience and dissociated control is debated chiefly in the literature on hypnosis (Kihlstrom, 1998; Kirsch & Lynn, 1998; Woody & Sadler, 1998), but the two competing formulations of neodissociation theory are clearly relevant to the dissociative disorders as well.

The Evolution of a Diagnosis

Dissociative disorders have a somewhat checkered history in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) periodically published by the American Psychiatric Association (Kihlstrom, 1994). In the first edition of DSM (DSM-I; APA, 1952) dissociative syndromes were classified as Psychoneurotic Disorders, in which anxiety is either “directly felt and expressed or ... unconsciously and automatically controlled” by various defense mechanisms“ (p. 32). Under this label, the dissociative syndromes included depersonalization, dissociated (multiple) personality, stupor, fugue, amnesia, dream states, and somnambulism. Precursors to DSM-I had grouped the dissociative and conversion disorders under the single rubric of “conversion hysteria,” but the two subclasses were now distinguished—dissociation by personality disorganization; conversion by isolated symptoms of anesthesia, paralysis, and dyskinesia. (DSM-I also carried a special listing of somnambulism, but this apparently referred specifically to sleepwalking.) The DSM-I conceptualization of the dissociative disorders was heavily influenced by psychoanalytic theory, as evidenced

by its reference to the discharge or deflection of repressed impulses.

In some respects, DSM-II (APA, 1968) reverted to pre-DSM practices. Here, Hysterical Neurosis, Dissociative Type, defined as an alteration in consciousness and identity, was joined by Hysterical Neurosis, Conversion Type, defined as a disorder of the special senses or the voluntary nervous system. Hysterical neurosis itself was characterized in psychoanalytic terms of the unconscious and automatic control of anxiety. However, explicit references to repression and the psychoanalytic theory of neurosis were absent from the description.

DSM-III (APA, 1980) and its revision, DSM-III-R (APA, 1987), abandoned both neurosis and hysteria as technical terms. The class of Dissociative Disorders included Psychogenic Amnesia, Psychogenic Fugue, Multiple Personality Disorder (MPD), and Depersonalization Disorder—as well as Atypical Dissociative Disorder. Conversion Disorder, by contrast, was grouped with Body Dysmorphic Disorder, Hypochondriasis, Somatization Disorder, and Somatoform Pain Disorder, under the heading of Somatoform Disorders. DSM-III-R stated that the essential feature of the dissociative disorders was “a disturbance in the normally integrative functions of identity, memory, or consciousness ...” in the absence of brain insult, injury, or disease. In the case of Psychogenic Amnesia, the essential feature is, of course, loss of memory. Psychogenic Fugue added the assumption of a new identity, as well as physical relocation away from the customary home or workplace. Somewhat surprisingly, however, the DSM-III-R criterion for Multiple Personality Disorder specified only the alternating control of behavior by at least two distinct personalities, permitted making the diagnosis on the basis of personality fragments rather than complex, integrated structures, and made no reference to interpersonality amnesia. Thus, the DSM-III-R criterion was rather liberal because it diagnosed patients who formerly might qualify only for Atypical Dissociative Disorder as instances of full-blown MPD. This liberal diagnostic criterion may account for some of the increased reporting of MPD in the 1980s and 1990s.

This situation was corrected, to some degree, in DSM-IV (APA, 1994), which returned an explicit criterion of amnesia to the diagnostic criteria for Multiple Personality Disorder, which was also re-

named Dissociative Identity Disorder (DID). Thus, it is not enough simply to find evidence of two or more “ego states” in the same person—a likely factor in the recent proliferation of the diagnosis. Some evidence of amnesia is also required, although the criterion does not specify interpersonal amnesia. Cases resembling DID, but without amnesia, are removed to the new category of “Dissociative Disorder Not Otherwise Specified” (DDNOS)—a category that also covers derealization in the absence of depersonalization and trance states such as *amok* and *latah*. DSM-IV also strengthens the emphasis, in diagnosing psychogenic fugue, on changes in personal identity, whether the loss of an old one or the assumption of a new one.

Dissociative (Psychogenic) Amnesia

Dissociative amnesia, also known as limited functional amnesia (Schacter & Kihlstrom, 1999), entails a loss of personal memory that cannot be accounted for by ordinary forgetting or by brain insult, injury, or disease (for other reviews, see Arrigo & Pezdek, 1997; Kopelman, 1995, 1997; Loewenstein, 1996; Pratt, 1977; Kihlstrom & Schacter, 2000; Stengel, 1966). The amnesia is typically retrograde, in that it covers a period of time before the precipitating event, although Janet (1893) did describe an unusual case of *anterograde* psychogenic amnesia, in which memory before the trauma remained intact, but the patient showed an inability, reminiscent of that observed in the organic amnesic syndrome, to remember events that transpired *since* the traumatic event. Nemiah (1979) distinguished three forms of psychogenic amnesia, depending on its extent: localized, covering hours or weeks; systematized, covering only specific events and related material; and generalized, involving a transitory loss of memory for one’s entire life—a condition that shades into psychogenic fugue.

Although dissociative amnesia, by definition, is not caused by brain insult, injury, or disease, the relationship between the syndrome and brain injury is better characterized as one of independence. Brain injury can occur without amnesia as one of its sequelae, and functional amnesia can occur in association with head injury (Treadwell, Cohen, & McCloskey, 1988). Although psycho-

genic amnesia has been the frequent subject of popular treatments, there has been very little research on the nature of the memory loss, its eliciting conditions, and the circumstances that lead to recovery of the lost memories (Kihlstrom & Schacter, 2000). Even Janet (1907) barely mentioned psychogenic amnesia outside of the context of somnambulism, fugue, and multiple personality. One important question for future research, especially in a forensic context, concerns the symptoms that differentiate organic and functional amnesias (Kopelman, 1995). Such information, in turn, would permit conclusions about the extent to which functional, psychogenic amnesias are misdiagnosed as organic amnesias, simply because they occur in temporal association with head injury.

Dissociative (Psychogenic) Fugue

Somewhat more is known about psychogenic fugue, also called functional retrograde amnesia (for reviews see Kopelman, 1997; Loewenstein, 1996; Pratt, 1977; Kihlstrom & Schacter, 2000; Stengel, 1966). Fugue adds a loss of identity to the loss of personal memory observed in psychogenic amnesia and sometimes physical relocation (hence the name), to boot. Fugue is often associated with physical or mental trauma, depression, problems with the legal system, or some other personal difficulty (Eisen, 1989; Kaszniak, Nussbaum, Berren, & Santiago, 1988).

Fisher (1945; Fisher & Joseph, 1949) distinguished three types of fugues. In the classic instance, there is amnesia for personal history, accompanied by a change in identity and relocation to another domicile. Fugue may also entail amnesia accompanied by the simple loss, but no change, in personal identity. Finally, a reversion to an earlier period in one’s own life may occur, with an amnesia for the interval between that earlier period and the present, but no change in identity. Clearly, the distinction between psychogenic fugue and psychogenic amnesia is difficult to make. One might say that fugues are simply very generalized amnesias, but the loss of identity that is pathognomic of fugue may be a qualitative difference.

The process of recovery from fugue is not well understood. Patients typically come to clinical attention when they become spontaneously aware of

the situation or when they fail to respond appropriately to specific questions about their background when questioned by the police, potential employers, or others. Some patients experience a sudden awakening to their original identity; others experience a sudden awareness that they do not know who they are. Nevertheless, when the situation is resolved, the patient is typically left with an island of amnesia that covers the period of the fugue state itself.

Although many clinical reports of psychogenic fugue exist, apparently only a single case has been subjected to controlled, experimental analysis. Schacter, Wang, Tulving, and Friedman (1982) performed such an analysis on a case, P.N., whose condition was apparently precipitated by the death of his grandfather. The boundaries of the amnesia were explored by the “Crovitz–Robinson” technique (Crovitz & Shiffman, 1974; Robinson, 1976), in which common words are presented as cues for retrieving conceptually related autobiographical memories. When tested during the fugue state, 86% of the patient’s memories were drawn from the period covered by the fugue—a stronger recency bias than is normally observed in such situations. Two weeks later, after the amnesia had remitted, fully 92% of the memories predated the amnesia (the lack of recency bias thus reflected an amnesia for the fugue itself). By contrast, when asked to identify pictures of famous people, the patient performed equally well during and after the amnesia. Such findings were interpreted by Schacter et al. (1982) as reflecting a selective impairment in episodic memory which spares semantic memory. However, it should be noted that semantic memory includes aspects of personal identity—one’s name, birthdate, physical and psychosocial characteristics, the names of family members, etc., as well as impersonal world knowledge (Kihlstrom & Klein, 1994, 1997). Fugue impairs semantic memory for personal information, as well as episodic memory for personal experiences.

Dissociative Identity (Multiple Personality) Disorder

Dissociative identity disorder (DID) takes the disruption of memory and identity observed in dissociative fugue one step further because there is an alternation of both memory and identity (for

recent reviews see Bliss, 1986; Putnam, 1989; Ross, 1997). When one ego state is in control of thought and action and is monitoring environmental events, memory is continuous within that ego state. However, when monitoring and control shift to another ego state, the new personality may have no access to memories of the activities and experiences of the other(s). However, some degree of cooperation is possible among ego states, when one has information or resources that the other one needs.

On the basis of their review of seventy-six named (mostly classic) cases, Taylor and Martin (1944) listed a number of features that distinguish the various ego states:

1. the “general quality” of the personality, as a whole;
2. propriety of behavior;
3. gender identity or erotosexual orientation;
4. age, handedness, or language differences; and
5. anesthesia in one or more sensory modalities, or paralysis in one or more limbs.

About two-thirds of the cases studied by Taylor and Martin were dual personalities, and about half of them showed a pattern of mutual or symmetrical amnesia. Of the remainder, most displayed only three personalities and a more complex pattern of asymmetrical amnesia. Ellenberger (1970) classified DID into three major categories: (1) successive multiple personalities, the usual case, with either symmetrical or asymmetrical amnesias (Ellenberger thought that “mutually cognizant” alter egos were infrequent); (2) simultaneous multiple personalities, very rare; and (3) personality clusters.

However, it is by no means a straightforward matter to discern which ego state, if any, is “primary.” Following the example of Eve (Thigpen & Cleckley, 1954) and perhaps influenced by the psychoanalytic concept of the repression of conflict-laden ideas, drives, affects, and impulses, there is some tendency to identify the primary personality with the ego-state that displays the most conventional, socially desirable qualities. However, Taylor and Martin (1944) argued that there was no clear pattern of “normality” or “pathology” that distinguishes the primary personality from the alter egos; sometimes, a normally subconscious personality is better adjusted than a normally conscious one. In most cases, it may be convenient to

assign the label “primary” to the ego state that is most frequently encountered or has the longest running identity. In the case of I.C. (Schacter, Kihlstrom, Canter Kihlstrom, & Berren, 1989), the pattern of memory deficit observed strongly suggested that the “primary” personality, defined in terms of frequency of encounter and degree of familiarity to other people, was actually an alter ego who first appeared when the patient was about 10 years old.*

The History of DID

The formal history of DID reaches back more than 200 years to the very beginnings of modern medical literature (Carlson, 1981, 1989).† What might be called a “classic period” for the study of DID extended from about 1880 to 1920, as reflected in the well-known reports of Azam, Janet, Prince, Sidis, and others. Of the seventy-six named cases covered by Taylor and Martin (1944) in their exhaustive review of the published literature, fifty-one (67%) were first reported during this period, and the vast majority of the rest shortly before or after it. Almost two decades later, Sutcliffe and Jones (1962) added only a single acceptable case, the “Three Faces of Eve” (Thigpen & Cleckley, 1954).

Case reports of DID fell off rapidly in the half-

century following 1920, a trend that may be attributable in part to the triumph of Freud over Janet, and in part to increased diagnosis of schizophrenia. Then, they took a sharp upward turn beginning around 1970—a trend that may be attributable in large part to the publication of *Sybil* in the popular press (Schreiber, 1973).‡ A literal avalanche of case reports followed that appeared in both the popular and professional press (Boor, 1982; Greaves, 1980; Kihlstrom et al., 1993). For example, a mail survey of selected clinicians identified 100 cases currently or recently in treatment as of 1982 (Putnam, Guroff, Silberman, Barban, & Post, 1986).

In the 1970s alone, at least by a liberal count, more cases of DID were reported than in all of the time since Mary Reynolds. Ross (1997) wrote that between 1979 and 1991 he saw “about 80” (p. 256) cases of DID in his practice in Winnipeg, Manitoba, and that between 1991 and 1997 more than 500 cases had been admitted to a single dissociative disorder treatment unit in Dallas, Texas. As if that were not enough, there has been a dramatic increase in the number of alter egos manifested in the individual case. The vast majority of cases listed by Taylor and Martin (1944)—forty-eight, or 63%—presented dual personalities, and only one case presented as many as twelve alter egos. By contrast, the majority of new cases listed by Greaves (1980) and Boor (1982) had three or more personalities, and the cases registered by Putnam et al. (1986) presented 13.3. Ross (1997) reported an average of 15.7 alter egos in a series of 236 patients.

The degree to which some of these cases are iatrogenic, or simply misdiagnosed, remains to be seen (Fahy, 1988). It is worth remembering that even in the heyday of multiple personality, around the turn of the century, when clinicians were very alert to the possibility of new cases, very few were actually diagnosed: even Janet and Prince described only four cases each (Taylor & Martin, 1944). And despite hundreds of referrals, Thigpen and Cleckley (1954) saw only one other case after Eve.

‡This claim has been made by Putnam (1989), Borch-Jacobson (1997), and Acocella (1998), among others. (For a description of the impact of this case on a DID patient, see Atwood, 1978). Interestingly, Herbert Spiegel, a Columbia University psychiatrist and distinguished hypnosis researcher who examined *Sybil* and also occasionally served as her surrogate therapist, has expressed doubts that she was a genuine case of multiple personality (Borch-Jacobson, 1997).

*Although DID is usually considered a syndrome of adult psychopathology, the fact that alter egos may begin to appear in childhood suggests that it can be diagnosed and treated in children as well (Main & Morgan, 1996; Putnam, 1997).

†The best known of the earliest cases is Mary Reynolds, reported by Mitchill (1816; see Carlson, 1984). Ellenberger (1970) cited this case on the basis of secondary reports by S. W. Mitchell (1888) and others. However, he was unable to locate the primary reference, attributed to the *Medical Repository* of 1815. A diligent search of the library shelves by Dr. Malcolm Macmillan, now of Deakin University, Australia, turned up the primary reference in the 1816 volume (Mitchell, 1816), as correspondence dated that year. The 1816 and 1817 volumes were bound together, which may explain why Taylor and Martin (1944) provided the correct volume and page number, but dated the article 1817. Ellenberger also misspells Samuel Latham Mitchill’s last name, and incorrectly identifies him with John Kearsley Mitchell, father of Silas Weir Mitchell (1888), who knew the Reynolds family and brought the case to the attention of William James (1890, pp. 359–363). I thank Dr. Macmillan for his kindness in sharing his detective work and refer readers to his important historical work on the relationship between Freud and Janet (e.g., Macmillan, 1996). For a further history of the Mary Reynolds case, see also Carlson (1981, 1984, 1989). For a history of another famous case, Miss Beauchamp, see Rosenzweig (1987, 1988).

Laboratory Studies

In view of the virtual avalanche of cases reported in both the professional and popular press since 1973, it is especially surprising that so few cases have been subject to controlled experimental analysis employing laboratory procedures. During the classic period, Prince and Sidis reported a number of studies of perception, reasoning, free association, and psychophysiology (for a review, see Kihlstrom et al., 1993). Later, Osgood and Luria (1954) and Osgood, Luria, Jeans, and Smith (1976; see also Kroonenberg, 1985) reported on blind analyses of semantic differential protocols collected from various personalities. The recent revival of interest in DID has yielded a number of psychometric studies that employed both projective and objective instruments (for a review, see Kihlstrom et al., 1993), but experimental studies have been somewhat rarer.

A salient exception to this rule is the case of Jonah, a man with three (perhaps four) alter egos, studied by Ludwig and his associates (Brandsma & Ludwig, 1974; Ludwig, Brandsma, Wilbur, Bendfeldt, & Jameson, 1972). Each of the four principal alter egos was administered a battery of personality and intelligence tests (including the MMPI and the Gough Adjective Check List, and the WAIS), a number of learning and memory tasks (including paired-associate learning and prose memory), conditioning, and psychophysiological recordings (including electrodermal responses, EEG, and event-related potentials). Another study employed experiential time sampling to document state changes in a woman vulnerable to extremely rapid alterations of personality (Lowenstein, Hamilton, Alagna, Reid, & deVries, 1987). Schacter et al. (1989) used the "Crovitz-Robinson" technique to study I.C., a case of DID with a very extensive childhood amnesia, compared to a carefully matched control group. Unfortunately, these investigators were not able to study autobiographical memory in any of the alter egos, although such an experimental case study was recently reported by Bryant (1995).

Further experimental study of DID is warranted because, although this syndrome is defined in DSM-IV as a disorder of identity and the integration of self, it is also fundamentally a disorder of memory. In every dissociative disorder, patients are unable to recollect some or all of their past actions and experiences, and in DID, an interper-

sonality amnesia reflects the inability of one alter ego to consciously recall the activities and experiences of others. However, there is more to memory than what the individual can bring to awareness, and there is evidence that memory of these forgotten events may influence the patient's ongoing experience, thought, and action outside of conscious awareness. In fact, as indicated earlier, clinical observation of such influences were the reason for the notion of "dissociation" in the first place.

In modern terminology, dissociative disorders may involve a dissociation between two expressions of memory, explicit and implicit (Schacter, 1987). Explicit memory refers to the person's conscious, intentional recollection of some previous episode, most commonly reflected in recall and recognition. Implicit memory, or memory without awareness, is reflected in any change in the person's experience, thought, or action which is attributable to some prior episode of experience, but which cannot be accounted for by explicit memory for that event. Dissociations between explicit and implicit memory are a common feature of the "organic" amnesias associated with brain insult, injury, or disease (Shimamura, 1989) and are found in the "functional" amnesias associated with dissociative disorders as well (Kihlstrom & Schacter, 2000).

Although hints of implicit memory are found in some of the earliest cases of DID, the first formal demonstration along these lines was reported in the case of Jonah (Ludwig et al., 1972), who was completely unaware of his three other alter egos. To document the pattern of interpersonality amnesia apparent on clinical examination and history, Ludwig et al. conducted various studies of verbal learning, classical conditioning, transfer of training, and learning-to-learn. For example, Jonah could not recall paired associates learned by the other personalities; and although the others could recall items learned by Jonah, they could not recall items learned by each other. However, when one alter ego was asked to learn (rather than remember) a list of paired associates initially mastered by another, each showed considerable savings. Thus, there was transfer of information between personalities on the paired-associate learning test, but not on the paired-associate recall test.

The dissociation between explicit and implicit memory observed by Ludwig et al. (1972) was further explored by Nissen, Ross, Willingham, Mackenzie, and Schacter (1988), who performed a

careful comparison between explicit and implicit memory in a single DID patient who had twenty-two different alter egos. On each test, items were presented to one alter ego, and memory for these items was tested in another; a total of eight personalities, each separated from the others by an amnesic boundary, were tested in the experiment. On two tests of explicit memory, cued recall and yes-no recognition, each ego state showed a dense amnesia for items presented to the others—in other words, there was no interpersonality transfer of explicit memory. The corresponding tests of implicit memory, however, yielded complex results: five tasks yielded some evidence of interpersonality transfer, but four others gave no evidence that implicit memory transferred between alter egos. Moreover, on some tasks there was less implicit memory between alter egos than within a single personality, indicating that even implicit memory sometimes failed to cross the amnesic barrier.

Recently, Eich and his colleagues reported a nomothetic comparison of explicit and implicit memory in nine DID patients (Eich, Macaulay, Loewenstein, & Dihle, 1997). As in Nissen et al.'s (1988) case study, free recall and cued recall tests of explicit memory yielded strong evidence of interpersonality amnesia that confirmed the clinical picture. However, a test of picture-fragment completion indicated that implicit memory was spared, but a test of word-stem completion did not. On the latter task, implicit memory was displayed only within, not between, alter egos. Eich et al. concluded that although tests of implicit memory could reveal transfer of information from one alter ego to another, "how much leakage occurs across personality states depends on the extent to which encoding and retrieval processes are susceptible to personality-specific factors" (p. 421). It would be tempting to conclude that implicit memory transfers across ego-state boundaries in DID, and explicit memory does not, but the actual pattern of results is somewhat more complex than this and remains to be clarified by further research.

A more recent development, reflecting the increased interest in biological processes in psychopathology generally, has been the use of brain-imaging techniques such as EEG frequency analysis and event-related potentials (for a review, see Kihlstrom et al., 1993). Putnam (1984) presented a preliminary report of a study of eleven DID patients and ten simulating controls that successfully

distinguished the two groups on the basis of event-related potentials. Within subjects, genuine alter egos showed greater differences in amplitude and latency than simulated ones. Mathew, Jack, & West (1985) reported a shift in regional cerebral blood flow (toward the right temporal lobe) in one patient, but there have been no similar studies employing PET or fMRI technologies. Given the enormous amount of interest in dissociative identity disorder, it is remarkable that these intriguing findings have not been followed up by studies using more rigorous methodologies that might reveal the biological substrates of amnesia, fugue, and multiple personality.

Sociocultural Influences

Some of the most difficult aspects of the current DID "epidemic" are the loosening of diagnostic criteria, the influence of popular culture (in the late nineteenth century, Stevenson's *Dr. Jekyll and Mr. Hyde*; in the late twentieth century, the cases of Eve and Sybil themselves) on patient and therapist alike, the investment that some clinicians seem to have in the syndrome, and the recent proliferation of cases with extremely large numbers of alter egos. Another troublesome aspect is the apparently common practice of eliciting alter egos through hypnosis, instead of observing them emerge spontaneously. Because the hypnotic interaction itself is highly suggestive, hypnosis affords an especially good opportunity to create alter egos out of whole cloth and for their nature to be shaped by the hypnotist's suggestions and other cues and demands contained in the hypnotic situation (Bowers & Farvolden, 1996; Frankel, 1994).

Drawing on his social-psychological analysis of hypnotic phenomena, Spanos (1986, 1994, 1996; but see Gleaves, 1996) offered an interpretation of dissociative identity disorder (and, by extension, the other dissociative disorders as well; see Spanos & Gottlieb, 1979) as a strategic social enactment in which an individual disavows responsibility for certain actions by attributing them to some "indwelling entity," "part," or "personality" other than the self (p. 36). Just as people learn the hypnotic role and then enact it under appropriate conditions, so people can learn to enact the role of multiple personalities—to create a social impression that is congruent with the diagnosis and that fulfills certain interpersonal goals. Just as the hypnotist abets this process by giving

suggestions as to how the subject should behave, so clinicians explicitly and implicitly shape the behavior of their patients by encouraging them to adopt the role in the first place, providing them information about how to do so convincingly (for example, by displaying interpersonality amnesia), and then validating the performance by conferring a psychiatric diagnosis, and offering a particular form of therapy. Thus, the multiple personality is not so much a discovery as a creation—a creation on the part of both patient and therapist. Even so, the benefits for achieving the diagnosis—relief from interpersonal distress, mitigation of criminal responsibility, control of others, permission for untoward behavior—may be so powerful as to lead patients to “become convinced by their own enactments and come to believe that they possess multiple selves” (p. 47).

The influence of interpersonal, cultural, and historical factors on dissociative identity disorder can hardly be denied, but it is also something of a puzzle. The fact that the diagnosis experienced a golden age, waned after 1920, and showed a resurgence in the 1970s makes one wonder about the social conditions in which dissociative behaviors are expressed and corresponding diagnoses are made. This point has been made most forcefully by Kenny (1986), who provided an ethnographic analysis of dissociative identity disorder and related conditions. Analyzing the classic cases of Mary Reynolds, Ansel Bourne, Miss Beauchamp, B.C.A., Eve, and Sybil, Kenny (1986) argues that DID is a response to changing conditions in American culture. For example, Mary Reynolds’ alter ego seems not so much an alternate to her normal state as a contradiction of it, a rebellion against her old self. Similarly, Ansel Bourne’s fugue state may be interpreted as a symbolic representation of his self-perceived status as a “changed man” following his religious conversion. Miss Beauchamp rebelled against the limitations imposed on women in turn-of-the-century America and was used as a vehicle for Morton Prince’s campaign against Freudian psychoanalysis. Kenney does not argue that most, or even many, cases of DID are fraudulent. He closes his book with an image of an intense and preoccupied Ansel Bourne, “trying—and failing—to remember something important” (1986, p. 188). Rather, his purpose is to understand how the definition and experience of self is shaped by the surrounding culture. There is no contradiction between excepting certain cases of dissociative

disorder as genuine and understanding the sociocultural context in which they occur.

Depersonalization and Derealization

In addition to the gross disruptions of autobiographical memory self-integration seen in psychogenic amnesia, fugue, and dissociative identity disorder, dissociative disorders include the experiences of depersonalization and derealization (Coons, 1996; Reed, 1979, 1988). As originally defined, it was thought that depersonalization and derealization co-occur. People experience themselves as totally different, and the world as strange and new. Later, they were construed as independent entities. Nemiah (1989) suggested that derealization is the more general case and depersonalization is a limited form in which only the experience of self is changed. Both depersonalization and derealization are frequently seen as symptoms of other syndromes, such as anxiety, depression, and obsession—for example, the phobic anxiety-depersonalization syndrome (Roth & Argyle, 1988). Depersonalization and derealization are nonspecific symptoms independent of other diagnoses (Brauer, Harrow, & Tucker, 1970; Fleiss, Gurland, & Goldberg, 1975), and are salient components in the “near-death experience” reported by those who have been rescued at the last moment from drownings, falls, and other kinds of accidents. However, depersonalization and derealization also constitute psychopathological syndromes in their own right.

As a primary diagnosis, the central feature of depersonalization disorder is a subjective awareness or feeling of change in oneself (depersonalization) or the world (derealization). This often occurs suddenly after awakening from sleep or after a frightening incident. The feeling puzzles the experiencers. The changed condition is perceived as unreal and as discontinuous with their previous ego states. The object of the experience, self (in depersonalization) or world (in derealization), is commonly described as isolated, lifeless, strange, and unfamiliar; oneself and others are perceived as “automatons,” behaving mechanically without initiative or self-control. Although the feeling of depersonalization and derealization may be pleasant when self-induced by psychedelic drugs, in clinical cases it is unpleasant, even aversive: the victims often feel as if they were going

insane, or dying. Throughout, however, the persons retain insight into what is happening: they remain aware of the contradictions between subjective experience and objective reality—it is only “as if” things were not real. Occasionally, the person will develop a delusional explanation about the experience (Kihlstrom & Hoyt, 1988), in which case both the puzzlement and the “as if” quality will disappear. Finally, depersonalization and derealization usually involve diminished emotional responsiveness—a loss of interest in the outside world, of feelings for other people, and of anxiety or depression.

Mayer-Gross (1935) noted that depersonalization and derealization may occur with a host of other symptoms, including *deja vu* (in which the sense of having been in a place before coexists with the knowledge that this is not the case) and *jamais vu* (in which a situation is experienced as unfamiliar, despite the person’s knowledge that it has been experienced many times before). In its totality, then, the experience of depersonalization is one of strangeness in oneself, in others, and of one’s relationship to them. Viewed from the perspective of cognitive psychology, these syndromes represent failures of recognition—an inability to match current experience with past memories, something like what happens when one enters a familiar room whose furniture or paint scheme has been changed (Reed, 1979, 1988). Especially important here is the disruption of self-reference, which seems so crucial to the experience of recognition (Kihlstrom, 1997).

Diagnosis and Assessment of Dissociation

The actual incidence and prevalence of dissociative disorders is hard to estimate. Dissociative disorders were excluded from the massive Epidemiological Catchment Area survey (Regier, Myers, Kramer, et al., 1984), presumably because appropriate diagnostic criteria were not provided by the standardized assessment instruments available at the time. This situation has now been corrected. Steinberg and her colleagues produced a version of the Structured Clinical Interview for DSM-IV Dissociative Disorders (SCID-D), which diagnoses these syndromes according to the rules of DSM-IV (Steinberg, 1996).

Several investigators have also developed questionnaire surveys of dissociative experiences that can be conveniently administered to large samples. The most popular of these is the Dissociative Experiences Scale (DES) of Bernstein and Putnam (1986; Carlson & Putnam, 1993) that holds promise as a diagnostic screening tool, locating high-scoring subjects who might be at risk for dissociative disorder (Carlson, Putnam, Ross, et al., 1993). For example, a doctoral dissertation by Angiulo (1994) found that college students who achieved extremely high scores on the DES were significantly more likely to qualify for a formal diagnosis of dissociative disorder (usually DDNOS) when subsequently administered the SCID-D. Of course, the DES and similar instruments can also be employed for research on normal personality structure and processes. For example, although the DES assesses levels of dissociation on a trait-like continuum from low to high, Waller and his colleagues (Waller, Putnam, & Carlson, 1996; Waller & Ross, 1997) employed taxometric techniques to argue that individuals who score high on the DES constitute a fairly discrete personality type.

Although instruments such as the SCID-D and the DES are intended to measure relatively stable trait-like dispositions toward dissociation, the Clinician-Administered Dissociative States Scale (CADSS; Bremner, Krystal, Putnam, Southwick, Marmar, Charney, & Mazure, 1998) was developed to measure episodic dissociative states and is suitable for measuring changes in symptoms. Examination of item content, however, indicates that the CADSS focuses on symptoms of depersonalization and derealization, not on the disruptions of memory and identity that lie at the heart of dissociative amnesia and fugue and dissociative identity disorder.

Forensic Aspects of Dissociative Disorder

In addition to being a puzzle for clinicians and experimentalists, dissociative disorders have created substantial difficulties for the legal system. A victim who cannot remember the circumstances of a crime cannot offer valuable testimony that might lead to a conviction, and amnesic defendants cannot assist in their own defense. Moreover, the presence of amnesia for a criminal act may suggest that the crime was committed in an altered state of

consciousness in which normal processes of monitoring and control were inoperative—thus potentially qualifying the defendant for the insanity defense. Unfortunately, the diagnosis of dissociative disorder is difficult to substantiate—even the structured clinical interview is susceptible to faking—and there is no way to tell for sure whether a particular suspect's claim of amnesia is genuine or simulated (Kopelman, 1995; Schacter, 1986a,b).

The legal problems associated with DID are especially severe, as illustrated by the case of Kenneth Bianchi, the “Hillside Strangler” (State v. Bianchi, No. 79-10116, Washington Superior Court, October 19, 1979).^{*} Bianchi was charged, along with his cousin, in ten rape-murders in Los Angeles, and alone in two similar cases in Bellingham, Washington (Allison, 1984; Orne, Dinges, & Orne, 1984; Watkins, 1984). According to his defense, the crimes were perpetrated by an alter ego, “Steve Walker,” a claim that was supported by evidence of high hypnotizability (a characteristic commonly associated with DID). However, the claim was undercut by other evidence suggesting that Bianchi had simulated hypnosis, and especially by inconsistencies in the self-presentation of the alter egos, psychological test evidence, and the lack of independent corroboration of the alter egos by people who knew him before he was arrested. Bianchi also had a great deal of background psychological knowledge, had practiced psychotherapy under a false name, and faked credentials (at one point in the proceedings he claimed that this was the work of a third alter ego, named “Billy”). Bianchi was convicted of eight counts of murder in the Hillside Strangler cases. Subsequently, he offered to testify against his cousin, who was also convicted.

Etiology of Dissociative Disorders

Stress, whether acute or chronic, is an extremely prominent feature in dissociative disorders—so much so that they are sometimes considered forms of posttraumatic stress disorder (PTSD; e.g., Putnam, 1985; Spiegel, 1984). The occurrence of depersonalization in response to life-threatening

danger and of psychogenic amnesia and fugue in victims of crime and disaster has already been noted, as has the apparent frequency with which amnesia and fugue are seen in cases of “war neurosis.”[†] In particular, many authorities have noted an apparently strong relationship between DID and a history of childhood physical and sexual abuse. For example, Putnam et al. (1986) noted that fully 86% of their 100 recent cases presented a self-reported history of sexual abuse, 75% reported repeated physical abuse (68% reported both kinds of abuse), and 45% reported witnessing a violent death during childhood; only 3% of these cases had no history of significant childhood trauma. Reflecting a broad consensus among clinicians and researchers, Horevitz and Loewenstein (1994) characterized DID as “a traumatically induced developmental disorder of childhood” (p. 290).

At the same time, it must be underscored that this consensus is largely based on retrospective surveys of a sample of patients (and clinicians) whose representativeness of the population of DID is unknown. The definition of childhood trauma in these surveys is often very broad, includes extreme neglect and poverty as well as sexual and physical abuse, and there is rarely any quantification of the number of traumatic episodes, their severity, or their duration. The extent to which reports of childhood sexual abuse and other trauma may be biased by the patients' or clinicians' own intuitive theories of DID is unknown, but it is fairly certain that those who seek evidence of abuse and other trauma in childhood will be able to find it. Self-reported histories of childhood trauma, abuse, and neglect are rarely subject to independent verification, perhaps because since the earliest days of psychoanalysis, the

[†]Even this evidence is ambiguous with respect to the traumatic etiology of dissociative disorder. For example, because depersonalization occurs in association with anxiety, the mere fact that disaster victims report increased levels of depersonalization (Cardena & Spiegel, 1993) cannot be taken as evidence that trauma causes any form of dissociative disorder. Similarly, biological factors such as concussive head injury and sleep deprivation cannot be ruled out in cases of war-related amnesia, and amnesia for crime may reflect intoxication (Piper, 1998; Pope, Hudson, Bodkin, & Oliva, 1998; Pope, Oliva, & Hudson, 1999). For a debate concerning the status of repressed or dissociated memories of trauma, see Schefflin and Brown (1996) and Piper (1997). For a critical analysis of the argument that traumatic memories are “special,” see Shobe & Kihlstrom (1997).

^{*}The Bianchi case was extensively documented in a two-hour *Frontline* documentary, “The Mind of a Murderer,” broadcast on PBS in 1984.

causal link between trauma and dissociation is so intuitively appealing.

Even with independent corroboration of abuse histories, most studies in this area are retrospective and necessarily overestimate the strength of the relationship, if indeed any relationship exists at all between childhood trauma and adult dissociative disorder (Dawes, 1993; Kihlstrom, Eich, Sandbrand, & Tobias, 1997; Pope & Hudson, 1995). For this purpose, the gold standard is provided by prospective studies that condition subjects on the antecedents—e.g., taking representative groups of abused and nonabused children and following them into adulthood to determine who among them develops dissociative disorder.

In fact, authoritative reviews of prospective research failed to find evidence of any specific impact of child sexual abuse on adult personality and psychopathology (Kendall-Tackett, Williams, & Finkelhor, 1993; Nash, Mulsey, Sexton, et al., 1993). This is not to say that child sexual abuse is benign—it is only to say that there are currently no empirical grounds to accept the proposition that childhood sexual abuse causes or even increases the risk for later dissociative disorder. Prospective analyses of other kinds of trauma yield similar findings. For example, Holocaust survivors may show signs of PTSD, but dissociative amnesia is not a prominent feature of their profiles (Wagenaar & Groeneweg, 1990). At this point, the traumatic etiology for dissociative identity disorder and other dissociative disorders must be considered a hypothesis—not an established empirical fact that can inform prevention and treatment.

Treatment of Dissociative Disorders

Other than dissociative identity disorder, little has been written about the treatment of dissociative disorders (Reid, 1989). Apparently, most cases of psychogenic amnesia and fugue resolve themselves spontaneously. Sometimes, patients recover their memories and identities unaided. In other cases, this process is prompted by contact with family and friends or by hints generated through free associations or dream reports. Many cases report that recovery was stimulated by the induction of hypnosis or sedation by intravenous barbiturates such as thiopental. However, these reports should be viewed against a background of

experimental literature indicating that hypnosis has no special efficacy for the recovery of forgotten, repressed, or dissociated memories (Kihlstrom & Barnhardt, 1992; Kihlstrom & Eich, 1994). Moreover, no clinical or experimental study of barbiturate hypnosis has attempted independent corroboration of the ostensibly recovered memories (Piper, 1993).

Depersonalization symptoms are typically intermittent. But because episodes are often associated with acute mood disorder, drug treatment for anxiety and/or depression is often recommended. Presumably, benzodiazepines and other psychoactive drugs act on the anxiety and depression in which depersonalization and derealization occur, rather than directly on the feelings of unreality.

With respect to dissociative identity disorder, the traditional approach to the treatment of DID, initially popularized by Thigpen and Cleckley (1957), involves psychodynamic uncovering, abreaction, and working through of the trauma and other conflictual issues presumed to underlie the disorder, followed by an attempt at integrating the personalities into a single identity (Braun, 1986). The cooperation of each personality is required, entailing considerable effort directed toward developing therapeutic alliances. Hypnosis is often used, both for communicating with the personalities and for the integration, which is sometimes performed almost as a ceremony. Of course, psychotherapy does not necessarily stop with fusion. Additional time may be required to work through the insights achieved earlier in therapy, support the new fusion among the alter egos, and cope with the changes produced by integration.

Even though the modal therapy for DID is insight-oriented, there have been occasional attempts at cognitive-behavioral treatments (e.g., Kirsch & Barton, 1988). Regardless of treatment approach, there is a general consensus that the syndrome presents a number of specific challenges to treatment (Reid, 1989), including secondary gain (for the patient and for the therapist); countertransference reactions of anger, exasperation, aggression (as well as sexual attraction); suggestibility (especially where the evidence for DID is elicited by hypnosis, without independent corroboration), and the integration of confabulations and other distortions into memory.

As with the other dissociative disorders, there is little in the literature by way of systematic outcome studies (Reid, 1989; Ross, 1997). One excep-

tion is a report by Coons (1986) on twenty cases; another is the periodic updates by Kluft (e.g., 1988) on a large series of cases. Ross (1997) reported a two-year follow-up of fifty-four patients (from an original sample of 103); only twelve of these patients had achieved a therapeutic goal of stable integration, although the group as a whole reported diminished levels of dissociative experiences. Still, as Ross (1997) notes, "strictly speaking, there are no treatment outcome data for dissociative identity disorder in the literature" (p. 247). Given all the attention that DID has received since 1980, the fact that whole units, if not entire hospitals, have been developed for treating it, and the ensuing claims for out-of-pocket and third-party payment, this situation is remarkable and deplorable.

Most current treatments of DID are predicated on the notion that the syndrome is caused by childhood trauma such as sexual and physical abuse (Horevitz & Loewenstein, 1994; Ross, 1997). Thus, after the patient has been stabilized, Kluft (1993) recommends a focus on uncovering and resolving trauma and abandoning dissociative defenses. This recommendation would make no sense if there were not memories of trauma to be uncovered and dissociative defenses against such memories to be eliminated. However, as noted earlier, it is not at all clear that the origins of dissociative identity disorder lie in sexual abuse or any other form of childhood trauma. In the absence of convincing prospective evidence that DID has its origins in childhood trauma, such a postcentered focus seems premature at best and at worst raises the possibility that false memories of childhood sexual abuse may be constructed during the course of treatment.

The Dissociative Spectrum

Dissociative disorders constitute only a portion of what was formerly described as "hysteria" (Kihlstrom, 1994). In his pioneering classificatory work, Janet was quite clear that the functional anesthetics, paralyses, and amnesias, including the amnesias of fugue and multiple personality, belonged together in a single class, distinct from phobias, obsessions and compulsions, and other subtypes of neurosis. Early diagnostic usage through DSM-II essentially honored Janet's principles. However, DSM-III and its revision, DSM-III-R,

abandoned hysteria and separated dissociative disorders from conversion disorders. Conversion disorders, in turn, were removed to the category of "Somatoform Disorders" along with somatization disorder (Briquet's syndrome), hypochondriasis, somatoform (psychogenic) pain disorder, body dysmorphic disorder (formerly known as dysmorphophobia), and the like (for reviews of the somatoform disorders, see Cloninger, 1996; Kihlstrom & Canter Kihlstrom, 1999). This separation persists in DSM-IV.

Put bluntly, this reclassification was, and remains, a mistake. It has long been known that conversion disorder, reflecting monosymptomatic disorders of the sensory-motor system, has nothing in common with Briquet's syndrome, hysterical personality, hypochondriasis, and the other somatoform disorders (Kihlstrom, 1992, 1994). They have much more in common with dissociative disorders. In both cases, events (in the current or past environment) have been registered and influence the patient's experience, thought, and action, even though the patient is not consciously aware of them.

The proper classification of conversion disorders, as essentially dissociative, is suggested by the pseudoneurological nature of their presenting symptoms and is further supported by closer psychological analysis of the paradoxes and contradictions in behavior observed in the classic cases described by Janet (1907). The functionally blind patient complains of being unable to see but correctly guesses how many fingers the examiner holds up before his eyes. Functionally deaf patients claim to be unable to hear but orient when their names are called from outside their fields of vision. In both cases, the patient's problem is in gaining conscious access to something that has been processed and registered in the sensory-perceptual system. But in the absence of conscious access, the percepts in question nevertheless influence the patient's experience, thought, and action outside of phenomenal awareness. The parallel to functional amnesia, where the patient complains of being unable to recollect past episodes but is nevertheless influenced by the unremembered events, is clear—at least to us. Just as functionally amnesic patients are not conscious of what they remember, functionally blind or deaf patients are not conscious of what they see or hear. This disruption of conscious awareness is the essence of dissociation.

By analogy with implicit memory, the paradoxes and contradictions in the behavior of conversion disorder patients may be labeled as expressions of "implicit perception" (Kihlstrom, 1996, 1999; Kihlstrom, Barnhardt, & Tataryn, 1992): they show the influence of events in the current environment without consciously perceiving these events.

Fundamentally, then, both dissociative and conversion disorders reflect a disruption of the normal functions of consciousness (Hilgard, 1977; Kihlstrom, 1984, 1992, 1994). These functions include (1) monitoring ourselves and our environment, permitting us to be aware of current events and to recollect the past, such that the world is accurately represented in phenomenal awareness; and (2) controlling ourselves, so that we have the experience of voluntarily initiating and terminating mental activities, at will, to achieve our personal goals and meet environmental demands. Accordingly, their essential unity should be reflected in our diagnostic nosology (for a similar suggestion, see Nemiah, 1989). Therefore, we suggest that henceforth the term "conversion disorder" be dropped from the diagnostic nosology as an inappropriate holdover from the days when psychoanalysis dominated our conception of the neuroses. Furthermore, the erstwhile conversion disorders should be removed from the somatoform category and regrouped with other dissociative disorders, forming three subcategories: (1) dissociative anesthesia, including psychogenic blindness, deafness, analgesia, and other functional disorders of sensation and perception; (2) dissociative paralysis, including psychogenic aphonia and other functional disorders of motor function; and (3) dissociative amnesia, including dissociative amnesia and fugue, dissociative identity, depersonalization and dissociation, and other functional disorders of memory and awareness.

ACKNOWLEDGMENT. Preparation of this chapter and the research that contributed to the point of view represented herein was supported in part by Grant #MH-35856 from the National Institute of Mental Health. I thank Douglas J. Tataryn and Irene P. Tobis (nee Hoyt) for the contributions to the version of this chapter published in the 2nd edition of this book (Kihlstrom et al., 1993). Some material from that chapter has been retained in the present edition, but a great deal of material had to be excluded for reasons of space. The interested

reader is referred there for more comprehensive treatment of the literature before 1990.

Mood Disorders: Unipolar and Bipolar

Lynn P. Rehm, Alisha L. Wagner,
and Carolyn Ivens-Tyndal

Diagnostic Distinctions and Clinical Phenomenology

Unipolar–Bipolar Distinction

A historical review of the conceptualization, diagnosis, and categorization of psychopathology reveals a series of attempts to develop meaningful distinctions or subcategories to reduce the heterogeneity of affective disorders. Kraepelin (1921) subsumed most major forms of depression under the rubric of “manic-depressive illness,” which he distinguished from dementia praecox (schizophrenia). This classification scheme prevailed for several decades and was reflected in the *Diagnostic and Statistical Manual of Mental Disorders*, 2nd edition (DSM-II; American Psychiatric Association [APA], 1968) which remained in use until 1980. Under this diagnostic approach, individuals with recurrent depressions and those with depressions plus manic episodes were both considered manic-depressive. Only involuntional melancholia, psychotic-depressive reaction, and depressive neurosis were differentiated from manic-depressive ill-

ness, chiefly on the basis of recurrence of depressive episodes.

As early as 1957, Leonhard suggested that individuals with depressions plus manic episodes (bipolar) should be distinguished from persons with only recurrent depressive episodes (unipolar) on the basis of differences in various clinical dimensions. During the following three decades, studies of clinical, familial, genetic, pharmacological, and biological factors supported such a distinction, resulting in a reversal of the old classification and conceptual framework such that current theories, diagnostic schemes, and treatment strategies treat unipolar and bipolar affective disorders as distinct entities. Among specific distinctions, age of onset for bipolar disorder tends to be significantly earlier than for unipolar depressions (Angst et al., 1973; Burke, Burke, Regier, & Rae, 1990; Gershon, Dunner, & Goodwin, 1971; Perris, 1966), and genetic factors have a more important role in the occurrence of bipolar disorder than that of unipolar disorder (Allen, 1976). Differences in specific depressive-episode symptoms have been observed; unipolar depressives are more commonly characterized by agitated psychomotor activity (Beigel & Murphy, 1971; Bunney & Murphy, 1973; Kupfer et al., 1974), hyposomnia (Detre et al., 1972; Hartmann, 1968; Kupfer et al., 1972), somatic complaints (Beigel & Murphy, 1971), and anger at self and others (Beigel & Murphy, 1971), and depressed bipolar subjects are characterized by psychomotor retardation, hypersomnia, fewer

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

somatic complaints, and mild or no anger. Although these data support the unipolar–bipolar distinction at a number of levels and in a number of arenas, including clinical presentation of depressive symptoms, the current diagnostic system, DSM-IV (APA, 1994), distinguishes between unipolar and bipolar mood disorders solely on the basis of a history of mania. There is no attempt to differentiate bipolar from unipolar depressive states on any other grounds.

Unipolar Depression Criteria

According to DSM-IV, criteria for a major depressive episode are (1) the presence of either depressed mood (in children or adolescents, depressed or irritable mood) or loss of interest or pleasure in all or most activities for a minimum of 2 weeks and (2) the presence of at least four criterion symptoms for a period of at least 2 weeks. The criterion symptoms include appetite disturbance; change in weight; sleep disturbance; psychomotor agitation or retardation; decreased energy; feelings of worthlessness or excessive or inappropriate guilt; difficulty with thinking, concentrating, or decision making; and recurrent thoughts of death or suicidal ideation or attempts. Symptoms must represent a change from previous functioning, be relatively persistent during the minimum 2-week period, and cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Historically, a distinction has been made between depressions believed to be caused by some external event (termed reactive or exogenous) and those believed to be caused primarily by internal biological factors (termed endogenous). Endogenous depressions are believed to be more severe and to be characterized by prominent somatic symptoms. Because the identification of an external cause is unreliable and because the identification of internal causes in other cases is only inferred from the lack of an external cause, this distinction was not included in DSM-II). However, DSM-III (APA, 1980), DSM-III-R (APA, 1987), and DSM-IV substituted major depressive episode, melancholic type, as a subgroup of unipolar depression defined in terms of current symptoms rather than a putative cause. The specific symptoms include (1) the presence of either loss of pleasure in all or almost all activities or a lack of reactivity to usually pleasurable stimuli and

(2) three or more of the following symptoms: distinct quality of depressed mood (a different kind of feeling than, for example, what is experienced after the death of a loved one); a diurnal variation of mood with a depression worse in the morning; early morning awakening (at least 2 hours before the usual time); marked psychomotor retardation or agitation; significant anorexia or weight loss; and excessive or inappropriate guilt.

Dysthymia, referred to as “depressive neurosis” by previous diagnostic systems, is also a common unipolar depressive disorder. Symptoms are fewer and typically less severe than in major depressive episodes, but these symptoms generally cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. The essential features of dysthymia are depressed mood (or irritable mood in children and adolescents) for most of the day during most days for at least 2 years (1 year for children and adolescents), and the presence of at least two of the criterion depressive symptoms described before as part of the unipolar diagnosis. As a stable and enduring disorder, dysthymia (along with cyclothymia, discussed later) was earlier considered among the personality disorders. Debate as to its status continues. The relationship between dysthymia and major depression is complex. The DSM system allows making both diagnoses simultaneously, sometimes referred to as double depression. In DSM-IV, sequence is also important. If the 2-year period begins with an episode of major depression, then the milder continuation is assumed to be part of the major depression, and the diagnosis is major depression in partial remission, not dysthymia.

A residual category of depressive disorder, not otherwise specified, is included in DSM-IV for disorders with depressive features that do not meet the criteria for any specific mood disorder, or for adjustment disorder with depressed mood. Examples of depressive disorder NOS include premenstrual dysphoric disorder; minor depressive disorder; recurrent brief depressive disorder; postpsychotic depressive disorder of Schizophrenia; and a Major Depressive Episode superimposed on Delusional Disorder, Psychotic Disorder NOS, or the active phase of Schizophrenia. Adjustment disorder with depressed mood is not classified as a mood disorder, despite the primary features of depressive symptoms, because adjustment disorders, it is assumed, cover temporary maladaptive reactions of

normal individuals to unusually stressful life events. Depressed mood is only one of several concomitant symptom patterns of adjustment disorder.

Three new specifiers included in DSM-IV to describe a current mood episode are "With Atypical Features," "With Postpartum Onset," and "With Catatonic Features." A diagnosis of With Atypical Features includes (1) mood reactivity, in which mood brightens in response to actual or potential positive events and (2) two or more of the following features: significant weight gain or increase in appetite, hypersomnia, heaviness in arms or legs, or a long-standing pattern of interpersonal rejection sensitivity that results in significant social or occupational impairment. A diagnosis of atypical features precludes an additional diagnosis of Melancholic or Catatonic features during the same episode.

The Postpartum Onset specifier, which is applied if the onset of the mood disturbance is within 4 weeks after delivery, generally includes the same symptoms in nonpostpartum mood episodes and may include distinct psychotic features. Additional symptoms may involve severe anxiety, panic attacks, disinterest in the infant, and initial insomnia. In early DSMs, postpartum depression was a separate diagnosis. Consensus grew that it was not really distinct from other depressions and could be considered a special case of reactive depression. It was dropped from DSM-III and now reappears in DSM-IV as a specifier.

The specifier "With Catatonic Features" is diagnosed when the clinical situation is characterized by two of the following: motoric immobility such as catalepsy or stupor; excessive, purposeless motor activity that is not influenced by external stimuli; extreme negativism or mutism; peculiarities of voluntary movement such as posturing, stereotyped movements, prominent mannerisms or grimacing, or echolalia or echopraxia.

The Seasonal Pattern Specifier, which was previously established, can be applied to Major Depressive Disorder, Recurrent, or to the depressive episodes in Bipolar I or Bipolar II. The character features are the onset and termination of episodes at particular times of the year. The symptom pattern of seasonal episodes often includes anergy, hypersomnia, overeating, weight gain, and a craving for carbohydrates. The most common seasonal pattern is an onset in fall or winter and a remission in the spring. According to DSM-IV, seasonal

depressive episodes must substantially outnumber nonseasonal depressive episodes over the course of one's life.

The symptoms in the depressive disorders are evident within the realms of mood, cognition and perception, and behavior and somatic functioning. Mood is the least varying of these symptoms, and the typical experience of the depressed individual is feeling pervasively sad, blue, or hopeless. Occasionally, individuals do not describe their moods as depressed, yet they are observed by others as appearing so. Depressed mood is often accompanied by excessive tearfulness, although some individuals may experience an inability to cry. Anhedonia, the loss of interest or pleasure in previously pleasant activities, is a common feature of depressed mood and may be experienced as apathy or as a painful inability to experience pleasure. With anhedonia, expression of affect may be blunted. DSM-IV considers that either sadness or anhedonia are essential to the diagnosis of depression. Further, depressed mood is often accompanied by irritable or angry mood, and such moods may be the predominant mood in depressed children and adolescents. The variants of dominant mood associated with depression have been suggested as an important diagnostic dimension with implications for pharmacological treatment selection (Overall & Zisook, 1980).

Cognitive and perceptual symptoms of depression involve the realms of cognitive functioning and of cognitive and perceptual style or content. Impairment of cognitive functioning is indicated by poor concentration, slowed thinking, indecision, and (in cases of depression with psychotic features) hallucinations. Complaints of memory problems are also common, but complaints are often exaggerated and when memory is actually assessed, it is usually not significantly impaired. Such an assessment is sometimes important in differential diagnoses, for example, in differentiating depression from Alzheimer's dementia. Depressive cognitive style or content involves suicidal ideation or preoccupation, ruminative morbid or hypochondriacal thinking, and negatively distorted perceptions and thoughts about oneself, the world, and/or the future, as described later in discussions of cognitive models of depression. Psychotic symptoms of delusions or hallucinations may be evident during depressive episodes. Any psychotic symptoms usually involve content that is clearly consistent with the predominant mood

(i.e., mood-congruent), such as delusions of persecution due to some personal inadequacy or transgression. Mood-incongruent psychotic symptoms are relatively rare.

Somatic symptoms, referred to as vegetative signs, include sleep and appetite disturbance, psychomotor agitation or retardation, and decreased energy. Sleep disturbance is among the most pervasive quantifiable and pathognomic symptoms. Insomnia is the most common form of sleep disturbance—sometimes initial insomnia (the inability to fall to sleep), but more commonly among depressed individuals, middle or terminal insomnia, where the individual awakens from sleep and experiences difficulty or inability to return to sleep. Hypersomnia (excessive sleep) is experienced, however, by a smaller but significant portion of depressed individuals. As with sleep disturbance and other somatic symptoms, the direction of appetite disturbance may be that of increase or decrease; more depressed individuals experience appetite and weight loss, but some experience increased appetite and consequent weight gain. Similarly, variance in psychomotor activity is observed across the population of depressed individuals. Psychomotor retardation (a slowing of movement and speech) is most common, although many depressed individuals experience psychomotor agitation in forms such as an inability to sit still or a subjective experience of nervousness or anxiety. Fatigue and decreased energy, as well as decreased libido or sexual interest, are also commonly experienced during a depressive episode.

Mania and Hypomania Criteria

DSM-IV criteria for a manic episode include (1) a distinct period of abnormally and persistently elevated, expansive, or irritable mood that lasts at least 1 week or less if hospitalization is necessary and (2) three or more associated symptoms such as inflated self-esteem or grandiosity, decreased need for sleep, pressured speech, racing thoughts, distractibility, increased involvement in goal-directed activity, psychomotor agitation, and excessive involvement in pleasurable but potentially harmful activities. Severity of disturbance sufficient to impair occupational, social, interpersonal, or personal functioning, or to necessitate hospitalization to prevent harm to self or others, is a defining criterion. This definition includes psychotic symptoms of delusions, hallucinations, or

catatonia coexisting with the mood disturbance, whether such psychotic symptoms are mood-congruent (i.e., delusions or hallucinations with content consistent with elevated mood) or mood-incongruent.

A hypomanic episode is defined by DSM-IV as a distinct period of abnormally and persistently elevated, expansive, or irritable mood lasting at least 4 days, with the associated manic symptoms but without the presence of delusions, and without disturbance severe enough to cause marked impairment in social or occupational functioning or to require hospitalization. As indicated by DSM-IV, the hypomanic episode must be distinctively different from the individual's typical nondepressed mood, and it must be a clear change in functioning.

The mild-to-moderate degree of symptomatology experienced as hypomania is often experienced by the individual as pleasant and/or productive and may in fact be productive if symptoms do not persist or intensify. The hypomanic mood, ranging from a general sense of well-being to euphoria, is typically enjoyable, and the experiences of increased physical and mental energy and activity and decreased need for sleep may be productive. Further, subjective report is that thought processes often become more fluid, creative, and productive during hypomanic episodes. There is some evidence that bipolar disorder is found at higher than chance levels among particularly creative people (Andreasen & Canter, 1974). These positive experiences of hypomania often prevent the individual from seeking treatment because the symptoms are not subjectively experienced as problematic. However, irritability, anger proneness, and/or affective lability are typically concomitant with such heightened mood states, and the hypomanic episode frequently intensifies into a full manic episode, especially among individuals who have histories of previous manic episodes.

In DSM-III-R, a mixed episode was classified as one subtype of Bipolar Disorder and did not have separate criteria. DSM-IV formalized diagnostic criteria, specifying that a mixed episode consists of criteria for both a Major Depressive Episode and a manic episode lasting almost every day during at least a 1-week period that causes significant functional impairment. Mixed episodes are considered by some the most severe form of bipolar episode.

Manic episodes may cause considerable impair-

ment in functioning and may be quite distressing or dangerous. By definition, mood during a manic episode is elevated, expansive, or irritable, and mania is most frequently described in experiences of elation or grandiosity. In reality, the mood profile across and within individuals who experience mania is more complex and paradoxical, and empirical studies have demonstrated that the mood during a manic episode is depressed and/or labile as often as euphoric, especially in the later stages of the episode. Irritability is the most common mood during a manic episode (Goodwin & Jamison, 1990).

Cognitive symptoms of mania may include both psychotic and nonpsychotic symptoms. The most common content of mania involves grandiosity, occasionally but not usually at a delusional level. This feature can range from unrealistic overconfidence in oneself to acting on unrealistic beliefs that one possesses certain abilities (e.g., creative, political, or medical) to delusional beliefs about identity. In terms of cognitive functioning, one of the most common symptoms during a manic episode is flight of ideas, subjectively experienced as racing thoughts and frequently observed as rapid, pressured speech. Results of empirical studies vary, and the reported proportions of manic patients who experience this symptom ranged from 41 to 100% (Abrams & Taylor, 1976; Braden & Ho, 1981; Carlson & Goodwin, 1973; Clayton, Pitts, & Winokur, 1965; Taylor & Abrams, 1973; Winokur, Clayton, & Reich, 1969). Other common nonpsychotic cognitive symptoms are distractibility, poor concentration, confusion, and (occasionally) disorientation. Psychotic symptoms of delusions and, less commonly, hallucinations have been documented. Delusions (usually of grandiosity or persecution and infrequently of passivity) have been reported across studies in 44 to 75% of manic patients (Black & Narsrallah, 1989; Carlson & Goodwin, 1973; Leff, Fischer, & Bertelsen, 1976; Winokur et al., 1969; Winokur, 1984). Hallucinations, predominantly auditory, have been reported in 14 to 40% of manic patients (Black & Narsrallah, 1989; Carlson & Goodwin, 1973; Winokur, 1984).

The most pervasive somatic and behavioral symptoms demonstrated among manic patients are sleep disturbance, hyperactivity, and speech symptoms. An average of 81% of manic patients experiences insomnia and/or a decreased need for sleep, 87% exhibits hyperactivity, and reports of increased, rapid and/or pressured speech range

from 75 to 100% (Abrams & Taylor, 1976, 1981; Carlson & Goodwin, 1973; Goodwin & Jamison, 1990; Leff et al., 1976; Loudon, Blackburn, & Ashworth, 1977; Winokur et al., 1969). Other behaviors exhibited in significant frequency among manic individuals include hypersexuality, spending sprees, violent or assaultive behavior, and frenzied or aimless activity. The social or occupational impairment and negative social consequences that result from these instances of lapsed judgment in manic episodes are the defining difference between manic and hypomanic episodes. Hypomanic episodes, by definition, do not lead to impairing consequences. This is another instance where the DSM system attempts to make discrete categories from a continuous severity dimension.

Bipolar Disorder Criteria

In the DSM system, the history of current and past episodes is used to determine the actual mood disorder diagnosis. A bipolar disorder diagnosis is given when both manic and depressive episodes have occurred. The most substantial change in DSM-IV criteria in the mood disorder section is in bipolar disorder. Bipolar disorder is now clearly separated into Types I and II, whereas in DSM-III-R, bipolar II was classified as "not otherwise specified." DSM-IV criteria for bipolar I disorder require one or more manic or mixed episodes, usually accompanied by one or more major depressive episodes. DSM-IV has added three new "most recent episode" categories to the existing mood subtypes. Bipolar I, most recent episode hypomanic, requires at least one manic or mixed episode and a current or most recent hypomanic episode. Bipolar I, most recent episode manic, requires at least one major depressive episode and a current or most recent manic episode. In bipolar I, most recent episode unspecified, there has been at least one manic or mixed episode, and there is a current or most recent manic, mixed, hypomanic, or major depressive episode that has not met the full duration criteria at the time of diagnosis.

Bipolar II, which was previously categorized as bipolar NOS, is now a separate category in DSM-IV. The individual must meet the criteria for at least one hypomanic episode (but not a manic or mixed episode) and one or more major depressive episodes. The presence of a manic or mixed episode changes the diagnosis to bipolar I. Epidemiologic studies suggest that bipolar I is almost

equally common in men and women, and bipolar II may be more commonly seen in women. Some authors (Akiskal, Downs, et al., 1985; Cassano et al., 1988; DePue & Monroe, 1978; Giles, Jarrett, Biggs, Guzick, & Rush, 1989; Winokur & Clayton, 1967) have identified and studied a subgroup of mood disorders (alternately referred to as "pseudounipolar," "unipolar II," or "bipolar III") with depressive episodes, no manic episode, and features including a family history of bipolar disorder, hypersomnia, psychomotor retardation, early age of onset, high frequency of depressive episodes, hypomania in response to antidepressant medication, and good prophylactic lithium response. However, this category has not been addressed by DSM-IV, so such individuals are diagnosed under major depression.

Cyclothymia is a chronic mood disturbance of at least two years (one year for children and adolescents), involving numerous hypomanic episodes and numerous periods of depressed mood of insufficient severity or duration to meet the criteria for a major depressive or manic episode. Thus, by definition, this disorder (considered by some a mild form of bipolar disorder) does not involve marked impairment in social or occupational functioning. Cyclothymia is seen in families of bipolar probands, and there is evidence that cyclothymia can be considered a risk factor for late bipolar disorder (DePue et al., 1981).

Overall, the phenomenology of bipolar disorder is varied and multifaceted across individuals and within individuals across time, in both symptom variability and severity previously discussed for depressive and manic episodes and in cyclicity, episode duration, episode sequence, and stability of states. Cyclicity (i.e., the length of time between episodes) can range from less than every 48 hours to many years, and there is considerable intraindividual variability but much greater interindividual variability. Generally, cycle length in bipolar disorder is less than in unipolar major depression. Approximately 13 to 20% of all bipolar patients can be categorized as "rapid-cycling" patients, defined by DSM-IV criteria and others (Goodwin & Jamison, 1990) as experiencing at least four distinct episodes (depressed or manic) per year. Rapid cycling is more common in females; the initial mood disorder episode is usually a depressive episode, and the rapid cycling generally develops later in the course of the disorder, preceded by one or more less frequent episodes. More ex-

treme and rare "ultrapid cycling" is discussed by Goodwin and Jamison (1990) and, along with rapid cycling, may constitute a separate subgroup of bipolar disorders. Further, distinct from rapid cycling, the cycling may, in some cases, be continuous, in which there is no symptom-free interval between episodes.

Episode duration tends to be independent of cycle length and is also variable across individuals, but with less intraindividual variability. The sequence (or order of manic and depressive episodes within the bipolar spectrum) varies also, so an individual may experience alternate manic and depressive episodes or several episodes of one polarity between consecutive episodes of the other. Frequently, an episode is immediately followed by a short episode of the other kind. Finally, stability and purity of state is a factor related to (but distinct from) cyclicity and is apparently independent of episode severity. This factor is related to the DSM-IV diagnosis of bipolar I disorder, mixed type, in which the full symptoms of both major depressive and manic episodes are present simultaneously or alternating rapidly, often within 1 day's time.

Other Diagnostic Distinctions

A primary-secondary depression distinction, first proposed by Robins and Guze (1972), differentiates between depression that arises during the course of a serious medical illness or preexisting psychiatric disorder and primary depression that arises in the absence of other disorders. This issue of comorbidity has been insufficiently researched because most depression research excludes subjects who exhibit secondary or even coexisting depression; however, particularly relevant are depression secondary to medical illness, depression secondary to other chronic psychiatric disorders, and substance-induced depression. In DSM-IV, Mood disorder due to a General Medical Condition is diagnosed when the mood disturbance is etiologically related to a specific medical condition, and a substance-induced mood disorder is diagnosed when the disturbance is the result of alcohol or drug usage.

Similarly, secondary mania has been identified in patients shortly after medical, pharmacological, or some somatic dysfunctions. Krauthammer and Klerman (1978) reviewed this literature and concluded that patients with secondary mania are phe-

nomenologically indistinguishable from patients with primary mania, except for a later age of onset for secondary mania. DSM-IV classifies secondary mania as mood disorder due to a general medical condition (if not induced by a substance) or as a substance-induced mood disorder (if manic symptoms are substance-induced).

The primary-secondary distinction causes some confusion as to the nature of hypothesized causes of depressions that might also be considered reactive. For example, as indicated before, depression after the birth of a child is seen as a distinct category. It is unclear whether postpartum depression and mania are most accurately conceptualized as secondary mood disorders or as primary mood disorder episodes precipitated by the psychosocial stress of childbirth. Increased affective episodes have been documented in women during the months following childbirth (Bratfos & Haug, 1968; Kendell, Chalmers, & Platz, 1987; Kendell, Wainwright, Hailey, & Shannon, 1976).

The primary-secondary distinction is further complicated by the fact that depression is often comorbid with a number of other psychiatric disorders. For example, individuals who meet depressive criteria also frequently meet criteria for generalized anxiety disorder. People diagnosed with posttraumatic stress disorder and/or substance abuse often have depression in the clinical picture. Whether one is primary and the other is secondary is generally defined by which came first. This judgment is frequently hard to make and is unreliable.

Bereavement is included in DSM-IV among "other conditions that may be a focus of clinical attention." This condition may resemble a full depressive episode but is considered a normal reaction to the death of a loved one. If impairment is prolonged and severe (still present at 2 months following the loss), the diagnosis of Major Depressive Episode is given. Many losses may produce brief, normal reactions of sadness; it is not clear why DSM-IV considers the death of a loved one a special case.

In DSM-IV, schizoaffective disorder is considered a separate diagnosis in the psychotic disorders section. It is diagnosed when there is a major depressive or a manic syndrome concurrent with psychotic symptoms of the active phase of schizophrenia, there has been an episode in which psychotic symptoms persisted at least 2 weeks in the absence of prominent mood symptoms, and

schizophrenia and organic factors have been ruled out.

Another difficult diagnostic distinction is that between mood disorders and certain personality disorders, particularly borderline personality disorder. It has been suggested that borderline personality disorder is best understood as a sub-syndromal form of affective illness (Akiskal, Yerevanian, Davis, King, & Lemmi, 1985; Gunderson & Elliott, 1985), whereas others maintain that the personality disorder is independent, although it frequently coexists with mood disorder (McGlashan, 1983; Pope, Jonas, Hudson, Cohen, & Gunderson, 1983). Coexistent unipolar depression has been clearly documented (Charney, Nelson, & Quinlan, 1981). However, the overlapping symptom patterns make it difficult to differentiate bipolar disorder from borderline personality disorder, and data regarding coexistence has been contradictory (Baxter, Edell, Gerner, Fairbanks, & Gwirtsman, 1984; Charney et al., 1981; Friedman, Aronoff, Clarkin, Corn, & Hurt, 1983; Gaviria, Flaherty, & Val, 1982).

Epidemiology

Affective disorders are among the most prevalent psychiatric disorders in the United States (Weissman et al., 1984). Two of the largest epidemiologic studies that examined the prevalence of mood disorders are the Epidemiologic Catchment Area Study (ECA) (Robins & Regier, 1991) and the National Comorbidity Study (NCS; Kessler et al., 1994). Analyses of data from all five sites of the Epidemiologic Catchment Area (ECA) program of the National Institute of Mental Health, the most comprehensive epidemiologic study of mental illness in the United States to date (Eaton, Regier, Locke, & Taube, 1981), indicates 1-month prevalence rates of 5.1% for all affective disorders, 2.2% for major depressive episodes, 0.4% for manic episodes, and 3.3% for dysthymia (Regier et al., 1988). The 1-year prevalence rate for a major depressive episode in the population is estimated at 10% (Kessler et al., 1994). Lifetime prevalence from the EPA report is estimated at 8.3% for all affective disorders, 5.8% for major depressive episodes, 0.8% for manic episodes, and 3.3% for dysthymia.

A particularly interesting finding of the NIMH study is the increased rate of depression among younger people (Myers et al., 1984; Robins et al.,

1984). The ECA lifetime prevalence rates for major depression in four age groups are 18–29, 5.0%; 30–44, 7.5%; 45–64, 4.0%; 65+, 1.4% (Weissman et al., 1991). Although the finding of increased depression in younger groups might be due, at least in part, to reporting and recollection biases, it has been confirmed in other studies (Klerman et al., 1985), and Seligman (1989) suggested that it may be attributable to historic factors that make individuals more vulnerable to depression now than in earlier eras.

Except for the Amish study (Egeland & Hostetter, 1983), both population studies (Kessler, 1994; Regier et al., 1988; Weissman et al., 1988) and familial investigations (Cadoret, Winokur, & Clayton, 1970; Perris, 1966; Reich, Clayton, & Winokur, 1969) consistently indicate that affective disorders in general are much more common in females than in males. This pattern of differences between males and females is consistent across different cultures (Klerman & Weissman, 1989). Recent reports show that the lifetime prevalence rates of major depression in women range from 7% (Weissman et al., 1991) to 21% (Kessler et al., 1994), and the range for men is reportedly 3% (Weissman et al., 1991) to 13% (Kessler et al., 1994). Conflicting findings have been reported concerning differential sex ratios between unipolar and bipolar disorders. For unipolar depression, estimated female-to-male ratios between 1.5:1 and 3:1 have been reported (Perris, 1973; Radloff, 1975; Regier et al., 1988; Robins et al., 1984; Weissman & Klerman, 1977; Weissman et al., 1988), except for Egeland and Hostetter's (1983) Amish study that revealed equal numbers of male and females with unipolar depression in that population. However, for bipolar disorder, female-to-male ratios of approximately 1:1 were reported by some investigators (Goetzl, Green, Whybrow, & Jackson, 1974; Perris, 1966, 1968, 1973; Weissman et al., 1988), and of as much as 2:1 by others (Cadoret et al., 1970; Robins et al., 1984). Although unipolar depression is clearly more prevalent among women, the sex ratio for bipolar disorder is less clear.

A survey of the empirical literature concerning the clinical course of mood disorders indicates reliable major differences between age at first onset of unipolar and bipolar disorders. Using hospital admissions as a criterion, unipolar subjects typically experience their first hospital admission

between ages 40 and 49. ECA data show that in the group of subjects who developed a major depressive episode, 20% had initial symptoms by age 19 and subsequently developed a major depressive episode by age 25; further, 50% showed depressive features by age 26 and developed a depressive episode by age 39 (Mzarek & Haggerty, 1994). Most bipolar first admissions occur between ages 20 and 29 (Angst et al., 1973; Gershon et al., 1971; Perris, 1966). Data from the five sites of the NIMH Epidemiologic Catchment Area (ECA) program reveal a median age at onset of 25 years for unipolar depression and 19 years for bipolar (Burke et al., 1990). Note that these data suggest a rather broad range around these medians and thus many first episodes during adolescence.

Results of urban–rural comparisons of incidence of mood disorders have been inconclusive. Early studies (Jaco, 1960; Malzberg, 1940; Sundby & Nyhus, 1963) reported a higher incidence of mood disorders in urban areas compared with rural areas. More recently, data from three ECA sites have shown nonsignificant increases of the incidence of mood disorders (both manic and major depressive episodes) in urban areas compared to rural (Robins et al., 1984). Initial data from the NCS generally indicated nonsignificant differences between urban and rural samples (Kessler et al., 1994). A closer examination of the ECA data indicated that results from the North Carolina site revealed significantly higher rates of depression in urban than in suburban areas, but no bipolar comparison was made (Blazer et al., 1985). These results suggest the possibility of higher prevalence rates of mood disorders in urban areas, but such differences may involve interactions among region, migration pattern, socioeconomic status, life-style, environment, and other related variables.

Data comparing the incidence of mood disorders among various races has often been inconclusive due to conflicting results, as well as methodological problems such as inconsistent or inadequate diagnostic criteria, confounding variables, and racial biases. A slight majority of studies reports higher rates of bipolar disorder in Whites than Blacks (Jaco, 1960; Marquez, Taintor, & Schwartz, 1985; Prange & Vitols, 1962; Simon, 1965), but many studies (Helzer, 1975; Weissman & Myers, 1978), including the ECA program (Blazer et al., 1985; Robins et al., 1984), report no

significant difference between Blacks and Whites. The NCS results contradict those of the ECA by showing that Blacks have significantly lower prevalence rates of affective disorders (along with substance use disorders) than Whites, which cannot be accounted for by education and income. Few comparisons among other races have been reported, but the ECA data from the Los Angeles site revealed nonsignificantly lower rates of manic and major depressive episodes in Mexican-American subjects compared with White subjects. In general, the ECA data found lifetime rates of affective disorders higher among Whites than Hispanics. The NCS, in contrast, reported prevalence rates of current affective disorders significantly higher in Hispanics than in Whites (Kessler et al., 1994). In sum, there is conflicting evidence at present to suggest that a race distinction exists in the prevalence and incidence rates of mood disorders.

As with studies assessing racial differences in mood disorders, studies of socioeconomic status have been hampered by methodological problems. Data from studies that examined social class and prevalence of bipolar disorder suggest a higher incidence of bipolar disorder among upper and possibly middle-class individuals (Coryell et al., 1989; Peterson, 1977; Weissman & Myers, 1978). Data from the NCS are in contrast with these results and show that rates of all psychiatric disorders decline steadily with income and education (Kessler et al., 1994).

Few systematic studies of cross-cultural differences in the prevalence and phenomenology of mood disorders have been reported; most such studies were carried out in industrialized Western nations. Regier et al. (1988) reviewed studies that assessed all major affective disorders and reported 1-month prevalence rates of 7.0% in London, 4.8% in Australia, 7.4% in Athens, 5.9% in Edinburgh, and 18.9% in Uganda. Studies conducted in Denmark, Britain, the United States, and New Zealand reveal remarkably consistent incidence data for bipolar disorder (Fremming, 1951; Helgason, 1979; James & Chapman, 1975; Parsons, 1965; Weissman et al., 1988; Weissman & Myers, 1978). A cross-cultural comparison within the United States is provided by the impressively comprehensive and methodologically sound Amish study (Egeland & Hostetter, 1983), which revealed only a 1% prevalence of mood disorder within the population of this culturally and genetically homoge-

neous subculture located in Pennsylvania. More surprisingly, the Amish study revealed no gender differences and a slightly higher incidence of bipolar than unipolar disorder.

Biological Perspectives

Genetics

Substantial data have been reported from investigations of family history and/or genetic variables for mood disorders. These studies are of four types: family studies, twin concordance, adoption studies, and mode of transmission studies. Case-controlled studies of mood disorder in relatives of patients and normal control subjects consistently show a higher frequency of mood disorders among relatives of bipolar probands compared with those of unipolar probands; reported incidences among first-degree relatives are approximately 12 to 22% versus 7%, respectively (Angst, 1966; Perris, 1966). Family pedigrees of bipolar subjects show a significantly higher incidence (approximately 11%) of bipolar disorder than pedigrees of unipolar subjects (approximately 0.4%; Angst, 1966; Perris, 1966; Winokur et al., 1969). However, these disorders do not necessarily "breed true" because unipolar depression is generally more common in relatives of bipolar subjects (Helzer & Winokur, 1974; James & Chapman, 1975; Loranger, 1975; Reich et al., 1969), although conflicting results have also been reported (Perris, 1966, 1968). Relatives of well-defined unipolar depressives seldom exhibit bipolar disorder (Gershon et al., 1971; Perris, 1966, 1968; Winokur et al., 1969). Based on such findings, Leonhard (1969) estimated the mood disorder morbidity risk for bipolar and unipolar probands' siblings at 10.6% and 4.6%, respectively, and for their parents at 9.5% and 5.3%, respectively, in contrast with the general population morbidity rate of about 2 to 4% (Fieve, 1975). In total, these investigations support the hypothesis of the existence of some genetic factors in mood disorders, particularly bipolar disorder, and more specifically support the unipolar-bipolar distinction within mood disorders. Another interpretation of the data, however, suggests that unipolar and bipolar disorder may be on a continuum. With a polygenetic disorder, the more severe form may be bipolar. With fewer of the genes, unipolar

disorder may result. Thus, beginning with a bipolar proband, you may see equally severe bipolars and less severe unipolars. With less severe unipolar probands, more severe bipolar relatives may be rare.

Twin studies consistently show that identical twins are far more concordant for mood disorder than fraternal twins, and this evidence strongly supports a predominantly genetic contribution to vulnerability. Allen's (1976) review of the extant twin literature on mood disorders indicates significant differences between concordance rates for monozygotic unipolar (40%) and bipolar (72%) twins and nonsignificant differences in concordance rates for dizygotic unipolar (11%) and bipolar (14%) twins. These results suggest that genetic factors may be more important in the occurrence of bipolar disorder than in that of unipolar depression.

In attempts to demonstrate that inheritance (or prenatal or perinatal events) is sufficient to determine predisposition to mood disorder, adoption studies have generally yielded inconclusive results. Examining twenty-nine bipolar adoptee probands, Mendlewicz and Rainer (1977) found significantly more biological parents with mood disorders (31%) than adoptive parents (12%), but these results have not been replicated by other methodologically sound studies.

More direct genetic investigations have addressed questions of the exact mode of genetic transmission and what exactly is transmitted. In unipolar depression, parent-child transmission does not follow patterns suggestive of a single dominant or recessive gene, and polygenic transmission seems most probable (Perris, 1968, 1969). Winokur, Cadoret, Dorzab, and Baker (1971) examined families of unipolar depressed patients and identified two subgroups, which they termed "pure depressive disease" and "depressive spectrum disease." The former is typified by late onset and equal numbers of male and female affected relatives; the latter is typified by earlier onset and families with depression among females and alcoholism and antisocial personality among males. In bipolar disorder, the low incidence of father-son pairs has suggested an X-linked genetic transmission (Mendlewicz, Fleiss, & Fieve, 1972; Winokur & Tanna, 1969). Linkage studies have also targeted chromosome 11, where a specific DNA marker was identified by Egeland et al. (1987) in

their study of bipolar disorder among the Amish. This initial report generated considerable excitement, but as additional families entered into the study, the strength of association weakened, and independent replications have not verified the finding (see Merikangas, Spence, & Kupfer, 1989). The current consensus is that bipolar disorder also has a polygenetic pattern.

Psychopharmacological Treatment

The psychopharmacological research of the past three decades has greatly changed the treatment of depression and has been very influential in the development of biological models of affective disorders. The basic assumption in this particular research area is that differential pharmacological response is associated with differences in biological dysfunctions and thus can be used as a basis for syndrome identification and classification. Although this assumption can be challenged (and indeed has been in many areas of psychopathology), this pharmacological strategy has been powerful in the development of models of mood disorders, particularly bipolar disorder. This is evidenced by the generally accepted view of researchers and clinicians that bipolar disorder is indeed a biological disorder, primarily (if not exclusively) treatable with medication, whereas numerous theories from psychodynamic, behavioral, cognitive, interpersonal, and biological frameworks abound concerning unipolar depression. The result is that psychotherapy for bipolar disorder has largely been ignored in the research literature. In practice, supportive therapy is frequently offered to help patients deal with the consequences of their disorders, and psychoeducational interventions are offered to try to increase medication compliance. This situation is gradually changing and forms of cognitive-behavioral interventions that target stress management, compliance, and manic cognitive distortions are beginning to be described. Comments on these appear later with regard to different approaches to psychotherapy.

Psychopharmacological treatments of mood disorders fall into an increasing number of categories. These include tricyclic antidepressants (TCAs), heterocyclic antidepressants, monoamine re-uptake inhibitors (MAOIs), selective serotonin re-uptake inhibitors (SSRIs), selective serotonin and norepinephrine re-uptake inhibitors (SNRIs), selec-

tive norepinephrine re-uptake inhibitors (NRIs), lithium salts, and a variety of additional drug types. A sample of representative generic names, common U.S. brand names, and applications are listed in Table 1 for these categories (*Physician's Desk Reference*, 1998).

Numerous studies with tricyclic antidepressants suggested that these drugs have a significant antidepressant therapeutic effect with some forms of unipolar depression, particularly the more severe episodes of major depression (Bielski & Friedel, 1976; Elkin et al., 1989; Klein & Davis, 1969; Klerman, Mascio, Weissman, Prusoff, & Paykel, 1974). Several studies (Akiskal, Downs, et al., 1985; Cassano et al., 1988; Prein, Klett, & Caffey, 1973) demonstrated the development of manic episodes in response to tricyclic antidepressant treatment of bipolar individuals and of some unipolar depressed individuals ("unipolar II" or "bipolar III" subgroups discussed earlier).

The second-generation heterocyclic antidepressants are modifications of the already well-established tricyclics. Reported advantages of most of these medications in treating depression involve faster onset of therapeutic action and fewer side effects, although some recent reviewers dispute these claims.

Recent reviews of studies of MAOIs suggested their efficacy primarily with "atypical" unipolar depressions (Pare, 1985; White & Simpson, 1985). The MAOIs are often reserved for use only after other antidepressants have failed because they have many side effects, and severe dietary restrictions are required of the patient who takes these medications. Individuals on this medication cannot tolerate tyramine, which is contained in cheese, beans, wine, and various meats.

Selective-serotonin re-uptake inhibitors (SSRI) are a unique class of antidepressants, that act by directly influencing serotonin neurons in the brain. Prozac, which was the first SSRI, is the most widely prescribed antidepressant in the United States. SSRIs are considered suitable first choice antidepressants because they lack lethality in an overdose, have a favorable side-effect profile, and are efficacious with a broad spectrum of symptoms. The limited number of brain chemical systems affected by SSRIs results in fewer side effects than with the tricyclics and MAOIs (Gorman, 1995). SSRIs are considered effective among tricyclic and MAOI nonresponders (Delgado, 1988; Weil-

burg, 1989). Further, SSRIs are efficacious in treating psychiatric disorders that are often comorbid with depression, such as OCD, PTSD, panic disorder, and eating disorders (Charney, Miller, Licio, & Salomon, 1995; Gorman, 1995).

Selective-serotonin and noradrenaline re-uptake (SNRI) inhibitors are new to the antidepressant medication field. One SNRI, milnacipran, selectively inhibits the re-uptake of serotonin and noradrenaline without directly affecting postsynaptic receptors sites (Lecrubier, 1997). In a controlled trial of milnacipran, this drug was superior in efficacy to SSRIs, particularly in severely depressed patients (Lecrubier, 1997). Like SSRIs, SNRIs work on a limited number of brain chemical systems and therefore produce fewer side effects than the other antidepressants (Gorman, 1995). According to Gorman (1995), the practice of adding a tricyclic antidepressant (which affects the noradrenaline system) to an SSRI nonresponder may be unnecessary with the advent of SNRIs.

New classes of antidepressants continue to come on the market. The NRIs and serotonin receptor agonists act in the neurotransmitter systems traditionally considered most associated with depression. New drugs acting in the dopamine system affect depression as well. One of the newest of these antidepressants, bupropion, may also offer special advantages to depressed bipolar patients due to specific effects on psychomotor retardation and the relatively decreased likelihood of precipitating a manic episode (Benfield, Heel, & Lewis, 1986; Fabre, Brodie, Garver, & Zung, 1983; Gardner, 1983; Shopsin, 1983). Overall, the various classes of drugs used for unipolar depression show about equal effectiveness regardless of the neurotransmitter system impacted. Side effect profiles, however, vary considerably in reliable ways, and the newer classes of drugs are better tolerated by patients. In addition to these regulated pharmaceuticals, an herbal remedy, St. John's Wort (hypericum), has been evaluated for treating depression and is about as effective as the regulated medications (Linde et al., 1996). St. John's Wort, it is thought, is a natural MAOI.

Lithium in the form of various salts such as lithium carbonate was the first and is still the most important of modern antimanic agents. It was discovered to have therapeutic value by physician John Cade (1949) but was not widely used in the United States until the late 1960s. In addition to the

Table 1. Common Medication for Mood Disorders

Generic name	Trade name	Indications
Tricyclic antidepressants		
Amitriptyline	Elavil, Endep, Entrofen	Depression, especially endogenous depression
Amoxapine	Ascendin	Reactive, endogenous, and psychotic depression
Desipramine	Norpramin, Pertfrane	Depression, especially endogenous depression
Doxepin	Adapin, Sinequan	Depression with anxiety; involuntal, psychotic, and bipolar depression
Imipramine	Tofranil	Depression, especially endogenous depression
Nortriptyline	Pamelor	Depression, especially endogenous depression
Protriptyline	Vivactil	Depression, especially atypical depression
Trinipramine	Surmontil	Depression, especially endogenous depression
Second-generation heterocyclics		
Trazadone	Desyrel	Major depression
Selective serotonin re-uptake inhibitors		
Fluoxetine	Prozac	Major depression with anxiety symptoms
Paroxetine	Paxil	Major depression with anxiety symptoms
Sertraline	Zoloft	Major depression with anxiety symptoms
Selective serotonin and norepinephrine re-uptake inhibitors		
Venlafaxine	Effexor	Major depression, melancholia, agitated or retarded symptoms, anxiety symptoms
Milnacipran		Major depression, especially severe depression
Selective norepinephrine re-uptake inhibitors		
Viloaxzine	Vivalan, Vivarint	Major depression
Reboxetine	Edronax	Major depression
Dopamine re-uptake inhibitors		
Bupropion	Wellbutrin, Zyban	Major depression, possibly bipolar depression
Serotonin receptor agonists		
Nefazodone	Serzone, Dutonin	Major depression
Dopamine receptor antagonists		
Amisulpride	Deniban, Solian, Sulamid	Major depression
MAO inhibitors		
Phenelzine sulfate	Nardil	Atypical unipolar depression; tricyclic nonresponders
Tranlycypromine sulfate	Parnate	Major depression without melancholia; tricyclic nonresponders
Antimanic medications		
Lithium carbonate	Eskalith, Lithium, Lithobid	Bipolar disorder treatment and maintenance
Carbamazepine	Tegretol	Mania: treatment and maintenance; especially rapid cyclers
Divalproex	Depakote	Manic episodes that do not respond to lithium

widely recognized therapeutic and prophylactic effects of lithium on manic symptoms, numerous controlled empirical studies have demonstrated clear therapeutic and prophylactic effects for lithium in depressed patients; the greatest effect is in depressed bipolar patients (Baron, Gershon, Rudy, Jonas, & Buchsbau, 1975; Goodwin, Murphy, & Bunney, 1969; Goodwin, Murphy, Dunner, & Bunney, 1972; Johnson, 1974; Khan, 1981; Mendels, 1976; Mendels, Secunda, & Dyson, 1972; Noyes, Dempsey, Blum, & Cavanaugh, 1974; Worrall et al., 1979). Despite the significant unipolar-bipolar group differences, it is important to note that a large subgroup of unipolar depressives (up to 40%) exhibits some therapeutic response to lithium and that up to 20% of bipolar depressives do not respond to lithium.

Other Medical Treatment

Electroconvulsive therapy (ECT) has re-emerged in the last few years due to improvement in the safety of administering it. ECT is typically now administered in six to twelve sessions, unlike in the past, where numerous sessions may have been prescribed unnecessarily. ECT is indicated for various patients, including delusional/psychotic depressives, extremely suicidal patients where it may be dangerous to wait for the effects of an antidepressant, severely malnourished patients who refuse to eat, patients with medical problems where antidepressants are contraindicated, and nonresponders to other antidepressants (Charney et al., 1995; Gorman, 1995). Researchers suggest that ECT is equal or superior in efficacy to tricyclics and monoamine oxidase inhibitors for treating severe depression (Charney et al. 1995).

There are some noted effects of ECT on memory. Abrams (1997) indicates that minimal side effects from bilateral ECT might consist of short-term memory deficits for information immediately before and after treatment that return to normal within a few weeks. More serious effects of bilateral ECT might include deficits for 6 months or more before treatment to 2 months or more afterward. Bilateral ECT does not result in permanent effects on procedural memory or the ability to retain new information. Right unilateral ECT shows considerably fewer side effects than bilateral ECT. Specifically, individuals suffer little or no memory deficits during or immediately after treatment, and any disturbances that occur may be

temporary and possibly undetectable (Abrams, 1997).

Biological Models

The somatic symptom patterns, the genetic findings, and the response to pharmacotherapy of depression have led to the development of biological theories of the disorder. Primarily as an outgrowth of pharmacological studies in humans and animals, much attention has been directed to neurotransmitter deficiencies as core deficits in depression. These monoamine theories have been developed by focusing on deficiencies in the neurochemical systems that involve the catecholamines, norepinephrine and dopamine (Schildkraut, 1965), and the indolamine, serotonin (Glassman, 1969). Mania, conversely, is viewed as due to an excess of neurotransmitters (Schildkraut, 1965).

Many lines of research implicate deficiencies in neurotransmitters. Some examples of the types of evidence include findings that tricyclic antidepressants increase functional levels of norepinephrine and serotonin in the synapse, probably by blocking re-uptake into the cell. The MAO inhibitor antidepressants inhibit the chemicals that break down neurotransmitters. Reserpine, an antihypertensive, depletes storage of monoamines and causes depression in vulnerable individuals (Redmond & Leonard, 1997).

Clinical research with humans has centered around measuring metabolites of the monoamines in blood, urine, and cerebrospinal fluid as possible biological markers of depression. Levels of 3-methoxy-4-hydroxyphenyl glycol (MHPG), a primary metabolic product of norepinephrine, are taken as an indirect index of norepinephrine in the central nervous system. Similarly, homovanillic acid (HVA) is a metabolic index for dopamine, and 5-hydroxy-indoleacetic acid (5-HIAA) is an index of serotonin. Overall, findings have been mixed, and it is clear that many factors influence the levels of these metabolites (Thase, Frank, & Kupfer, 1985). Their utility as diagnostic markers or as symptom or trait measures is questionable; the same neurotransmitters are deficient in other disorders as well (e.g., Nicol & Gottesman, 1983). Recent research has begun to implicate additional neurotransmitters, such as acetylcholine and gamma-aminobutyric acid (GABA), as dysfunctional, suggesting that more generalized processes of neurochemical dysregulation may be acting in de-

pression (Thase et al., 1985; Redmond & Leonard, 1997).

Endocrine models of depression have developed because of the observation that diseases of the endocrine glands often present with depressive symptoms and because of the discovery of feedback regulation systems connected to sleep, appetitive, and libido centers and related to the monoamine systems. A finding that has received much attention is that plasma cortisol levels are elevated in a high proportion of depressed persons. Although cortisol elevations occur as a normal response to stress, they are elevated in depression without accompanying stress symptomatology. Clinical research has emphasized the dexamethasone suppression test as a possible biological marker for depression (Carroll, 1982). Dexamethasone, a cortisol-like drug, suppresses cortisol secretion for 24 hours in normals. It is estimated that 30 to 70% of depressed patients fail to suppress; nonsuppression, however, is not specific to depression nor to unipolar versus bipolar type, and it is affected by many conditions such as alcohol and drug use, weight loss, and older age. As such, the test's specificity and sensitivity are not sufficient to make it diagnostically useful. It does not differentially predict drug response, though some argue that its association with indicators of severity suggest it should predict differential response to pharmacological versus psychological intervention. Suppression does return to normal following successful treatment (Redmond & Leonard, 1997).

Studies of thyroid function suggest the possibility that hypothyroidism may be implicated in depression. Low levels of secretion produce symptoms that mimic depression, and thyroid replacement relieves depression in a small percentage of cases. Thyroid-releasing hormone (TRH) has a diminished effect on thyroid-stimulating hormone (TSH) in regulating thyroid hormone production, but this may be due to extraneous factors (Loosen & Prange, 1982).

A number of other endocrine systems have also been studied, including insulin tolerance, growth hormone, somatostatin, prolactin, and endorphins. These are interrelated and involve the monoamine systems (Howland, Thase et al., 1985).

Several of the endocrine systems show abnormalities in their daily or circadian rhythms in depressed individuals, and it has been noted that the symptoms of depression may also show diurnal variation. For these and other reasons, recent

attention has been turned to the possibility of dysregulating biological clock mechanisms in depression. Neuroendocrine, neurophysiological, and thermal regulation normally cycle on a 24-hour clock. Other biological clocks operate in shorter "ultradian" rhythms, such as 90-minute sleep cycles, and still other clocks operate on a yearly or "circannual" rhythm. Each has been implicated as dysfunctional in depression. Circadian rhythm research regarding depression has suggested a 4- to 6-hour clock advance in the sleep-wake cycle and in temperature regulation. Basic research, however, suggests that multiple clocks may be implicated in circadian rhythms and that dissociation between systems may be a more likely pattern.

Sleep EEG research has looked at various ultradian factors in sleep. Rapid eye movement (REM) cycles are disrupted in various ways, and measures such as total REM sleep sometimes differentiate depressed samples. The most robust findings is the observation of reduced REM latency in depression. Whereas normals take about 90 minutes to go into their first REM sleep period, this is significantly reduced for many depressed patients (Kupfer & Foster, 1972). Reduced REM latency is currently the most reliable and useful biological marker of depression.

The observation that depression regularly occurs in the fall and winter in some individuals, followed by normal or manic functioning in the spring and summer, has suggested the possibility of circannual dysregulation in some persons. The diagnosis of "seasonal affect disorder" (SAD) has been suggested for identifying individuals with this pattern, who have atypical depressions in many ways (Rosenthal et al., 1984). Recent evidence suggests that phototherapy (prolonged exposure to artificial light) may ameliorate SAD, although the hypothetical mechanisms of resetting the annual biological clock may not be valid (Wehr et al., 1986).

Ehlers, Frank, and Kupfer (1988) draw a theoretical connection between the research on biological rhythms and research on stress as precipitants of episodes of depression. They note that biological rhythms are set by the pace of life events, termed *zeitgebers* ("time givers"). *Zeitgebers* include persons, social demands, and tasks that we encounter in regular patterns. If social rhythms are disrupted by relationship changes or losses, increases or decreases in demands, or task changes, this social disruption may result in unstable bio-

logical rhythms and thus induce depression in vulnerable people.

Environmental Perspective

The biological contributions to depression are often discussed in terms of a diathesis-stress model. Biological predisposition or risk is a diathesis that is insufficient to produce depression, except in interaction with life stress. Psychological models propose psychological diatheses as well, and these will be discussed later. As with many medical and psychological disorders, there is evidence that periods of stress are likely to precede episodes of depression. It is debatable whether these are a subset of reactive or exogenous depressions, or whether all depressions vary in the degree of contribution of diathesis and stress.

Life events appear to precede depression, and, in some cases, to precipitate episodes (Lloyd, 1980a,b). This appears to be true for bipolar as well as unipolar depressions (Ellicott, Hammen, Gitlin, Brown, & Jamison, 1990). Questions arise as to the specificity of vulnerability and event type. There is evidence that certain types of events may be specific to increased risk for depression. Events linked to depression have included those characterized as long-term or ongoing difficulties and those that involve severe undesirable events, exits by significant others from the person's life, and individual versus shared stresses (see Brown & Harris, 1978; Monroe, 1990).

Brown and Harris (1978; Brown, Bhrolchain, & Harris, 1975) proposed a model in which provoking events interact with psychosocial vulnerability factors. In their study of women in a suburb of London, they found that four vulnerability factors increased the probability that provoking events would produce depression: (1) the lack of a confiding relationship with a male, (2) having three or more children under age 14 in the home, (3) not having a job outside the home, and (4) loss of the subject's mother before the age of eleven. Low socioeconomic status also appears to be a depression vulnerability factor, especially for women (Radloff, 1975). As suggested by Brown and Harris, there is also evidence that social support may have a mitigating effect that decreases the effect of life stress (Barnett & Gotlib, 1988; Monroe, Bromet, Connell, & Steiner, 1986). Hooley, Orley, and Teasdale (1986) presented evidence

that the level of expressed emotion in families is a moderator of relapse in depressed persons. In families that are high in conflict and criticism, the probability of relapse is increased.

Overall, the evidence supports the effects of life stress on depression and supports the interaction between life stress and psychosocial vulnerabilities. Some studies also look at interactions with biological vulnerability in the sense of looking at biologically vulnerable individuals based on their own history or their family history.

Psychological Theory and Research

As with biological models, psychological theories are diathesis-stress theories. Therefore, they assume that reactive depressions are the basic model for the disorder. Psychological diatheses or vulnerability factors interact with environmental stress to precipitate depressions. Each of the theories has led to research that explored implications for assessment, etiology, and psychotherapy for depression. To varying degrees, these approaches have been used to explicate problems of classification, epidemiology, sex differences, and biological interactions.

Psychodynamic Models

Psychodynamic theory has contributed a number of models to the understanding of depression. Freud's classic psychoanalytic paper "Mourning and Melancholy" (1917/1957) describes depression as the reaction to the loss of an unconscious object. Because of a loss of part of oneself, anger and reproach become self-directed. In mania, Freud speculated that the conflict is the same, but the energy is released outward. A more elaborate early discussion of manic-depressive conditions was offered by Abraham (1911/1949), who speculated that mania represented the failure of repression to contain self-hatred and guilt arising from the need to give up a sexual aim without gratification. The emphasis on internalization of anger seems at odds with the frequency with which anger toward others is expressed in depression, although Abraham suggests that this anger may be a projection of self-hatred.

A number of more recent theorists from this general perspective focused on differentiating two types of depression or depression proneness. Arieti and Bemporad (1980; Bemporad, 1971) em-

phasized the failure to internalize standards as the basis of dependency depression and internalization of stringent standards as a basis for dominant goal depressions. The individual who has failed to internalize standards depends on the judgments of others for self-esteem. Dominant goal personalities are vulnerable to depression when they fail to meet their own unrealistically high standards.

Other theorists describe similar distinctions. Blatt (1974; Blatt, Wein, Chevron, & Quinlan, 1979) differentiates anaclitic or dependency depressions, which stem from early loss, from introjected or self-criticism depressions that are based on later acceptance of external negative evaluations. The Depressive Experiences Questionnaire (Blatt, D'Affliti, & Quinlan, 1976; Blatt, Quinlan, Chevron, McDonald, & Zuroff, 1982) was devised to differentiate dependency from depressions due to self-criticism. Beck (1983) uses the terms sociotrophic versus autonomous depressions. Sociotrophic individuals depend on interpersonal relationships for positive self-evaluation, and autonomous individuals depend on achievement and status. The type of loss a person suffers (interpersonal or status) would produce depression only for the person with the corresponding personality type. A Sociotropy–Autonomy Scale (Beck, Epstein, Harrison, & Emery, 1983) was developed to measure the concepts as two independent dimensions. Hammen, Ellicott, Gitlin, and Jamison (1989) reported results supporting the idea that interpersonal life stresses were more likely to precede depression for individuals high on sociotropy, whereas achievement stresses were higher before depression for individuals high on autonomy.

The idea of a depressive personality, defined by various traits, has had a long history in psychodynamic personality theory. Results demonstrating such a personality type have been mixed at best. Recent research seeing personality factors as interacting with life stress are a more fruitful line of inquiry; several reviews cover the area (Barnett & Gotlib, 1988; Chodoff, 1974; Hirschfeld & Cross, 1982; Nietzel & Harris, 1990).

Psychodynamic therapy in a short-term form tailored to depression has been described by Strupp, Sandell, Waterhouse, O'Malley, and Anderson (1982). Relatively little has been published on controlled outcome studies of psychodynamic therapy for depression. Results have not been as strong as for the cognitive and behavioral approaches (Lipman & Covi, 1976; Steuer et al.,

1984; Thompson, Gallagher, & Breckenridge, 1987). However, a recent study by Gallagher-Thompson and Steffen (1994) found that brief dynamic therapy is effective in treating depressed family care givers.

Reinforcement Model

Behavioral approaches to depression share a basic assumption that depression arises from a disruption of response–reinforcement relationships. Charles Ferster (1973) viewed depression as a generalized reduction of rates of response to external stimuli. His basic analogy in learning terms is to the process of extinction. Major losses in life can be seen as losses of important sources of reinforcement. Generalization of the effects of the loss occur because other behavior was chained to, or organized by, the central source of reinforcement.

Peter M. Lewinsohn's behavioral theory of depression (Lewinsohn, 1974; Lewinsohn, Biglan, & Zeiss, 1976) posits that depression is a response to a loss or lack of response-contingent positive reinforcement. Insufficient reinforcement in major life domains leads to dysphoria and a reduction in behavior, which are the primary phenomena of depression. Other symptoms of depression, such as low self-esteem and hopelessness, follow from the reduced level of functioning.

According to this theory, there are three ways in which insufficient reinforcement may occur. First, the environment may produce a loss of reinforcement or may be inadequate in providing sufficient reinforcement to maintain adequate functioning. For example, the loss of a job would represent a significant loss of a source of reinforcement, and chronic underemployment might represent a continuing lack of sufficient reinforcement. Second, the person may lack the requisite skills to obtain reinforcement in an environment where it is potentially available. For example, poor interpersonal skills might prevent a person from developing satisfactory social relationships. Third, reinforcers might be available to people, but they may be unable to enjoy or receive satisfaction from them. The reason for this condition would ordinarily be interfering anxiety. The socially anxious person does not functionally receive the reinforcers, even if they are emitted by an amiable social environment.

Another feature of the theory is the suggestion

that once depression occurs, depressive behavior functions to elicit reinforcement from others as concern and succor. The person who is experiencing insufficient reinforcement obtains reinforcement for acting in a depressed manner. Depending on the nature of the contingencies, selective reinforcement by others could contribute to a natural resolution of the depression, but importantly, reinforcement of the depressed behavior *per se* can function to maintain the depression. Although depressive behavior elicits positive responses from others in the short run, continued depression is aversive to these others, and eventually they begin to avoid the depressed person, and the ultimate effect is that reinforcement is again lacking. The result is that the depressed behavior is maintained on a thin schedule of reinforcement. Reinforcement continues to be insufficient to overcome the depression and, instead, maintains it in a self-perpetuating cycle.

A primary area of research that stems from Lewinsohn's theory involves the relationship between mood and daily events. On the assumption that positive and negative events can be thought of as rewards and punishments, this research looks at mood as a consequence of reinforcement. Contingency between the event and the person's behavior is assumed, but is usually not demonstrated in these studies. Findings are generally consistent with the theory. Daily mood is positively correlated with pleasant events and negatively correlated with unpleasant events, whereas the two types of events are uncorrelated with each other (Grosscup & Lewinsohn, 1980; Lewinsohn & Graf, 1973; Lewinsohn & Libet, 1972; Rehm, 1978). Depressed persons have lower activity levels, report less pleasure from positive events (i.e., are less able to experience reinforcement), and obtain less total pleasure (i.e., experience a relative lack of reinforcement) compared to normals or psychiatric controls (MacPhillamy & Lewinsohn, 1974, 1982). The corresponding effects occur with unpleasant events, though with somewhat less consistency (Lewinsohn & Talkington, 1979). With treatment, scores improve on event scales in appropriate directions (Lewinsohn, Youngren, & Grosscup, 1979). These studies also support the assumption of continuity between depressed mood and clinical depression. All levels of depression or sadness are seen as responsive to reinforcement conditions.

Lewinsohn's reinforcement theory leads di-

rectly to a therapeutic approach based on the three posited causes of a loss or lack of reinforcement (Lewinsohn et al., 1976). Initially, a series of depression therapy "modules" were developed to match the therapy to the primary deficit of the particular depressed person. People with insufficient reinforcement in their environments would be matched to an activity-increase therapy module in which the goal of treatment would be to identify potentially reinforcing activities and to encourage the patient to increase these activities. An interpersonal skill training module was developed to intervene where social skill deficiencies were evident, and a desensitization module was developed for patients who demonstrated interfering anxiety. Later, a cognitive model was also developed. Zeiss, Lewinsohn, and Munoz (1979) found, however, that interpersonal, cognitive, and activity-increase modules were helpful in ameliorating depression, regardless of the pattern of deficits shown by the patients at pretest. Regardless of the therapy module that patients received, they also improved in all three areas. Because matching was not productive, the modules were joined together in a structured therapy program (Lewinsohn, Antonuccio, Breckenridge, & Teri, 1987) that has been effective in various formats (Brown & Lewinsohn, 1984).

Lewinsohn, Hoberman, Teri, and Hautzinger (1985) reviewed research and the theory of depression and developed an expanded version of the behavioral reinforcement approach. They suggested that cognitive factors involving increased self-awareness may mediate between reduced reinforcement and dysphoria/depression. Other modifications of the approach involved considering the ways in which the consequences of depressed behavior may affect depression by influencing evoking events, reinforcement, and self-awareness. The feedback loops created by the consequences of depression amplify and maintain the depression. The elaborated approach attempted to incorporate a wider range of research findings into a more comprehensive theory.

Social Skill Models

Social skill deficits have been identified as primary causes of depression by a number of theorists. In Lewinsohn's reinforcement model, social skill deficits are one of three causes for a lack of sufficient response-contingent reinforcement.

Wolpe (1979) saw an anxiety-based inability to control interpersonal situations as one route to neurotic or reactive depressions, which he saw as always secondary to anxiety. Gotlib and Colby (1987) make a case for interpersonal deficits as central to depression and review a variety of evidence. Joiner and Coyne (1999) take the argument one step further in a book reviewing interpersonal aspects of depression. They view depression as a phenomenon that should be seen as interpersonal. Other theorists focused on more specific domains of interpersonal behavior as underlying depression. Nezu, Nezu, and Perri (1989) argue that depressed persons are deficient in problem-solving skills, especially interpersonally. The review literature supports the position in terms of comparisons between depressed and nondepressed peoples' performance on multiple components of the problem-solving process.

Several theorists identified marital communication skills as important in depression (Beach & O'Leary, 1986; Jacobson, Holtzworth-Munroe, & Schmalting, 1989; McLean & Hakstian, 1979). The marital relationship is an important basis for interpersonal support, self-esteem, and social satisfaction. A related approach to depression from a different theoretical tradition is the basis for Klerman, Weissman, Rounsaville, and Chevron's (1984) interpersonal therapy for depression. Derived from a Sullivanian or Meyerian psychodynamic paradigm, the underlying rationale is that depression is caused by unresolved disturbances in important interpersonal relationships.

Research evidence from many sources supports the social skill deficit approach to depression. Lewinsohn, Mischel, Chaplin, and Barton (1980) demonstrated that depressed individuals are perceived by themselves and by others as low in social skill. Interestingly, depressed subjects rated their own skills at the same level as they were rated by others. Normals and psychiatric controls rated their own skills higher than they were rated by others. Both self-ratings and the ratings of social skill by others improved with therapy. Several studies demonstrated that depressed persons have a negative impact on those with whom they interact (e.g., Coyne, 1976). What specific behaviors produce this negative reaction has been difficult to determine. Jacobson and Anderson (1982), for example, found that mildly depressed college students who interacted with nondepressed peers

made more negative self-statements and self-disclosed at inappropriate times that switched the focus of the conversation to themselves following a self-disclosure by the other person.

Hammen and Peters (1977) looked at the reactions of male and female college students to written sketches of a depressed fellow student who was given either a male or a female name. Students of both sexes were more sympathetic to the female and more rejecting of the male. These results suggest that depression may be acceptable in our society for women and may actually be reinforced, whereas for males, it is not accepted and might be punished. This is consistent with the idea that males may handle their difficulties through other means, such as alcohol, in circumstances where women might become depressed.

Studies of marital interactions where one spouse is depressed suggest a mutually coercive and aversive pattern of interaction. For example, depressive complaints and nagging may be negatively reinforced by spouses who give in to the complaint (Hautzinger, Linden, & Hoffman, 1982). The nondepressed spouse is reinforced for apology and for giving in and is punished for making requests or demands by further depressive behavior. Bipolar depression has been studied less in terms of social skill issues, but research on the long-term functioning of bipolars indicates poor marital stability (Angst et al., 1973; Brodie & Leff, 1971; Dunner et al., 1976). This could be due to the consequences of the disorder but might also indicate skill deficits.

Another area of research that demonstrates the interpersonal nature of depression consists of studies of the impact of the interaction with depressed parents (primarily mothers) on childhood depression and the psychological development of the child (Gelfand & Teti, 1990). Depressed mothers are less active, less responsive, and less synchronous in their interactions with their infants and young children (e.g., Bettis, 1988; Cole & Rehm, 1986). The children of depressed mothers are less firmly attached and seem less well able to regulate their emotional states (e.g., Cohn & Tronick, 1983; Field, 1984; Zahn-Waxler, Cummings, Iannotti, & Radke-Yarrow, 1984). These effects are lasting and may lead to general or specific vulnerabilities for later psychopathology in the children (Cole & Kaslow, 1988; Zahn-Waxler et al., 1984). The research of Zahn-Waxler et al. is

notable for including study of the children of bipolar parents.

For the most part, these theoretical perspectives were developed in developing and evaluating treatment approaches to depression. Each conceptualization of interpersonal skill deficits leads to a corresponding skill training program. A general social skill training approach involving role-playing with coaching and feedback was evaluated by Hersen, Bellack, Himmelhoch, and Thase (1984), who found that this approach compared favorably to treatment with a tricyclic antidepressant. Other studies of social skill training raised the question whether depressed persons have a true skill deficit or whether, when depressed, they merely perform in a less skilled fashion as a symptom of their depression (Rehm, Fuchs, Roth, Kornblith, & Romano, 1979; Rude, 1986).

Interpersonal therapy (Klerman et al., 1984) was evaluated in the large National Institute of Mental Health collaborative research program on the treatment of depression (Elkin et al., 1989). Interpersonal therapy was compared to cognitive therapy, a tricyclic antidepressant plus clinical management, and a drug placebo plus clinical management. Interpersonal therapy did equally as well as the other two active treatments and was superior to the placebo. It is notable that this therapy approach is aimed more at resolving specific current interpersonal disturbances as opposed to teaching more generalizable interpersonal skills.

Problem-solving therapy with a particular orientation to depression was evaluated by Nezu (1986) and found superior to control conditions at posttest and 6-month follow-up. Marital therapy, it has been demonstrated, is effective in treating depression either as the sole focus of treatment (Beach & O'Leary, 1986) or as a component of a larger therapy program (McLean & Hakstian, 1979). Social skill approaches are beginning to be applied to depressed children (e.g., Matson et al., 1980). Parent training of depressed parents is also a viable treatment modality (see Rogers & Forehand, 1983).

Overall, the social skill approaches represent a diverse group of theoretical positions, research strategies, and therapeutic methods. They share the orientation of looking at depression in terms of its interpersonal causes, manifestations, and effects on others. Putting depression and other forms of psychopathology into a more interpersonal per-

spective is a potentially useful trend that contrasts with the traditional medical model of the disorder.

Learned Helplessness Theory

Martin E. P. Seligman's (1974, 1975) learned-helplessness theory of depression was derived from an animal model for the disorder. Dogs exposed to unavoidable shock are subsequently deficient in learning an escape or avoidance response in a shuttle-box apparatus (e.g., Seligman & Maier, 1967). These dogs were seen as having acquired a generalized helplessness, that is, a perception of lack of contingency between responses and outcomes. Dogs with equivalent, but response-contingent shock learned later to escape and avoid like dogs with no preconditioned experience. The behavior of these animals is analogous to human depression in several ways. Induction by inescapable shock is a parallel to the traumatic loss that often precipitates depression. The animals' behavior included passivity, weight loss, and lack of appetite. Moreover, the learned helplessness effect dissipated with time, as does normal depression.

In 1978, a more cognitive, attributional revision of the learned-helplessness theory was published (Abramson, Seligman, & Teasdale, 1978). The revision adapted concepts of attribution of responsibility from social psychology (Weiner et al., 1971). The revised model hypothesizes that a particular attributional style is typical of people at risk of depression. Depression-vulnerable individuals habitually attribute negative outcomes to internal, stable, global causes and positive events to external, unstable, specific causes. In other words, following a failure, the depression-prone person accepts blame and assumes that the cause is general and persisting. Following a success, the same person takes no credit and assumes that it has no implication for other behavior or for the future.

A person with this depressive cognitive-diathesis is likely to make a depressive attribution when a major aversive event occurs. To make such an interpretation is to perceive oneself as helpless (e.g., "I am unable to avoid failure and unable to produce success"). The nature of the attribution for a specific aversive experience determines the nature of the depression. An internal attribution determines whether the person's self-esteem is affected, a stable attribution determines the chronicity of the depression, and a global attribution

determines the generality of the feelings of depression. The intensity of the depression is determined by the aversiveness of the event and also by the person's consequent attributions.

Later papers concerning the theory have made additional revisions. Alloy, Clements, and Kolden (1985) and Abramson, Alloy, and Metalsky (1988) emphasized the idea that attributional style is neither a necessary nor sufficient cause of depression but only a contributory cause or a risk factor along with many other possible risk factors. A depressive attribution about a particular adverse event is only partly predictable from attributional style. Many other paths to depression may exist, and the model applies to only a subset of depressions. The revisions also add another step in the causal sequence by asserting that helplessness leads to depression when it leads the person to be hopeless about the future. Hopelessness is seen as the proximal antecedent cause of only a subset of depressions. The authors refer to this as a revised "helplessness model" of depression.

A number of lines of research resulted from the learned-helplessness theoretical position. Studies of helplessness induction in humans have followed the analogy to the animal experiments. Humans who experience noncontingent aversive stimulation show deficits on subsequent task performance that parallel the behavior of depressed persons (e.g., Miller & Seligman, 1975).

The Attributional Style Questionnaire (Peterson et al., 1982) has been employed in many studies to assess the consistent individual difference posited to represent vulnerability to depression. It is clear that a depressive attributional style is a concomitant or symptom of depression, but evidence is less clear that it is a preexisting causal trait (see Barnett & Gotlib, 1988, for a review of the evidence). Evidence is mixed as to whether attributional style remains depressive in remitted patients (Eaves & Rush, 1984); the weight of evidence suggests that it returns to normal levels (e.g., Zeiss & Lewinsohn, 1988). Prospective studies of attributional style as a predictor of depression are few and do not tend to support its predictive value (e.g., Lewinsohn, Steinmetz, Larson, & Franklin, 1981), although positive findings have been found in studies looking at the specific interaction of attributional style and an adverse life event (e.g., Metalsky et al., 1982; O'Hara, Rehm, & Campbell, 1982). An innovative study by

Needles and Abramson (1990) demonstrated that a positive attributional style for positive events interacts with the occurrence of positive events to predict recovery from episodes of mild depression.

Seligman's model does not differentiate between unipolar and bipolar depression with regard to attributional style, and most research has excluded bipolars. However, recent studies (Ivens, 1988; Seligman et al., 1988) indicate that attributional styles of unipolar and bipolar depressed patients do not differ significantly.

The learned-helplessness theory has been employed to explicate the problem of differential sex ratio in depression. Dweck suggests that children receive differential feedback as to the causal attributions for their failures (Dweck & Bush, 1976; Dweck, Davidson, Nelson, & Enna, 1978). In effect, boys are told that their failures are due to lack of effort (an unstable cause), whereas girls are more likely to be told that failure is due to lack of ability (a stable cause). The implication is that women are more likely to be socialized to make depressive attributions for failure. Radloff (1975; Radloff & Rae, 1979) employs the helplessness model to explain sex differences in an analysis of epidemiologic data that partition the contributions of marriage, out-of-home employment, and satisfaction with job and marriage to depression in women.

A different tack in dealing with sex differences was proposed by Susan Nolen-Hoeksema (1987). She notes that there are individual differences in cognitive response to aversive experiences. Some people tend to ruminate over the causes and implications of the event and thereby maintain and extend the depressive mood. Others may use strategies to minimize the psychological impact of an aversive event, such as distraction or purposefully focusing on more pleasant topics, which help to terminate a depressive mood. Women are more likely to have a ruminative style, and men are more likely to have a distracting style.

No therapy program has been developed directly from the learned-helplessness perspective. Seligman (1981), however, suggested that four basic therapeutic strategies are consistent with the tenets of the theory. The first is environmental manipulations, which involve putting the person in an environment (such as a psychiatric hospital) that promotes a recovery of a sense of control over

daily events. The second is skill training (e.g., in job skills or social skills) to give the person actual increased ability to control the environment. Third, Seligman suggests the possibility of resignation training to help people give up unrealistic goals that they are helpless to achieve and replace them with more realistic and controllable goals. Fourth, attribution retraining would be directed at the depressive attributional style itself to avoid initiating new depressive episodes.

Learned-helplessness theory has been very influential in generating research to test hypotheses that it has generated. It is an evolving approach that has been revised in response to the data generated. It remains to be seen what utility will be added to the theory by the recent hopelessness revision. It may be difficult to operationalize the constructs of attributional style, helplessness, and hopelessness as entities separate from depression itself. Recent extensions of the theory focused on the converse implications of the theory. A pessimistic attribution style as a vulnerability characteristic implies that an optimistic attributional style may be a protective immunity characteristic. Implications of this premise have been elaborated by Seligman (Seligman et al., 1995).

Self-Control Theory

Models of self-control are concerned with the ways by which people manage their behavior to obtain long-term goals (e.g., quit smoking, or start exercising for long-term health). As applied to depression, the self-control approach focuses on the inability of depressed people to manage their behavior toward long-term goals. Depressed people feel helpless, they are hopeless about the future, and behavior formerly organized by long-term goals is most likely to deteriorate.

Lynn P. Rehm (1977) presented a self-control model of depression that attempted to integrate aspects of the theories of Lewinsohn, Beck, and Seligman in a self-control framework. The framework was an adaptation of Kanfer's (1970) model of self-control; Kanfer described people's efforts at controlling their behavior to obtain long-term goals in terms of a three-stage feedback loop consisting of self-monitoring, self-evaluation, and self-reinforcement. Kanfer assumes that people can control and influence their own behavior using the same reinforcement principles that would ap-

ply to the control of someone else's behavior. Self-reward and self-punishment act as supplements to the external rewards and punishments of the environment and function to maintain behavior when external reinforcement is not immediate.

The self-control model of depression (Rehm, 1977) postulates that the behavior of depressed people could be characterized by one or more of six deficits in self-control behavior. First, depressed persons selectively attend to negative events in their lives, to the relative exclusion of positive events. This self-monitoring deficit describes the phenomenon discussed by Beck (1972) as selective attention in depression. Second, depressed people selectively attend to the immediate (as opposed to the delayed) consequences of their behavior. Depressed persons have difficulty in looking beyond the demands of the present when making behavioral choices.

Third, depressed people set stringent self-evaluative standards for themselves. They are often perfectionistic, and standards for themselves are more stringent than those applied to others. Fourth, depressed people make depressive attributions about their behavior. In the original paper, the internal-external dimension was addressed, and a global-specific dimension was discussed in terms of breadth of standards applied. With the advent of the attributional revision of the learned-helplessness theory (Abramson et al., 1978), later versions of the model incorporated a three-dimensional analysis of helplessness theory.

Fifth, depressed people administer insufficient contingent rewards to themselves to maintain important domains of behavior. Sixth, they administer excessive self-punishment. Self-punishment suppresses constructive behavior in many areas. These deficits in the self-reinforcement phase of self-control are partly the consequence of deficits in the earlier phases of self-control behavior. For example, monitoring negative events and setting high standards minimizes reward and maximizes punishment.

Self-reinforcement is seen as supplementing external reinforcement. The nondepressed person can maintain behavior toward goals, even when the external environment does not reinforce that behavior. The depressed person depends on external sources of reinforcement and becomes depressed when they are insufficient (as suggested by Lewinsohn). When environmental contingen-

cies change, the individual is faced with organizing efforts to readjust and reorient toward distant goals. The self-control model is a vulnerability or diathesis-stress model in the sense that poor self-control skills, as described earlier, place people at risk for depression under adverse conditions of external reinforcement.

Research relevant to the self-control model of depression is diverse (Rehm, 1982, 1988), and only a few examples will be cited here. Roth and Rehm (1980) examined the self-monitoring behavior of depressed and nondepressed psychiatric patients who viewed themselves interacting on videotape, and counted specified positive and negative behaviors. Although there were no objective differences between groups, the depressed patients counted fewer positive and more negative behaviors than the nondepressed patients. Though the study does not distinguish between selective attention and different standards for calling an event positive or negative, it does point to a depressive tendency to self-monitor in a biased fashion.

Rehm and Plakosh (1975) found that mildly depressed college students were more likely to express a preference for a small immediate reward in contrast to a larger delayed reward. In another study, however, when subjects were faced with a real (as opposed to hypothetical) choice, depression scores did not predict the choice of a delayed, but larger payment for research participation (O'Hara & Rehm, 1982).

Studies that show negative self-evaluation in depressed persons are plentiful (e.g., Lewinsohn et al., 1980, discussed earlier). Performance standards of depressed persons appear to be higher because depressed persons often evaluate the same actual performance as less positive than that of nondepressed persons. Shrauger and Terbovic (1976) demonstrated that college students with low self-esteem rated themselves lower on a task than they rated a confederate who was duplicating the subject's performance.

Self-reinforcement studies compared the rate at which depressed and nondepressed subjects administer token rewards and punishments to themselves based on their evaluations of their own performance. For example, on a recognition memory task, Rozensky, Rehm, Pry, and Roth (1977) found that depressed psychiatric patients self-rewarded less and self-punished more than nondepressed patients, even though their actual performance was equivalent. By and large, these

studies have not differentiated self-reinforcement from self-evaluation. Gotlib (1981) found that these effects were not specific to depression but characterized psychopathology generally.

Ivens (1988) administered the Self-Control Questionnaire, a scale developed to measure the specific self-control deficits that, it was hypothesized, are related to depression (Rehm et al., 1981), to pharmacologically treated unipolar, bipolar, and schizophrenic outpatients. There were no significant differences between groups, although questionnaire scores within each group correlated with depressive symptoms on the Beck Depression Inventory.

One line of research from this perspective has been the development and evaluation of a therapeutic program based on the self-control model. Self-management therapy is a structured, manual, group-format program that presents the depression concepts of the model to participants and uses weekly homework assignments to modify their self-management behavior. The program was evaluated in outcome studies by Rehm and his colleagues and in a number of independent replications (Flemming & Thorton, 1980; Fuchs & Rehm, 1977; Kornblith, Rehm, O'Hara, & Lamparski, 1983; Rehm et al., 1979; Rehm, Kaslow, & Rabin, 1987; Rehm et al., 1981; Rehm, Lamparski, Romano, & O'Hara, 1985; Rude, 1986). The program was also adapted for children (Stark, Reynolds, & Kaslow, 1987), adolescents (Reynolds & Coats, 1986), and the elderly (Rokke, Tomhave, & Jovic, in press).

Kanfer and Hagerman (1981) presented a revised model of self-control and discussed its applicability to depression. The revision elaborates on the sequences of decisions that are made in the self-control process. For example, attributional processes are incorporated at both the self-monitoring and self-evaluative stages of regulation. The revised model also elaborates on the interaction of short- and long-term goals and standards that may be applied to specific behaviors.

Rehm (1988) used the self-control model to organize current research on depression. He noted the problems of the underlying self-control model, especially regarding the heterogeneity of self-monitoring processes and the concept of self-reinforcement (see Catania, 1975). Alternative models of self-regulation may be desirable to account for the ways in which people solve problems and plan based on biased inferences, negative bias

in recall, unrealistic standards, and negative expectancies. Rehm and Naus (1990) present one example of an approach to developing such a model.

Cognitive Theory

Aaron T. Beck developed a cognitive theory that initially focused on depression and has been expanded to other areas of psychopathology and psychotherapy. Beck's (1972) theory defines depression in cognitive terms. He sees the essential elements of the disorder as the cognitive triad: (1) a negative view of self, (2) a negative view of the world, and (3) a negative view of the future. The depressed person views the world through an organized set of depressive schemata that distort experience about self, world, and future in a negative direction; schemata are complex units of stored information that also serve as templates for interpreting new experience. A number of typical forms of cognitive distortion were identified early in the development of the theory (Beck, 1963). Arbitrary inference involves the arbitrary assumption that some negative event was caused by oneself. Selective abstraction occurs when the person focuses on the negative element in an otherwise positive set of information. Magnification and minimization involve overemphasizing negatives and underemphasizing positives. Inexact labeling involves giving a distorted label to an event and then reacting to the label rather than to the event.

It is a basic tenet of the cognitive approach that a schematic interpretation always mediates between an experience and the emotional response to that experience. The schematic inferences and interpretations that a person makes in a particular situation are termed automatic thoughts. They are automatic in the sense that the person is not aware of the interpretive process and may not even be aware of the thought itself, but only of the emotional consequence of the thought. These specific thoughts can be distinguished from underlying assumptions, which are more basic interpretive rules that form the automatic thoughts. In depression, the theme of the automatic thoughts is the perception of loss. Loss is the cognition that relates to depression. In contrast, perceptions of gain produce euphoria, perceptions of danger produce anxiety, and perceptions of offense produce anger.

Depressive schemata are activated when a major loss is perceived. An organized set of negative

schemata is activated that replaces nondistorted schemata when the person becomes depressed. The schemata are formed earlier in life and are reactivated when major losses are experienced. They represent organized and elaborated views of self, world, and future. They may be replaced by more realistic schemata under usual life circumstances, but they remain intact as "latent" schemata with the potential to reactivate under circumstances of loss. With time and the improvement of circumstances, these schemata may again become latent, unless they are modified by some form of intervention.

Beck addresses the problem of mania from the point of view of his model. Systematic positive distortions occur automatically and appear plausible to the patient. In mania, cognitions are less amenable to change by reasoning and contradictory evidence. Manic patients perceive significant gain in life experiences, indiscriminately attribute positive value to experiences, unrealistically expect positive outcomes for endeavors, and have exaggerated estimates of their abilities. These distorted inferences lead to feelings of euphoria and energize high levels of activity. Only a few studies to date have addressed cognitive distortion in mania. The Automatic Thoughts Questionnaire, a measure of negative thinking in a depressed state, discriminates between unipolar and bipolar patients (Hollon & Kendall, 1980). However, the Dysfunctional Attitude Scale, a measure of more trait-like underlying assumptions, has yielded contradictory results in comparisons between unipolars and bipolars (Hollon, Kendall, & Lumrey, 1986; Ivens, 1988; Silverman, Silverman, & Eardley, 1984).

Many areas of research support components of the general cognitive theory, and the theory has been influential in increasing research interest in new areas of cognition and information processing in depression (and in psychopathology generally). The negative biases of the cognitive triad are well established, and the premise that cognition precedes emotion has utility in studying emotion, although it is a debatable assumption (see Zajonc, 1980).

Self-referent encoding research elaborates on the implications of the development of a negative schema regarding self in depression. In an incidental memory task, subjects are asked to recall adjectives that they had seen in another task wherein they had processed the adjectives either

by structure (identify as small versus large letters), by semantics (means the same as X), or by self-reference (describes you or not). Self-referent adjectives are recalled best, presumably because the structure of information about oneself serves as a heuristic for organizing the new information. Depressed subjects recall more negative adjectives, suggesting an organized set of negative information (i.e., a negative schema) about oneself (Derry & Kuiper, 1981).

Research on mood-congruent recall (Blaney, 1986) is consistent with the idea that negative schemata influence the processing of information in depression. Current mood affects the recall of personal information. In general, a sad mood leads to enhanced recall of sad memories and poorer ability to recall happy memories (Natole & Hantas, 1982; Teasdale, 1983). The effect is robust in that it occurs with induced mood, naturally occurring mood shifts, and clinical depression, including shifts due to diurnal variation in depression (Clark & Teasdale, 1982).

A related phenomenon has been referred to as mood-state-dependent recall, wherein neutral information learned in a particular mood state is later recalled better in the same than in a different mood state (Bower, 1981). This phenomenon has been difficult to replicate reliably, and Bower believes that mood state dependent learning occurs only when the material is thematically related to the mood state in which it is learned (Bower, 1983). The concept was extended to mania by Weingartner, Miller, and Murphy (1977) in a study of manic-depressives in manic and normal moods. They found that recall of verbal associations was better in the same mood than at contrasting mood points.

The importance of these findings for the cognitive theory of depression is that they provide an empirical base for Beck's concept of a latent schema. Mood activates congruent schemata that facilitate congruent recall and inhibit incongruent recall. Such schemata also organize new information and affect interpretation and inference. Miranda and Persons (1986) demonstrated that scores on the Dysfunctional Attitude Scale (Weissman & Beck, 1978)—thought to assess stable, trait-like underlying assumptions—are influenced by mood for those subjects who have histories of depression. In other words, for those who had developed organized depressive schemata while depressed in the past, current mood activated them to the de-

gree that they affected responses to the questionnaire.

Mood-congruent recall and related phenomena are becoming central data for new developments in cognitive theories of depression and mania (e.g., Ingram, 1984; Rehm & Naus, 1990; Teasdale, 1983). For example, memory models of long-term storage suggest alternative ways of conceptualizing the shift in thinking that occurs in depression. The question has to do with whether alternative "latent" schemata are activated or whether mood simply affects retrieval within one schema system. Other cognitive phenomena have also been the focus of recent theoretical developments in depression, for example, internal focus of attention (Pyszczynski & Greenberg, 1987), control theory (Hyland, 1987), and self-worth contingency (Kuiper & Olinger, 1986).

Beck's cognitive theory was developed in the development of cognitive therapy for depression (Beck, 1976; Beck, Rush, Shaw, & Emery, 1979). Cognitive therapy is a complex collection of behavioral and cognitive techniques that share as their goal identifying and challenging unrealistic automatic thoughts and underlying assumptions. Cognitive therapy is the most thoroughly researched of the cognitive-behavioral approaches to intervention in depression, and several reviews are available (e.g., deRubeis & Beck, 1988; Dobson, 1989; Rehm & Kaslow, 1984; Rehm, 1995; Williams, 1984). Two findings in cognitive therapy research are particularly notable. The first is that cognitive therapy produces effects equal to or superior to tricyclic antidepressants in ameliorating depression (Beck, Hollon, Young, Bedrosian, & Budenz, 1985; Blackburn, Bishop, Clenn, Whalley, & Christie, 1981; Elkin et al., 1989; Murphy, Simons, Wetzel, & Lustman, 1984; Rush, Beck, Kovacs, & Hollon, 1977). Second, evidence suggests that the effects tend to be better maintained, especially in reducing future episodes of depression. The cognitive skills acquired help avoid or diminish future episodes by providing more adaptive ways of coping with stress. Another recent development in cognitive therapy has been extending the therapy to bipolar disorder (Beck, 1997; Scott, 1996). This extension of cognitive therapy has yet to be empirically evaluated.

Beck's theory has been very influential in clinical psychology. It has developed rapidly as a school of psychotherapy with research and application far beyond depression. As a theory, it has

borrowed terms and constructs from cognitive psychology and has facilitated the connection between clinical and cognitive psychology.

Conclusions

The knowledge base for the psychopathology of depression has expanded greatly in recent years. We know much more about its epidemiology, genetics, and biochemistry and about its affective, cognitive, behavioral, and physiological symptomatology. We also know more about the environmental, interpersonal, and psychological antecedents, correlates, and consequences of depression, and we have pharmacological and psychological interventions that are proven effective.

The development of theoretical models has hastened and directed research in depression. In turn, new research findings have led to revisions of existing theory and to the development of new theories and models. As new areas of research develop, theories develop using the new data as focal points for theory development. For example, the developments in research on memory and emotion have led to models of depression where these phenomena are central (e.g., Ingram, 1984; Rehm & Naus, 1990; Teasdale, 1983). Similarly, new research on biological rhythms has led to biological models of depression that focus on their dysregulation.

Although new developments in theory advance our thinking and point to new research directions, it should also be pointed out that most contemporary theories of depression tend to focus on specific areas and incorporate at most one or two dimensions. Biological models tend to focus narrowly within a single biological system and are largely silent with regard to psychological or social issues. With minor exception, psychological theories do not address the theoretical status of subtypes of depression, nor do they recognize endogenous or bipolar depression. Stress is incorporated as a second dimension in either biological diathesis or psychological diathesis theories, but few theories have addressed the biological-psychological interaction. Although some psychological theorists may acknowledge the contributions of biological factors in etiology, the connection to psychological factors is not articulated, and for the most part, specific mechanisms have not been spelled out.

Research and theory in the future need to take a broader view and to begin to model the interaction between biological, environmental, and psychological factors into a true biopsychosocial model. Some examples of effort in this direction are Akiskal and McKinney's (1973) final common pathway model, the article by Ehlers et al. (1988) on social zeitgebers and biological rhythms, and the integration by Lewinsohn et al. (1985) of a range of factors that influence depression. Integrative theories may be most helpful in directing research into the complex problems of etiology, treatment, and prevention of depression.

CHAPTER 12

Delusions

Brendan A. Maher

Introduction

Delusions are defined in the 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) of the American Psychiatric Association (1994) as follows:

Delusion. A false personal belief based on incorrect inference about external reality and firmly sustained in spite of what almost everyone else believes and in spite of what constitutes incontrovertible and obvious proof or evidence to the contrary. The belief is not one ordinarily accepted by other members of the person's culture or subculture (i.e., it is not an article of religious faith). When a false belief involves an extreme value judgment, it is regarded as a delusion only when the judgment is so extreme as to defy credibility. (DSM-IV, p. 765)

Delusions are reported in connection with a wide range of psychiatric, neurological, and other medical disorders (e.g., Manschreck, 1979). Systematically speaking, a delusion has been regarded as a symptom, a syndrome, or as a component of diseases of the schizophrenic, affective, somatic, or reactive type. Their frequency and importance are such that we might expect that a clear definition of a delusion would have been well established by now. As will be evident in the discussion that follows, the ambiguity of the definition of delusions has plagued the attempt to investigate questions of etiology, pathology, prognosis, course, and treatment.

Brendan A. Maher • Department of Psychology, Harvard University, Cambridge, Massachusetts 02138.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

Problems in Defining Delusions

At first sight, the definition given before seems clear enough, but upon close inspection, it becomes clear that there are many problems. The heart of the matter is that it depends upon the following assumptions and that it includes a hypothesis about the underlying pathology:

1. The truth or falsity of a belief statement about external reality can generally be ascertained on the basis of evidence sufficient to confirm or refute it.
2. There are well-established objective principles by which it is possible to draw correct inferences from factual evidence, and normal individuals follow these principles.
3. A belief that is not supported by evidence but that is shared by most people in a culture cannot properly be regarded as arising from a defect of inference similar to that postulated in the case of delusions. This is consistent with the emphasis upon a delusion that it is a *personal* belief.
4. Value judgments may be assessed on a scale of credibility. Extreme cases that “defy credibility” are properly included in the definition of delusion.

The hypothesis is that the core of the pathology that produces delusions lies in a defect in these processes of inference. A corollary of this is the assumption that in the general population, inferences are typically drawn according to the objective principles assumed before.

Criticisms of the Assumptions

Each of these assumptions has been the subject of criticism that can be summarized as follows:

1. *The formal criteria for deciding truth and falsity.* The definition of truth or falsity has long been a matter of debate in the philosophy of knowledge. Space does not permit an extended discussion of the issue here. However, we may usefully distinguish between the definition of truth as a *correspondence* between a statement made and a set of facts to which the statement refers. The statement, "It is raining outside," may be checked for correspondence by looking outside to see if rain is falling. The examination will reveal that the statement is true or false; it cannot be both. A second form of truth is *coherence*. The coherence view of truth asserts that a statement is true if it is consistent with another set of propositions. In essence, this definition is the same as that of the logical *validity* of the conclusion of a formal syllogism. It need have no correspondence with actual observation.
 2. *Physical reality and social reality.* One source of criticism comes from the distinction between external facts about physical reality and external facts about social reality. A patient who states that there is a microchip in his frontal lobe is talking about a set of allegedly physical facts.* We have clear definitions of the meaning of the term "microchip" and "frontal lobe," and we have methods to determine whether the patient's statement is literally true or false. When a patient states, "I am being deliberately harassed by my neighbors," the definition of the relevant "facts" is much more difficult. With some difficulty, we might be able to establish what the neighbors are doing, but it is much harder to establish that their acts are deliberate attempts to harass. Consequently the clinician is often left with the alternatives of making a judgment or abandoning as futile the task of deciding whether the speaker has a problem that merits the diagnosis of delusion. Psychopathologists who define themselves as social constructionists argue
- that human clinical judgment that a social statement is true or false is the major determinant of the diagnosis of delusions (e.g., Harper, 1992, 1994). Such fallible judgments are, they assert, inevitably affected by political, social-power concerns, professional status, and other such scientifically irrelevant factors. This criticism has not gained much support in the years since it was first adumbrated. Critical responses to it may be found in Garety (1994) and Walkup (1994).
3. *The empirical requirements for demonstrating truth and falsity.* We must also note that the task of demonstrating unequivocally that some specific factual assertion is true is often difficult, but it is generally even more difficult to demonstrate unequivocally that something is false. For example, take an individual's belief that his mental processes are being influenced by emissions from high-tension overhead power lines near his home. He complains to the power company which sends a technician to test the individual's environment for emissions. The technician finds that they are present. We conclude that the individual was certainly right about the emissions and may possibly be right about their effect upon him. If the technician fails to find them, we suspect that the individual complainant may be delusional. If we challenge his belief, he may respond by doubting the reliability of the measuring instruments (measuring instruments do sometimes fail) and persist in the belief. Alternatively, or additionally, he may doubt the honesty of the technician (employees of large corporations have been known to lie about the hazards created by their products). Because this argument is extremely difficult to rebut, we turn to an alternative criterion for identifying a delusion. This is the criterion of *probability*, rather than of unequivocal truth or falsity.
- Because of difficulty in producing definitive evidence of truth or falsity, the diagnosis of delusion in actual practice is often based on the criterion of probability. As we shall see later, this raises many questions about calculating the probabilities. Not the least of these is the lack of empirical data about the actual probabilities of most events.
4. *The rationality of normal inference processes.* Demonstration of the falsity (or im-

*Whether or not patients mean such statements literally or metaphorically is not always clear.

probability) of a delusional belief itself is, of course, insufficient to establish that the belief arises from a process of faulty inference. To escape circularity of reasoning when we seek to establish the cause of a clinically manifest symptom, we must show on the basis of evidence other than the symptom itself, that there is an identifiable pathological process whose existence can be demonstrated in other ways. If we wish to hypothesize that the deluded patient suffers from a basic defect in reasoning, we must demonstrate this defect in other circumstances and in relation to other beliefs. If the alleged defect in reasoning is found only in matters closely related to the core topic of the delusion, we have not discovered a cause. We have merely established the boundaries of the delusional belief.

By and large, it is assumed that rules of inference involve either or both of two sets of rules. One is provided by the logic of syllogistic reasoning; the other by the rules of Bayesian (statistical probability) inference. Correct deduction from the premises created by induction, it is assumed, follows syllogistic rules. Correct induction of empirical probabilities, it is assumed, follows Bayesian rules. From this standpoint, any belief may be judged in terms of the process by which it arose; if that process violates "correct" principles it is, by definition, defective.

According to this perspective, normal human beings form beliefs about their world in about the same way that idealized natural scientists do. At the risk of oversimplifying it, this involves a sequence whereby empirical observations are made and regularities noted, and proper allowance is made for negative instances and for the limitations of sample size. In due course, all of this eventuates in the formulation of a hypothesis about these regularities. This hypothesis is held with a certain degree of confidence—much as an empirical finding is held by a scientist with a degree of probability exemplified by the concept of statistical significance. The individual then conducts empirical tests to see if the hypothesis survives refutation, a step that will, presumably, ultimately lead to retaining or modifying the hypothesis or developing a better hypothesis.

Once the probability value attached to a hypoth-

esis reaches a critical magnitude the hypothesis becomes a basis for action. Most often the scientist's main "action" is acquiring and reporting knowledge. In the general environment, the criterion for action is determined by the individual's assessment of the costs, potential benefits, and potential risks attached to the various options for action.

Before we can employ this paradigm as a guide to the possible loci of impairment in delusional patients, we need to establish that it provides an accurate account of the way in which normal human beings (including scientists) actually form and modify their beliefs. When we examine the data from empirical observation of nondeluded (i.e., "normal") individuals, we find that the alleged rules of correct procedure are quite commonly broken. Hence the crucial objection to the assumption that there are rules of inference (deductive and/or inductive) that guide the belief formation of nondeluded individuals is that this is, in fact, not the case.

Evidence on this point is reviewed later when we consider theories of the etiology of delusions. There is a large and expanding literature about the processes of normal belief formation. In our review, we shall touch only on those aspects of it that are relevant to the definitions of delusion that we presented earlier.

Other Definitions

Oltmanns's Definition

Problems in the definition of delusions have led to the development of alternatives. Oltmanns (1988) proposed to use descriptive dimensions as the defining characteristics of or criteria for delusions. He provides a list of seven characteristics that "... draw attention to the fact that specific beliefs may be considered more or less delusional, depending largely upon the number of specific features that are present.... It should be noted that some of these characteristics may not be unique to delusional beliefs" (Oltmanns, 1988, p. 5).

Oltmanns's defining characteristics are as follows:

- a. The balance of evidence for and against the belief is such that other people consider it completely incredible.
- b. The belief is not shared by others.
- c. The belief is held with firm conviction. The

person's statements or behaviors are unresponsive to the presentation of evidence contrary to the belief.

- d. The person is preoccupied with (emotionally committed to) the belief and finds it difficult to avoid thinking or talking about it.
- e. The belief involves personal reference, rather than an unconventional religious, scientific or political conviction.
- f. The belief is a source of subjective distress or interferes with the person's occupational or social functioning.
- g. The person does not report subjective efforts to resist the belief (in contrast to patients with obsessional ideas). (Oltmanns, 1988, p. 5)

Unfortunately, most of the variables listed in these criteria need further definition, ultimately operational. Thus, a reliance on clinical judgment to establish the degree of "preoccupation," "firm conviction," "incredibility," and so on, defers the task of precise definition to a later as yet undefined stage of development.

Definitional Concepts of the Heidelberg School

European psychiatry has been heavily influenced by the work of psychopathologists at the University of Heidelberg. Karl Jaspers—the founder and best-known member of the Heidelberg School—introduced three criteria for the definition of delusions: (1) subjective certainty, (2) incorrigibility, and (3) the realistic impossibility of the content (later attenuated to falsity of content, because many delusions are in principle actually possible). Jaspers took pains to point out that these criteria, especially the third, do not *define* delusions but rather give practical hints for detecting them.

Jaspers drew a distinction between *primary* and *secondary* delusions. He defined the primary delusion (very problematically) as a fully formed belief that appears in consciousness and arises without detectable antecedents. It is incomprehensible, in the sense that neither the patient nor the clinician can understand how it arose. In an attempt to clarify the definition, Jaspers commented,

We find there arises in the patient certain primary sensations, vital feelings, moods, awareness: Something is going on. This general delusional atmosphere with all its vagueness of content

must be unbearable. Patients obviously suffer terribly under it and to reach some definite idea at last is like being relieved of some enormous burden. (Jaspers, 1963, p. 98)

Secondary delusions, on the other hand, arise from identifiable antecedents in the life of the patient. Here the delusion follows from some conscious anomalous perception or experience. The belief, although delusional, is understandable in the context of the patient's experiences.

A somewhat similar dichotomy is that of Kurt Schneider's (1959) concept of *delusional beliefs* and *delusional perceptions*. It rests upon an assumed difference between delusional beliefs that arise autonomously, that is, without any intermediate processing of environmental input, versus those that arise from a mediating process of perceiving some environmental event. The former sound somewhat related to Jaspers's primary delusion, whereas the latter correspond to the concept of the secondary delusion.

The Empirical Approach

Contrasted to the phenomenological position is an approach based upon the search for empirical independent validities for the definitional categories employed. It begins with the observation that reliable descriptive categories may be established based on attributes that have no functionally significant relationship with anything else of clinical importance. For instance, it may be entirely possible to define subsets of delusions based upon the similarity of the specific content of each subset, only to find that the distinction between, let us say, a subset of delusions that refers to control by demonic forces and a subset of those that refer to control by inanimate physical forces is unaccompanied by any correlated difference in their etiologies, related pathologies, natural course, or response to treatment.

Lacking any correlated validities of this kind, the result of purely descriptive definitions is to create a lexicon of technical labels that can be reliably applied by those who have been trained to make the relevant distinctions. Although this is a necessary first step, it is of little scientific value in itself, unless it is followed by further demonstrations that the labeled categories do indeed have predictive relationships to other phenomena. Empirical investigation may, and frequently does, show that phenomena that have been classified

into a single category are multifactorial in their relationships to other measures and/or, by the same token, that categories that are differentiated descriptively are unifactorial in their relationships to other measures. Progress in our understanding of pathology accrues by a gradual convergence of a scheme of definitional categories or dimensions with the pattern of construct validities attached to each category. With these reservations in mind, we may turn to historical and current attempts to classify delusions.

Classification of Delusions

Early Classification Systems. Classification of delusions* by content has a long history. In 1806, Thomas Arnold proposed a classification system which included

Scheming Insanity: ... the patient thinks himself ... by his superior knowledge or cunning capable of doing great things, which few, or none, but himself, are able to accomplish.

Vain or Self-Important Insanity: ... with which they who are possessed, have a very exalted opinion of their own imaginary dignity, opulence ... learning, or some other valuable quality.

Hypochondriacal Insanity: in which the patient is forever in distress about his own state of health. (cited in Hunter and Macalpine, 1964, pp. 470–471)

Rejecting content as a basis for classification, Southard (1916a,b) suggested that the grammatical structure of the delusional belief might provide a better framework. At that time, grammarians emphasized the organization of statements into four basic “moods,” the indicative, the subjunctive, the imperative, and the optative. He conducted a series of pioneering autopsy studies of deceased deluded patients, from which he was able to demonstrate significant correspondence between the explanations incorporated in the delusions and the conscious concomitants of the diseases from which the patients suffered. Southard’s work attracted little attention at the time, no doubt in large part due to the enthusiasm of his later colleagues for psychodynamic explanations of delusional content. Mention of him here is important to acknowledge his early recognition of the function of delusions in explaining anomalous experiences for which no alternative rational explanation has been initially available.

*By classification here, we mean a system for bringing order to various kinds of delusions. It is not intended to imply a system of disease entities.

Contemporary Classification: DSM-IV. In the Glossary of the DSM-IV (pp. 765–766), we find a subclassification of delusions divided according to their content. Extracts from descriptions of some of the more common types are listed here.

Controlled: A delusion in which feelings, impulses, thoughts, or actions are experienced as being under the control of some external force rather than under one’s own control.

Bizarre: A false belief that involves a phenomenon that the person’s culture would regard as totally implausible.

Grandiose: A delusion of inflated worth, power, knowledge, identity, or special relationship to a deity or famous person.

Jealousy: The delusion that one’s sexual partner is unfaithful.

Persecutory: A delusion in which the central theme is that one (or someone to whom one is close) is being attacked, harassed, cheated, persecuted, or conspired against.

Reference: A delusion whose theme is that events, objects, or other people in the person’s immediate environment have a particular and unusual significance. These delusions are usually negative or pejorative but may also be grandiose in content. This differs from an idea of reference, in which the false belief is not as firmly held nor as fully organized into a true belief.

Somatic: A delusion whose main content pertains to the functioning or appearance of one’s body.

To this list we may add delusions of poverty, delusions of guilt (the idea that one is responsible for all kind of misery), nihilistic delusions (that one is dead or that the world has come to an end), querulent delusions, and the delusions of misidentification discussed later.

Delusions may be *mood-congruent* or *mood-incongruent*. Mood congruence or incongruence is defined by the relationship between the affective state of the patient and the content of the delusional theme. Depressed patients with delusions of personal worthlessness, guilt, disease, death, etc., have delusions that are congruent with the depressed mood. A patient who is clinically depressed but has delusions of great personal fame or wealth, etc., has mood-incongruent delusions.

Notice that the level of abstraction of the types listed by DSM-IV is not always the same: some types refer to content, others to specific features of

delusions, regardless of their content. Thus, delusions of persecution may be systematized or not, and grandiose delusions may be mood-congruent or not. The contents of delusions (guilt, persecution, jealousy), etc., have also been called *themes*; these themes vary from very specific (i.e., a certain person loving oneself, the spouse being involved with a specific person), to quite general (e.g., where “everything” somehow refers to the patient). The list of themes seems to be limited although there is no clear-cut, agreed-upon final total of such themes. Systematization and mood congruency, although related to content, are matters of degree and can be applied to any content. They belong to what we may call the descriptive dimensions of delusions and must be addressed separately.

Descriptive Dimensions

Some psychopathologists have turned from categorical classifications to dimensional descriptions. The use of continua to describe psychotic phenomena such as hallucinations and delusions was proposed by Strauss (1969). Since then, this proposal has gained some conceptual and empirical support from other authors. A factor analytic study by Heilbrun and Madison (1978), for example, studied a sample of verbatim transcripts of patient interviews from thirty-two schizophrenics. They postulated that four orthogonal factors arise from the content analysis of this material but cautioned that the limited number of patients involved constrains the reliability of their data. Later, in a study involving fifty-two delusional patients, Kendler, Glazer, and Morgenstern (1983) found five dimensions* which turned out to be independent of each other. Garety and Hemsley (1987, 1994) use a scale containing eleven dimensions which, they report, are independent of one another. The eleven characteristics are intensity (strength of conviction), preoccupation (time spent thinking about it), interference (extent to which it affects behavior), resistance (like/dislike of thinking about it), dismissibility (ability to stop thinking about it), absurdity (seems sensible/senseless),

*The five dimensions, assessed by interviewer rating, were (1) conviction, (2) extension (the degree to which the delusional belief involves various areas of the patient's life), (3) bizarreness, (4) disorganization, and (5) pressure (the degree of preoccupation and concern).

self-evident (seems obvious/implausible), reassurance (seeks reassurance), distress/worry (thinking about it causes worry), distress/mood (thinking about it causes unhappiness), and pervasiveness (cannot think about other things at the same time). In addition to these dimensions, other characteristics are worthy of note. These are the general theme of the delusion (see earlier), other symptoms present (psychic and/or somatic), and time course (rapidity of onset, stability, duration, and remission).

The utility of a system that permits us to identify differences between delusional patients lies in its potential to relate these differences to other clinical and laboratory-based variables.

Hypotheses about the External World Versus Descriptions of Internal States

Our earlier discussion dealt with the processes by which beliefs about the environment are formed and held, given externally available evidence that is relevant to their validity. Now, we turn to a different aspect of delusional thinking. The question is, are there any judgments about which we are so certain that we would never accept any refutation of them? If the answer is “yes,” then these judgments would have something in common with delusions.

There are judgments about which we are perfectly certain so that no counterevidence is possible. These are statements about our primary conscious experience. If I feel pain in my right foot (even if I did not actually have a right foot†) there is no evidence that can refute the fact of the primary experience. The experience that “something in the environment has changed” is a common normal reaction to the existence of a yet undetected actual change. An intense version of this kind of experience, that is, that events, objects, or other people in the immediate environment have changed or acquired a yet unexplained significance, has been reported in about 70% of all schizophrenics (Murray, 1986, p. 342). We cannot refer to the feeling of significance as a “false, idiosyncratic belief,” inasmuch as the feeling it-

†Even if I never had a right foot, I might rightly claim to have pain in it, as findings in patients with phantom limbs from birth on (especially the thalidomide cases) show.

self is primary and undeniable, and the task of providing counterevidence (that things do not have significance) is impossible. Similarly, utterances of depressed patients, that their thoughts have stopped or their feelings of worthlessness should be understood, not as "false beliefs about external reality," but as the patients' best attempts to communicate what they think and how they feel, that is, what their experiences are like. Here, as with schizophrenia, we can make sense about the relatively high frequency of these experiences in depressed patients by interpreting them as direct results of the basic pathological changes brought about by the disorder rather than due to defects of inference about the environment.

Methods for Investigating Descriptions of Delusions

Idiographic description is surely the oldest method used in studying delusions. Although now rejected as unscientific by many researchers, the descriptive method still has a place among the various attempts to investigate delusions. Single cases do not allow inferences to support a theory; they can disprove theories by providing contradictory ("falsificatory") evidence for general theories. Moreover, single cases can provide the empirical researcher with hypotheses that may be tested later with more rigorous and more quantitative approaches.

Transcultural Psychiatry

As early as 1904, Kraepelin was the first psychiatrist who tried to determine the extent to which psychiatric symptoms are influenced by culture. Delusions are one of the most difficult symptoms to assess cross-culturally, but we may note that cross-cultural comparisons are addressed to several different kinds of classification: (1) structural (i.e., grandiose, paranoid, etc.), (2) content (i.e., somatic, religious, misidentification, etc.), and (3) frequency (the epidemiology of delusions in terms of both structure and content).

The literature on this general topic is substantial. Studies of frequency are of course also influenced by differential frequency of the psychiatric disorders in which delusions commonly occur. Some authors have reported that the frequency of

paranoid schizophrenia is increasing whereas the catatonic and hebephrenic types of schizophrenia have decreased in this century (Kranz, 1967; Magaro, 1980). For example, Achte (1961), cited in Lenz (1964), investigated 200 schizophrenic patients from 1933–1935 and from 1953–1955 and found an increase of paranoid schizophrenia from 36 to 59%. Others did not find any change in the frequency of subtypes of schizophrenia. Cultural background seems to influence the temporal course of delusions (and influences on prevalence may be explained in those terms). Piedmont (1966) compared German and Polish immigrants with delusions who lived in New York and found that the Germans had more delusions, were more consequential in their elaboration and systematization, and maintained them for a longer time. The authors interpreted this as a reflection of the influence of German culture with its emphasis on "reason" and "consequence." On the other hand, members of cultures, where it is common to be "possessed by a ghost," relinquish their delusions more readily, presumably because one can be abandoned by a ghost as easily as one can be possessed by it. Several authors have interpreted the degree of systematization in delusions to the dominance of rational, materialist thinking in Western cultures (Kiev, 1972; Lambo, 1965).

As the culture changes over time so, it appears, does the specific content of delusions. Kranz examined case reports of 651 schizophrenic and 243 cyclothymic patients (the latter would now most likely be diagnosed as suffering from major affective disorders) from the years 1886, 1916, and 1946 to investigate changes in the themes of delusions. He found that delusions of being controlled occurred in a stable proportion of schizophrenia patients with a frequency of 72% (1886), 75% (1916), and 72% (1946), respectively. Grandiose delusions in schizophrenia patient declined from 24% (1886) to 17% (1916), and to 11% (1946). Similar studies also showed a decline in delusions of grandeur in schizophrenia patients, as well as a decreasing frequency of religious delusions (Lenz, 1964; Streinbrunner & Scharfetter, 1976). The frequency of delusions of grandeur also reportedly decreased in patients with general paralysis (Paulikhoff, 1962; Vurla, quoted from Lenz, 1964, p. 71).

Kranz reported that the frequencies of the classic delusions of guilt and poverty, as well as hypochondriac delusions in depressed patients, were

relatively stable over time, and von Orelli (1954) found a decrease of delusions of guilt and an increase of hypochondriac delusions—a finding which might be related to the decreasing influence of religion.

That the content of delusions varies somewhat with culture is hardly surprising. Studies have shown that delusions mirror culture in broad terms. For example, witches played a role in delusions of the last century in Europe, but this is no longer the case. The frequency of technology as the major theme in delusions of schizophrenia patients has reportedly increased from 12% in 1900 to 31% in 1960 (Achte, 1961). Lenz (1964) gives a vivid account of changes over time in the identity of alleged persecutors in relevant delusions:

In the realm of delusions of persecution before 1880 the content was “the Prussians” as a result of the war between Prussia and Austria in 1866.... In 1921 ... the Social Democrats, who had overthrown the Kaiser, played a major role as the evil enemy who had once been the devil, later the Prussians and, before World War II, the SS and SA, and after World War II the Russians and Communists. (pp. 53–54)

The delusional complaint of having AIDS is now encountered in depressed patients as a substitute for other symbols for the feeling of guilt, being punished for bad life-style, etc. (e.g., Mahorney and Cavenar, 1988; Shetty, 1988).

On the basis of a comprehensive survey of cross-cultural studies, Westermeyer (1988) offered some general conclusions. Chief among them were

1. The structure and content of most delusions are not culture-bound and can readily be identified across cultures. The structure of delusions varies little, if any, across cultures, whereas the content may be influenced by culture.
2. In developing countries, culture-bound delusional content tends to involve religious and traditional world views, especially those that are challenged by modern secular society.
3. Elements of culture-bound content in delusions have been acquired in childhood rather than from later experience or experience in other cultures.
4. Gender differences in delusional content are minimal, except where the socialization of males and females is markedly different.
5. Culture-bound and secular elements in delusions may be found together in the same individual.

6. Where the content of the idea expressed in the delusion is culture-bound, the structure of the delusion becomes more important.

Hypotheses about the Etiology of Delusions

There is no generally accepted theory of the etiology of delusions. Instead there are some limited models each of which deals with some subset of delusions and invokes an etiological process that may have limited application to the total array of delusions found in clinical practice.

Winters and Neale (1983) organized all of the theories of delusion formation in terms of motivation or defect; this is useful for many instances, but not for all. There is still need for a general strategy of explanation in this field. In this connection, it is crucially important that we take account of the fact that delusions are found in a very wide range of medical disorders, only some of which are regarded as primarily psychopathological. Hence, any attempt to offer a general theory of delusion formation that does not account for their widespread occurrence can hope to gain only limited credence. For our description, it is convenient to place etiological hypotheses about delusion formation into these three broad categories.

1. There is a fundamental cognitive defect by which the patient's capacity to draw valid conclusions from evidence is impaired. A neuropsychological or other biological anomaly is posited to explain the defect.
2. There is a pattern of deviant motivation, such that an otherwise intact cognitive system is distorted in the service of motivation.
3. There is no abnormal cognitive defect. Cognitive processes in the deluded patient are fundamentally the same as those in non-deluded persons. The delusion arises from the operation of normative cognitive activities directed at explaining abnormal experiences. These experiences may be internal; they may be due to improbable but genuine anomalous events in the external environment.

We must note that although these options have been presented as mutually exclusive, this need not be the case. Normal beliefs are acquired by different routes: direct personal experience, indoctrination, observation of the experiences of others,

the influence of the popular media, and so forth. Many, perhaps most, of the disorders in which delusions are found are themselves heterogeneous. Schizophrenia is a prime example. It is quite possible—and perhaps probable—that delusional beliefs, like normal beliefs, may arise as the outcome of different etiological sequences.

Delusions Due to Cognitive Defect

Alternatively, we may decide to compare the belief processes of a psychiatrically defined group with the belief processes of a normal control group. Both groups may violate the rules of correct procedure, but both may do so in similar ways and with similar frequency. If this empirical comparison demonstrates that deluded patients do not differ from controls in their adherence to, or departure from, rules of induction and deduction, we are compelled to conclude that delusional pathology does not lie in the realm of processes of inference, no matter what the DSM-IV definition states to the contrary.

To demonstrate that delusions arise because of a more basic pathology in inferential reasoning or some other cognitive process, certain methodological requirements must be met. First, because our task is to explain why deluded patients have delusions and nondeluded patients do not, it is necessary to compare deluded patients with nondeluded controls, rather than with some formal standard of correct inference. Differences that may be found, however, must be such that the deluded patients' performance departs from the ideal standard more than the performance of controls. In brief, there must be a defect—not an advantage—in inferential processes. Second, we need to show that the putative defect is not confined to the topic of the delusion itself but can be demonstrated independently in other neutral topic areas. Third, but (unfortunately) ideally, we should be able to show that the defect in inferential processes antedated the appearance of the delusion. This latter is a condition met adequately only in high-risk studies, and these are few and far between. A rough approximation to it can be reached in searches for premorbid evidence of reasoning defects, but these are fraught with all of the usual dangers of retrospective investigations. Finally, the experiments that test these hypotheses should have ecological validity for delusional behavior itself, for example, they should demonstrate the

tendency to develop improbable beliefs, incorrigibility of belief in the face of counterevidence, etc.

Empirical Studies of Normal Belief Formation

Data from several kinds of systematic empirical observation are available. One is the study of the prevalence of irrational beliefs in the general population. Another is the comparison of the performance of deluded and nondeluded samples in formal reasoning tasks. A third is examination of the performance of samples of normal individuals in reasoning tasks evaluated against objective criteria of accuracy.

Broadly speaking, these approaches reflect either a *normative* standard or a *prescriptive* standard of inferential reasoning (Maher, 1992). The prescriptive standard simply assesses the discrepancy between an individual's inferences and some objective standard of what the correct inference should be. By this standard, both deluded and nondeluded persons may make errors.

The basis of the normative standard is the fact that if we are to understand why some people develop delusions and others do not, we must show differences between deluded persons and nondeluded persons. Whether or not deluded persons make errors of inference is irrelevant, unless it is clear that nondeluded persons do not make such errors or make substantially fewer of them. In this latter case, it is also necessary to show that the difference in error-proneness between the two groups is sufficiently large in absolute terms to explain the presumably large difference between delusions and normal beliefs. Some deluded individuals believe that some outside source is transmitting thoughts into their heads, and many normal individuals believe in mental telepathy. If we wish to attribute the first to an inferential process of delusional severity and the second to a normal process, we need to show a comparable difference of severity of impairment in the inferential processes of the two groups.

The Prevalence of Irrational Beliefs in the General Population

Gallup and Newport (1991) report that 14% of a sample of 1236 adult members of the U.S. population believes that they have seen unidentified flying objects (UFOs); 10% report having seen or been in the presence of ghosts, and 25% believe in

telepathy. Ross and Joshi (1992) report that in a sample of 502 adult members of the normal population of Winnipeg, 16% expressed a belief in telepathy, and 5% claimed contact with ghosts. In short, in the normal population, the general prevalence of beliefs that lack adequate support in evidence is quite high. All of these beliefs have the characteristic that evidence sufficient to refute them would require proof of negative propositions, that is, there are no ghosts, there are no witches, no extraterrestrial flying vehicles have ever come within detectable range of earth, etc. As we have already pointed out, many delusional beliefs fit this description, and we are left with the conclusion that the discrimination between delusional beliefs and popular beliefs that lack evidential support is far from clear.

Studies of Normal Belief Formation

There are two sources of systematic empirical evidence. One is the study of normal samples of the population. The other comes from the behavior of normal control subjects in studies that compare deluded and nondeluded individuals. We turn first to empirical studies limited to normal individuals. This is a large literature, and we shall confine the discussion to those factors that are directly relevant to the definition of delusions.

1. Do people readily change their beliefs in the face of evidence sufficient to refute the beliefs?

There is a substantial body of evidence to support the conclusion that once a belief has been formed by normal persons, they are reluctant to change it even in the face of clearly contradictory evidence. Studies confirming this have been reported by Wason and Johnson-Laird (1972); Anderson, Lepper, and Ross (1980); Nisbett and Ross (1980); Ross and Lepper (1981); and Ross and Anderson (1981). In this connection, it is interesting to note that Kuhn (1962) and Feyerabend (1970) commented on the incorrigibility of scientists in the face of evidence disconfirming their hypotheses, especially in the early instances of disconfirmation.

2. Do people normally actively check their beliefs by searching for possible counterevidence?

Mynatt, Doherty, and Tweeny (1977, 1978) investigated the behavior of normal

subjects presented with the choice of either conducting observations that could potentially disconfirm a previously formed hypothesis or of conducting observations that could either confirm or be irrelevant to, but not disconfirm the hypothesis. Their data showed that a significant number of subjects selected the latter option. The investigators termed this effect, "confirmation bias." They found that it was generally unrelated to the capacity of subjects to respond to disconfirming evidence when it turned up. However, when the experimenters made the task of evidence-sifting more complex, the confirmation bias survived, even in the face of contradictory evidence. "The more complex environment," they wrote, "may have made the generation of new hypotheses, and hence, the abandonment of disconfirmed hypotheses, more difficult" (Mynatt et al., 1978, p. 404). Human beings in their natural habitats (in contrast with their situations when serving as experimental subjects) are in very complex environments. Hence Mynatt's comment is particularly pertinent to the question of normative thinking. Wason and Johnson-Laird, summarizing the results of their studies of thought processes in normal individuals who failed to seek appropriate disconfirmation of their hypotheses, commented, "... it is not just particular mechanisms and logical factors which are diagnostic of thought disorder. We have demonstrated that such effects can readily be induced in normal individuals under rather special tasks. Different ways of evading reality are not the prerogative of the mentally ill" (Wason & Johnson-Laird, 1972, p. 239).

What needs to be emphasized here is that patterns of reasoning in normal people in their natural habitats are tested daily, not by their capacity to conform to rules of inference, but by their effectiveness in producing adaptive responses to the actual environments in which individuals live. The notion that behavior ought to be rational in the sense that it ought to and does conform to the rules of deductive and inductive reasoning in a Platonic ideal or academic view of rationality. From the perspective of survival, maladaptive *behavior* is selected against, not illogical deductions or incorrect estimates or objective probabilities (Maher,

1990). Thinking serves purposes, and the purposes that it serves are those of survival and effectiveness in the real world.

This leaves us with the possibility that the kinds of defects of inference involved in delusions differ from the flawed processes of inference found in the nondeluded or that the flaws are similar but that the magnitude of the difference between deluded and nondeluded is very great. We will return to explore this possibility later.

Comparative Studies of Deluded and Nondeluded Individuals

Formal Reasoning. Although it has long been known that intelligence and the capacity for formal reasoning do not protect an individual from developing delusions and although by definition delusions do not involve formal thought disorder, it has often been proposed that a formal thought disorder is their cause. von Domarus (1944) postulated that delusions in schizophrenic patients arise from faulty logical reasoning; the defect consists of the assumption of the identity of two subjects on the grounds of identical predicates (“Napoleon was incarcerated; I am incarcerated; therefore, I am Napoleon”). The hypothesis was quite popular in the 1950s (see Arieti, 1955), but empirical investigations failed to find any evidence in favor of a specific kind of logical error made by paranoid schizophrenic patients (Nims, 1959; Williams, 1964). Spitzer (1989) pointed out that the apparent logical content of delusional statements can be interpreted retroactively as due to any one of several kinds of formal logical error, in addition to the principle of identity proposed by von Domarus, and that the hypothesis implied by the von Domarus principle is not falsifiable and hence not acceptable scientifically.

In Paris, De Bonis, Epelbaum, Féline, Grize, Hardy and Somogyi (1990) investigated the reliability of psychiatric judgments of deficiencies in logical reasoning in a schizophrenic patient. They found nonsignificant levels of agreement between the judgments of thirty-two psychiatrists; furthermore, a logician who performed a detailed analysis of the most contradictory seeming verbal productions of this patient concluded that the internal relationships in his statements were in fact logical.

There have been several studies of what is termed *belief bias*. This refers to a normal bias

toward accepting a statement that is believable on the basis of personal experience, even if it is arrived at by an invalid process of reasoning (Garnham & Oakhill, 1994). Kemp, Chua, McKenna, and David (1997) report an investigation of belief bias in delusions. In a task of syllogistic reasoning, deluded and nondeluded subjects were asked to choose between logically fallacious and logically valid conclusions, together with content that was more or less believable. Deluded patients endorsed marginally fewer unbelievable conclusions than the nondelusional subjects. The authors conclude that cognitive deficit is not sufficient to explain delusional thinking. As with other studies, normal controls made many errors of reasoning.

All of the systematic empirical evidence available points strongly to the conclusion that the formation of delusions is not attributable to some defect in formal reasoning that is absent in nondeluded persons but present in the deluded.

Bayesian Reasoning. Contemporary models of human reasoning rarely invoke the syllogism as an appropriate paradigm to describe how human beings actually develop beliefs, make decisions, and so forth. Instead, emphasis is placed upon a model of Bayesian processes. According to this model, individuals assign probabilities to propositions about reality. These probabilities range hypothetically from zero to 100% (0.0 to 1.0), although the two extreme values are rarely if ever found in nature. Thus, effective reasoning is based on correctly assessing the probabilities inherent in empirical evidence. This weighing of evidence requires recognizing base rates for the occurrence of classes of events, due allowance for small sample effects and also for the biases that might be inherent in collecting the evidence presented. Contemporary statistical methods provide a clear example of this approach.

Bayesian procedures imply a sequence of steps that go into forming and testing a belief:

1. Identifying and selecting observations and other sources of evidence that are relevant to the validity of the belief.
2. Assessing the significance of the evidence obtained in relation to the belief and to other competing beliefs.
3. Compiling the total data available from all sources (a meta-analysis so to speak) and assessing its impact upon the belief.
4. Selecting an appropriate course of action.

However, the analogy between human decision-making and the scientist/statistician's ascertainment of probabilities to arrive at a decision that a hypothesis has been rejected or not—the usual standard in the application of tests of statistical significance—has limited validity. Where specific action is contemplated, as in item (4) before, the computation of the probability of Type I and Type II errors is substantially modified by computing the costs and benefits associated with accepting or rejecting the hypothesis. Competent practical application of the Bayesian model requires basing the action decision on an assessment of the *consequences* of the action, not merely on the numerical value assigned to the probability that a belief is valid. Thus the finding that using an experimental drug to treat AIDS has been followed by a slightly better survival rate (with no or minor side effects), than when the drug is not used, may lead to a decision to apply the drug even though the rate of improvement did not reach conventional levels of statistical significance. Low levels of significance are sufficient for action provided that the consequences of inaction are judged sufficiently serious.

Hemsley and Garety (1986) suggested that delusions may result from defects in the ability to weigh evidence along Bayesian lines; the general tenor of the defect is that the deluded patient accepts conclusions at levels of probability too low for acceptance by normal persons. Their hypothesis necessitates, of course, that the kind and quantity of evidence available to, and the costs and benefits of the decision to be made by, the deluded patient are also the same as for the normal individual. One recent test of this hypothesis was reported by Huq, Garety, and Hemsley (1988). Deluded schizophrenic subjects and appropriate controls (psychiatric and nonpsychiatric) were presented with a laboratory task in which the investigator explained that colored beads would be drawn from one of two jars. One jar contained pink and green beads in the ratio 85/15, and the other jar contained beads of the same colors where the ratio was reversed. After this explanation, the jars were concealed, one was selected, and the subject was presented with beads drawn from that jar, one at a time; the bead was returned to the jar after each drawing. Various experimental conditions were employed; the major response element was elicited by asking subjects at each draw to estimate which jar was being used; the degree of probability attached to that estimate and the relative

probabilities that the subject assigned to each of the two possible jars had been chosen. Errors of decision were also recorded. Each subject's first two draws were beads of the same color, thereby creating an objective probability of 0.97 that this was the color of the predominant portion of beads in the jar. Hence the correct application of Bayesian principles should lead a subject to make the decision at that point.

Very few decision errors were made by any group, and there was no significant difference between groups on this measure. In brief, the deluded patients made as many correct decisions as the other subjects. However, the deluded arrived at their correct decisions after significantly fewer draws than the other subjects and did so with greater estimates of confidence in their decision. Their mean total of draws to decision was 2.2, which is the point at which a proper Bayesian decision could be made. The authors state, "Thus it may be argued that the deluded sample reached a decision at an objectively 'rational' point ... the two control groups (being) somewhat overcautious" (p. 809).

This finding clearly fails to support the notion that deluded patients are poorer at Bayesian reasoning than normal subjects. Surprisingly, the authors are uncomfortable with that conclusion, stating that "Although the deluded sample's response ... appears more 'Bayesian,' ... it is not possible to argue that deluded people are better reasoners"* (p. 810). In defense of their own refusal to accept the obvious implication of their findings, the authors suggest that the overcautiousness of the control groups is evidence for a normal "conservatism" bias and that the better performance of the deluded patients can be explained away post hoc by assuming that deluded patients do indeed have a tendency to make hasty judgments on insufficient evidence, but that this is mitigated by the presence of a conservative bias in the deluded patients also; the arithmetical summation of these two tendencies produces a result that is pseudo-reasonable.

*The statement that "it is not possible to argue" that people who have performed better than others on a reasoning test are therefore better reasoners is *prima facie* absurd. It can only be impossible to investigators who have already assumed the truth of the proposition that their experiment purported to test, that is, they assume that deluded patients are by definition cognitively impaired. If this is the case, the experiment is a pointless exercise in begging the question.

None of this argument was adduced before the experiment was conducted, nor was any independent evidence provided for the supposed summation. Furthermore, it seems highly likely that had the results come out the other way, where the deluded patients made fewer draws than Bayesian rules prescribe and the controls made the appropriate decision after two draws, the study would have been regarded as good evidence for the original hypothesis of impaired reasoning in the deluded. Post hoc rejection of refutational findings is generally a rather problematic procedure.

In the present writers' opinion, there were important methodological problems in designing the task employed, such that only very limited conclusions can be drawn. The ratios employed made the correct Bayesian decision possible after only two draws had been completed. Hence, the degrees of freedom for being impulsive were extremely limited, whereas the degrees of freedom for being overcautious were considerable. As a result, the test lacked sensitivity to impulsiveness, but not sensitivity to over cautiousness, and was thus psychometrically inadequate to test the hypothesis. Had the ratios been less imbalanced and required more draws before the objectively correct decision could be made, the hypothesis might have been tested more convincingly. At this point, all that we can say is that the control subjects failed to conform to Bayesian rules in this task, whereas the deluded patients, for whatever reason, conformed very closely to them. Hence, a reasoning defect in deluded patients remains to be demonstrated. The failure of the search so far conveys an increment of support for the possibility that there is no defect to be found and that hence the cognitions that produce delusions are fundamentally normal.

Delusions and Anomalous Experience

A model of delusion formation that emphasized the role of anomalous experience was presented by Maher (Maher, 1970, 1974, 1988a,b,c, 1990, 1999; Maher & Ross, 1984; Maher & Spitzer, 1995). These are the formal propositions of this model:

1. Delusional thinking is not in itself cognitively aberrant. This means that the cognitive processes by which delusions are formed

are in no important respect different from those by which normal beliefs are formed. Parenthetically, in neither case are beliefs typically formed by a process of syllogistic deductive reasoning.

2. Delusions are like scientific theories to the extent that they serve the purpose of providing order and meaning for empirical observations.
3. As in the case of normal scientific theorizing, the necessity for a theory arises whenever nature presents us with a puzzle. Puzzles arise when predictable events fail to occur and/or unpredicted events do so in their place, i.e., when observation is discrepant with expectation.

Events appear to be predictable rather than surprising insofar as the individual can process information provided by concurrent or recent prior events in ways that permit effectively anticipating what is normally likely to happen next. If a friend calls to say that he will be coming over to visit in the next ten minutes, and this is followed in order by the sound of a car pulling up outside, a car door opening, and the sound of the doorbell, we are not surprised to find our friend at the door when we open it. We might be mildly surprised but not puzzled to find a stranger at the door, but would assume that the expected visit will follow a little later anyway. We would be very puzzled only if we should find nobody at the door.

On the other hand, if our capacity to process current contexts or sequences so as to generate normal expectancies were impaired, many events would be at least slightly surprising even though they had occurred at the end of a predictable sequence of prior events. Impairment of the capacity to use redundancies to predict events would be likely to make many normal events seem puzzling and thus set the ground for vulnerability to delusional interpretations.

There is substantial evidence that the information processing of many schizophrenic patients exhibits impairment in using contexts and redundancies. Examples are to be found in many studies, including those of Lewinsohn and Elwood (1961); Chapman, Chapman, and Miller (1964); Lawson, McGhie, and Chapman (1964); Salzinger, Portnoy, and Feldman (1964); Gerver (1967); Levy and Maxwell (1968); Truscott (1970); Silverman (1972); Koh, Kayton, and Schwarz (1972);

Hart and Payne (1973); Manschreck, Maher, Rucklos, and White (1979); Maher, Manschreck, and Rucklos (1980); Maher (1983); and Maher, Manschreck, and Molino (1983).

4. When unpredicted and hence discrepant events occur, they attract attention and give rise to an experienced feeling of significance accompanied by some tension.
5. This tension motivates a search for explanation; the search is continued until some explanation is found. The longer the search without an explanation, the greater the tension.
6. Explanations bring relief even if the explanation is not fully adequate to the situation. A partially defective or incomplete explanation is experienced as better than no explanation at all.
7. Once the explanation has been established, dissonant new data are disturbing and will be either ignored or reinterpreted to fit the explanation. Data that are consistent with the explanation give additional relief, and are therefore sought after.

It is important to note that experiences of surprise are not limited to situations in which the individual has been unable to predict events either because the events fail to occur in their predicted pattern or because the individual suffers from an information-processing defect. The same thing can happen when two sequences of events, hitherto believed to be unrelated, turn out to have strikingly similar patterns. In science, of course, similarity of patterns in two seemingly independent phenomena often gives rise to the tentative hypothesis that the processes underlying one may be the same as those underlying the other; scientific theories often gain in generality from evidence sought on the basis of this kind of coincidence.

Noticed coincidences feature with some frequency in the developing stages of delusion formation (Maher, 1988a, pp. 29–30). What seems to characterize the phenomenon in deluded patients is the triviality of the coincidences that are noticed, a circumstance that suggests hyperattentiveness due to either attentional focusing impairment or created by the search process activated by an autonomous sense of significance.

8. Theories will be judged delusional by others if any of the following circumstances exist:

(a) They are based upon observations made by the patient that are unavailable to others. Thus beliefs arising to account for hallucinations, input affected by unrecognized sensory defect or other private sensory anomalies, or from veridical observation of highly improbable events, are likely to be judged delusional. (b) The data are available to others, but they do not appear anomalous to others. Thus where the motor or verbal behavior of the patient is discrepant with the patient's intended behavior, the patient's experience is anomalous ("Somebody else must be speaking through my mouth because the words coming out are not what I want to say"). In like manner, the patient who cannot focus attention but finds that external or internal input disrupts conscious organization has anomalous experiences in an environment that appears normal to others. (c) The feeling of "discrepancy" and "puzzlement" is activated neuropathologically when there is no actual discrepancy in the sequence of external events. Thus there is generated a need to explain, but no clear clue as to what is to be explained.* Activation of this kind has been reported by normal subjects who take psychoactive drugs, are placed in unusual sensory environments, or are hypnotized. As we describe later, many cases of delusions associated with somatic disorders exhibit feelings of puzzlement (often called feelings of significance). The condition is well exemplified by the concept of delusional mood, its vague suspiciousness, and the sense of relief when a delusional resolution of the indefinable "discrepancy" has been created.

Anomalous experience presents a problem to be explained by the person who experiences it. The problem is, How is this experience being induced? Who is doing the inducing? Why are they doing

*From time to time, many normal people experience the feeling that "something has changed" in an otherwise familiar environment in which a change has actually taken place; however, it is common to be conscious of the general experience of change some time *before* we manage to identify what specifically has changed. This sequence strongly suggests that the experience of puzzlement may be activated by an automatic detection of a mismatch between an actual observation and expected observation some time before the concrete nature of the discrepancy itself has been identified.

this to me and not to other people? and (sometimes) Why are other people denying the reality of my experience?

Because the anomalous experience, which the delusion is developed to explain, cannot generally be related to visible external causes, answers to the first question frequently have recourse to invisible influences likely to be part of the patient's cultural milieu. Thus, reference to scientific nonvisible forces such as radar, radio, television transmissions, magnetism, cosmic rays, etc., appear quite frequently in delusions; similarly, interpersonal influences such as hypnotism or religious influences such as divine or diabolical power are also common. Because the operation of such influences implies some agency powerful enough to do so, answers to the second question frequently have reference to the FBI, the Communist Party, the government, some specific religious body, God, the Devil and the like. Answers to the third question lead to persecutory and/or grandiose answers: "They are doing this to me because I am evil." "They are doing this to me because I am really a very important person," etc.

Like other explanations, the coherence and quality of the delusion is likely to be influenced by the intelligence and educational level of the patient, the repertoire of culturally common explanations available to the patient, and the degree to which it is couched in nonfalsifiable terms.

What evidence might be adduced in support of this model? Negative evidence that is implicitly supportive comes from (a) the repeated failure of attempts to find a fundamental defect in the cognitive processes of delusional patients and (b) the evidence that the processes of belief formation in normal subjects are indistinguishable in form from those supposed to be characteristic of delusional patients.

Positive evidence comes from (a) the prevalence of delusions in a wide range of disorders in which the deluded individuals have no prior history of cognitive impairment; (b) evidence that delusions can be induced in normal subjects under conditions in which they have anomalous experiences; (c) the presence of delusions in cases of undiagnosed sensory defect; (d) the coexistence (and possibly development) of delusions and (from) psychotic symptoms such as hallucinations, thought insertion, thought withdrawal, passivity phenomena, and the like; (e) the explanatory format of the fully elaborated delusion; and (f) re-

ports that cognitive therapy derived from this model has been effective in some cases (Chadwick & Lowe, 1990).

Empirical studies have reported that anomalies of experience are correlated with the presence of delusions in many different ways.

Delusions and Time Sense

Melges and Freeman (1975) proposed a cybernetic model of the formation of delusions that is based on the assumption of a temporal disturbance of formal thought as the primary cause of delusions. The disintegration of the temporal sequence of thought is experienced by patients as loss of control that leads in several stages to the formation of delusions. First, the loss of control is experienced as mysterious and "uncanny" and leads to the notion that unidentified others might have taken control of the patient. This is the "premonition stage." This leads to anger and rage and fear that these feelings will be discovered. This is the "pursuit stage," and, later, fear that the others will make reprisals, is the projection stage. This circle of persecution and projection amplifies the fears of loss of control on the patient's part and continued fear of the presumed others. In a final "protest" stage, the patient may take hostile action against the others.

Delusions and Attention

An attentional defect as the basic disturbance in paranoid patients was proposed in 1903 by Berze. Recent years brought a revival of those ideas, when the concept of attention was refined by experimental psychological methods. However, the concept of attention was used mainly to explain schizophrenic symptoms, which include disordered attention in general rather than single symptoms such as delusions (cf. McGhie & Chapman, 1961; Shakow, 1962). Frith (1979) believed that delusional patients suffer from an abnormal increase in the content of consciousness which is explained—by processes of normal reasoning—in a way that results in developing delusions. Some authors claim that paranoid schizophrenics differ strikingly in their attention deficit from nonparanoid schizophrenics (see Magaro, 1980); the former are

extensive scanners of the environment, and the latter are poor scanners.

Perception

Pavlov (1934) was the first to propose a theory that related delusions of reference and of being controlled to the existence of perceptual disturbances which he conceived to be due to pathological inertness of cells of the sensory cortex. A consequent pathological hyperarousal in other cells causes irrelevant ideas to intrude into consciousness. According to Pavlov, a delusion consists of reflections on such irrelevant ideas. The theory of Pavlov has some resemblance to attributional theories which were formulated much later. However, it had little clinical impact nor did it lead to fruitful hypotheses for empirical research.

It has long been known that delusions may develop in patients with hearing deficits. Kraepelin (1909, pp. 102–103) discusses the “psychosis of the cloth-eared,” and empirical studies showed a clear increase in the frequency of delusions in patients with hearing deficits (Houston & Royse, 1954), as well as an increased number of hearing deficits in paranoid patients (Kay & Roth, 1961). Visual disturbances also have been found more frequently in paranoid patients (Herbert & Jacobson, 1967), and Cooper and Curry (1976), Cooper and Porter (1976), as well as Kay (1972), demonstrated that paranoid patients had a much higher incidence of perceptual disturbances in the visual and auditory modality, compared to patients with affective disorders. Further support was provided by the data of Zimbardo, Anderson, and Kabat (1981) who were able to demonstrate that hypnotically induced hearing loss in normal subjects led to higher scores on the paranoia scale of the MMPI.

Motivational/Affective Models

The idea that delusions may result from some disordered affect dates at least to 1870, when Hagen stated that delusions “grow rapidly in the breast-warmth of affect and passion” (Hagen, 1870, p. 59). He responded to the objection that changes in affect are not frequently seen in delusional patients by emphasizing that delusions may be so striking that the observer simply overlooks

changes in other mental faculties. Kraepelin was another proponent of the affective causation of delusions, “... the roots of which lay in the intellectual processing of intuitions which are influenced for instance by feelings and affects ...” (Kraepelin, 1889, p. 109). About 10 years later, Specht (1908) argued that the incorrigibility of delusions strikingly resembles the way in which strong emotions make human beings resistant to reasoning. By this analogy, delusions and emotions are similar in being resistant to rational argument. In 1906, Eugen Bleuler suggested that emotions weaken “normal” associations between thoughts and lead to the development of delusions in schizophrenic patients, whereas in paranoid patients, emotions lead to pathologically stubborn adherence to the delusional idea.

In contrast, Karl Jaspers and Kurt Schneider proposed that the distinction between primary and secondary delusions (discussed earlier in this chapter) is related to the role of affect. Secondary delusions were “understandable” in terms of some underlying or associated affect, whereas the primary delusion, *by definition*, is not understandable at all in terms of any related factors. The problem of whether emotions play a major role in the genesis of delusions thus was solved by asserting that with respect to primary delusions—those that occur in schizophrenia—this is never the case. This opinion is widely held by clinicians; as stated by Arthur (1964, p. 110), “However many leading psychiatrists deny that delusional persons show any excessive affect, or that it was present before the delusions appeared.” Nevertheless, many clinicians, as well as researchers, have been dissatisfied with this approach because it excludes empirical research into the role of affect in the forming of delusions.

Some psychopathologists have emphasized the possible role of specific pathological motivational states in the genesis of delusions. The best known of these and for a long time the most influential single hypothesis in the field was that of Freud.

The Freudian Hypothesis

Freud’s basic hypothesis was that delusions stem from repressed homosexual impulses. He developed his hypothesis from his interpretation of the case of a German judge, Daniel Paul Schreber, who developed what today would have been

called schizophrenia, paranoid type. Freud never met Schreber and based his interpretation on an autobiographical account that Schreber published in 1903. It was referred to Freud by C. G. Jung, who also commented on the case in 1908.

Freud's hypothesis was elaborated in his monograph, *Psychoanalytical Remarks on an Autobiographical Case of Paranoia (dementia paranoides)*. It consisted of three parts: the first was the "case report," the second was "interpretational attempts," and the third "on the paranoid mechanism." Freud did not develop his hypothesis through inductive reasoning from the facts of the case. He reported the case quite selectively, ignored certain facts, and emphasized others. Furthermore, he stated directly that he had developed his theory *before* he learned about the Schreber case, having already become convinced of the connection between homosexuality and delusions before he read the Schreber memoirs. In brief, the case was cited not as grounds for the hypothesis, but as a demonstration of a hypothesis that Freud had already developed.

Freud's demonstration of the link between homosexuality and delusions rests on an isolated element in Schreber's book. It went as follows:

... once in the morning lying in bed (I do not know any more whether I was yet half sleeping or already awake) I had a sensation which struck me in a strange way when I later was completely awake and thought about it. It was the idea, that it should be pleasant to be a woman having sexual intercourse. [Schreber comments on this experience in relating it to other experiences of thought control:] This idea was very strange to my whole character. I would have, so to say, consciously rejected it with so much anger that after all I have experienced so far I cannot dismiss the possibility of some external control having given this idea to my mind. (Schreber, 1985, pp. 30–31)

From this comment, Freud proceeded to demonstrate his hypothesis through the systematic examination of the forms of a logical syllogism and its contradictions.

After all it remains curious, Freud remarked, that the most well known main form of paranoia may be conceived entirely as contradictions to the one statement "I (a man) love him (a man)"; furthermore they [the main forms] exhaust all possible formulations of that contradiction. (Freud, 1978/1911, p. 299)

His deductions run as follows: The basic premise or proposition is "I (a man) love him (a man)"; this is unacceptable and cannot come to consciousness. Therefore, it is repressed. However, it finds its way into consciousness after some distortions (i.e., psychodynamics), through delusions

each of which takes the form of a contradiction of the basic proposition. Thus,

1. The delusion of *persecution or being followed* contradicts the basic proposition by the statement, "I hate him, and he hates me, and hence he is after me."
2. The delusion of *being loved* provides a contradiction in the form, "I love her and she loves me."
3. The delusion of *jealousy*: a contradiction of the form: "I do not love him, she loves him and he loves her."
4. The delusion of *grandeur*: a contradiction of the form. "I do not love him, I love myself, and others love me."

Despite the tentative formulation in which Freud first put forward his hypothesis, it soon was "accepted as absolute truth" (Klaf & Davis, 1960, p. 1070) and became part of the rock on which further theory was built. In 1915, Freud published a case that seemed to contradict his theory, but having made some additional assumptions post hoc, offered it as further confirmation.

Freud's "theory" may be criticized on different levels with reference to (1) internal consistency, (2) the long accumulated clinically based psychiatric knowledge about delusions, and (3) studies that have been done to test Freud's hypothesis with empirical data. First, from a formal logical viewpoint there is only one negation to a sentence. In this case, the proper and essential contradiction to the statement "I love a man" is simply "I do not love a man." Nothing more is needed. Once this simple principle is overlooked, any delusional statement that does not state "I love a man" can be interpreted as a contradiction of that statement only by virtue of the fact that it does not make the statement.

Second, Freud dealt only with four kinds of delusions, and he provides no basis for defining them as "the main forms." He failed to mention delusions of sin, being poor, of guilt, somatic delusions, delusions of thought insertion or thought control, and so forth. In spite of these fatal weaknesses in the hypothesis, the English translation of Schreber's book as well as Freud's interpretation of it led to a number of empirical studies of the relationship between homosexuality and delusions, mostly in the 1950s and 60s. Although Freud himself showed little interest in the empirical confirmation of his hypotheses, these conse-

quences of this hypothesis can be tested empirically:

1. Delusions should be found more frequently in a homosexual group compared with a nonhomosexual group.
2. Patients with delusions should tend to be homosexual.
3. In the case of a delusion of being followed, the gender of the person who follows and the gender of the patient should be the same.
4. There must not be a homosexual delusion of being loved by a man.

There are few data on the frequency of delusions in homosexuals, and they indicate only a slight correlation at best (Anderson, 1944; Cattell & Morony, 1962). A few studies sought to detect homosexual tendencies in deluded patients (mostly schizophrenics or patients with delusions but without a more specific diagnosis) (Gardner, 1931; Page & Warkentin, 1938; Norman, 1948; Klein & Horowitz, 1948; Klaf & Davis, 1960; Planansky & Johnson, 1962; Moore & Selzer, 1963; Altman, Sletten, Eaton, & Ulett, 1971). There are many problems with these and other studies, quite apart from the inconclusiveness of their results. Many depend on the questionable interpretation of alleged "signs" of homosexuality, interpretations that are made by interpreters who are not blind to either the diagnosis or the hypothesis, and who generally use projective test "signs" of unknown validity (Eriksen, 1951; Aronson, 1952; Grauer, 1954; Daston, 1956; Zamansky, 1958; Watson, 1965).

However, a key problem is the interpretation of results: the finding that patients with delusions show or report more overt homosexuality than normal controls or nondeluded schizophrenics (who would be the only relevant control group) necessarily contradicts the hypothesis because Freud postulated that the homosexual wish had to be repressed and disguised to turn it into a delusion.

The results of studies using test "signs" claim to indicate a tendency toward problems in gender identity related to delusions, but because the validity of the signs themselves is unknown, the findings cannot be accepted with confidence.

Studies of the gender of the "follower" in patients of both sex with delusions of being followed produced inconclusive results (Greenspan, 1963; Klaf, 1961; Modlin, 1963). There are cases of a homosexual delusion of being loved (Doust &

Christie, 1978; Möhr, 1987; Peterson & Davis, 1985).

Finally, it is of interest that there has been a controversy among psychoanalysts about Freudian theory in this matter. Homosexuality in these cases has been seen as a consequence of delusions and termed "pseudohomosexuality" (Ovesey, 1955), and both delusions and homosexuality have been regarded as the consequence of some common underlying pathology (Ehrenwald, 1960). Carr (1963) referred to Hastings (1941), Lagache (1950), and Glick (1959) to explain the finding that homosexuality and delusions were present at the same time by proposing two kinds of homosexuality, one conscious and the other unconscious, a device that renders the hypothesis completely untestable. Lester (1975) tried to explain the co-occurrence of overt homosexuality and delusions by referring to the differential timing with which both occur.

To summarize: There are no studies of purely paranoid patients and homosexuality. The studies and established facts about schizophrenics are inconclusive for the most part. Any existing tendency of some deluded schizophrenics to have problems with gender may easily be understood in terms of the general problems of schizophrenic patients with social identity and need not indicate an underlying homosexual problem.

Delusions as Expressions of Hatred

Swanson, Bohnert, and Smith (1970) proposed a theory somewhat similar to Freud's but based on hatred rather than homosexuality. Although aggression can frequently be found in schizophrenics, its presence has correlated with the presence of delusions (Overall, Gorham, & Shawver, 1961), and Silverman and Candell (1970) found that the subliminal presentation of aggressive stimuli can aggravate schizophrenic symptoms, these findings are inconclusive (Heilbrun, 1980) and difficult to interpret.

Delusions as Expressions of Humiliation

Adler (1927) stipulated a loss of self-esteem as the main reason for the development of delusions, and Colby (1975) saw humiliation as the chief

cause. Tölle (1987) tries to show how delusions develop in physically disabled patient by using the same concepts. Faight, Colby, and Parkinson (1977, p. 156) refer to the “transfer of blame [that] is reflected in the interpersonal behavior of the paranoid person,” thus also referring to some form of projection. This approach to the role of shame in delusions has been extended and applied most recently by Ballerini and Rossi Monti (1990).

The “Inflammation Model” of Delusions

As we have already seen, the origin of delusions has been linked to disturbances of thought, attention, affect, motivation, perception, and sense of time, as well as homosexuality, humiliation, and hatred. Nevertheless, the formal structure of all of these theories is remarkably similar and may be called the “inflammation model” of delusions. Analogous to the development of an inflammation, delusions have been conceived of as a *normal reaction to some underlying pathology*. The underlying disturbance, it has been thought, refers either to some mental faculty or psychological process; the disturbance of this in most cases is conceived ultimately to be biological.

Hughlings Jackson was among the first to present such a theory of delusions. According to Jackson, the nervous system is such that neurological as well as mental signs and symptoms are to be understood in terms of lesions, on the one hand, and disinhibition (of nonaffected brain structures or functions), on the other hand. “When a general paralytic believes himself to be Emperor of Europe, I submit that this delusion does not arise during activities of any nervous elements touched by any sort of pathological process; but, on the contrary, that it is framed during activities in what remains of his highest centres, that is to say, in what disease has spared ...” (Jackson, 1958, Vol. 2, p. 406). The same approach was proposed by Bickel (1920, p. 132).

Social Attribution Explanations

Social attribution refers to the processes by which individuals explain their own behavior and that of others by ascribing traits and motives to the persons concerned. Its first consistent formulation is in the seminal works of Heider (1944) and Kel-

ley (1967). Although the underlying model is quite complex, the central concern here is the observation of the seeming universality of the so-called fundamental attribution error, the tendency to ascribe the causes of another person’s behavior to characteristics of the person concerned, regardless of the circumstances that exist at the time. Kaney and Bentall (1989) suggested that the development of delusional beliefs might be understood in terms of social attribution processes, specifically that delusions of persecution might be associated with a particular style of social attribution. In their investigations, deluded and nondeluded patients were required to respond to a questionnaire in which they could make attributions to hypothetical situations. By and large, deluded patients did not differ from depressed controls but differed from each other on one or two of the various comparisons made. Given that this rather slight association is reported in patients who had already developed delusions of persecution of sufficient intensity to require psychiatric care, it is quite unclear that any significant causative role can be assigned to attributional style.

In summary, there is no compelling evidence at this time to support the view that processes of deductive or inductive reasoning are impaired in persons with delusional beliefs. When we consider the wide range of conditions in which delusions are found and that in many of these conditions there is no evidence whatever of prior thought disorder in the patients who develop delusions, the most parsimonious and comprehensive conclusion is that delusions arise on the basis of cognitive processes that are indistinguishable from those of nondeluded persons.

The Neuropsychology of Delusions

Current work on the question of neuropsychological factors in the genesis of delusions centers on the search for identifiable organic lesions or anomalies associated with the presence of delusions in general, and/or with specific types of delusion.

Hemisphere Differences

One approach has focused on the role of hemisphere specialization, as well as the limbic system, for the formation of delusions. Based on the obser-

vation that left temporal brain lesions are correlated with hallucinatory-delusional states and that right parietal damage frequently causes two specific types of abnormal belief, Capgras syndrome and anosognosia, Cutting (1985) stressed the importance of these two brain areas in developing and possibly maintaining delusions. Using hemisphere differences—the left hemisphere is involved in verbal activities, whereas the right hemisphere mediates more perceptual, affective, and visuospatial functions—as his starting point, Cummings (1985) emphasized the role of the limbic system and the basal ganglia in the development of delusions because these structures form an integrated system that mediates mood and motivation.

The Frontal Lobes

The frontal lobes have been implicated in many kinds of cognitive defects. Stuss and Benson (1986) reviewed much of the relevant data and concluded that the prefrontal areas of the brain were responsible for self-analysis, executive control, sequencing, and drive. They comment, “The ability to self-monitor and to be self-critical must be functional for recognition of the inappropriateness of delusional interpretation or the incorrectness of an imagined sensory perception.” Benson and Stuss (1990) report five cases in which delusions were accompanied by direct evidence of frontal damage due to accident or disease.

Malloy and Richardson (1994) reviewed the published literature on monosymptomatic or “content-specific” delusions. These include syndromes such as misidentification syndromes, delusions or jealousy (the “Othello” syndrome), de Clérambault’s syndrome, specific hypochondriacal syndromes such as parasitosis, and body dysmorphic syndromes (e.g., Cotard’s syndrome, koro). Their conclusions are consistent with the suggestions of Stuss and Benson (1986):

Crucial factors in the persistence of delusions may be the length of time that the perceptual distortion continues and the ability of the patient to correct the misperception on the basis of new information. Frontal lesions may affect the self-corrective function, making it impossible to resolve the conflicting information. (Malloy & Richardson, 1994, p. 463)

In terms of possible neurotransmitter involvement, dopamine is a plausible candidate. Dopaminergic substances that are given to patients with Parkinson’s disease frequently cause hallucinatory-

delusional syndromes and antidopaminergic substances, that is, neuroleptics, can be used to treat delusions. There is biochemical evidence that cocaine has dopamine-like effects, and recently it was demonstrated that an infusion of cocaine causes suspiciousness and paranoid thinking in normal subjects (Sherer, Kumor, Cone, & Jaffe, 1988). Gawin (1986) had already found that cocaine-induced paranoia can be reduced by neuroleptics. Nevertheless, it is known that delusions may take a while before they gradually disappear when treated with neuroleptics and in many cases—especially when they are highly systematized—may not disappear at all. Because noradrenergic substances like methylphenidate can cause a schizophrenia-like syndrome and because LSD, which acts as serotonergic receptors, can cause some fleeting delusions, norepinephrine and serotonin are likely to play a role in the genesis of delusions as well.

Nosology and Classification

As we said in the first section, delusions have been related to schizophrenic, affective, somatic, or reactive disorders. Because these disorders themselves have undergone considerable conceptual changes within the last decades, seemingly simple questions like “What is the frequency of delusions of kind *x* in disorder *y*?” are quite difficult to answer. Moreover, mainly for historical reasons, the various concepts that have been developed to account for different delusional syndromes overlap. In this section, we try to give a short summary of the classificatory attempts that have been made.

Delusional Disorder

Delusional disorder (formerly paranoia) is plagued by the conceptual confusion that surrounds the concept of delusion itself. It has been classified as a subgroup of schizophrenia, an independent third kind (next to mania and depression) of affective disorder, a disorder related to brain damage, and a disorder of personality development, that is, a disorder of a reactive type. In what follows, we will first present the current DSM-IV definition of delusional disorder and then discuss the various approaches that have been taken to evaluate current practice and concepts.

The essential feature of Delusional Disorder is the presence of one or more nonbizarre delusions that persist for at least 1 month (Criterion A). A diagnosis of Delusional Disorder is not given if the individual has ever had a symptom presentation that met Criterion A for Schizophrenia (Criterion B). Auditory or visual hallucinations, if present, are not prominent. Tactile or olfactory delusions may be present (and prominent) if they are related to the delusional theme. . . . Apart from the direct impact of the delusions, psychosocial functioning is not impaired, and behavior is not markedly odd or bizarre (Criterion C). If mood episodes occur concurrently with the delusions, the total duration of these mood episodes is relatively brief compared to the total duration of the delusional period (Criterion D). The delusions are not due to the direct physiological effects of a substance (e.g., cocaine) or a general medical condition (e.g., Alzheimer's disease, systemic lupus erythematosus (Criterion E)). (p. 296)

In Delusional Disorder the following delusional themes are commonly seen: erotomanic, grandiose, jealous, persecutory, and somatic. The type of Delusional Disorder is based on the predominant delusional theme. This way of classifying disorders with delusions as the main symptom has been criticized for being much too narrow (Munro, 1987) and not supported by any empirical facts (Kendler, 1984); there are no specific types of delusions by which a diagnostic distinction may be made without knowing other features of the disorder.

The relationship between delusional disorder and schizophrenia is unclear. The fact that genetic studies show no excess of schizophrenia in first-degree relatives of patients with paranoid disorder (Kendler, Glazer, & Morgenstern, 1983) is usually interpreted as a sign that the two conditions are unrelated. Nevertheless, from a clinical point of view, it is known the cases of paranoia can deteriorate and develop schizophrenic symptoms so that the diagnosis has to be changed to schizophrenia.

Munro (1987) proposes a "paranoid spectrum" with paranoid schizophrenia, on the one hand, and paranoia, on the other hand, and paraphrenia, a condition not included in the DSM-IV but found in the International Classification of Diseases, 9th revision (ICD-9), and characterized by the predominance of delusions and less deterioration and fewer other symptoms than in paranoid schizophrenia, but more than in delusional disorder. Some clinicians such as E. Bleuler, Jaspers, Schneider, and others have argued that all cases of paranoia (delusional disorder) are simply members of a paranoid subgroup of schizophrenia. Clinical experience shows that there certainly are patients who develop a system of delusions with-

out ever having any other sign of psychopathology, but they are comparatively uncommon.

Delusions in Schizophrenia

Delusions encountered in schizophrenia include the belief or experience that as one's thoughts occur, they are broadcast from one's head to the external world so that others can hear them (thought broadcasting); that thoughts that are not one's own are inserted into one's mind (thought insertion); that thoughts have been removed from one's head (thought withdrawal); or that one's feelings, impulses, thoughts, or actions are not one's own but are imposed by some external force (delusions of being controlled).

Some of these delusions occur with a frequency of up to 70% in all schizophrenic patients across different cultures (Murray, 1986, p. 342). This fact raises interesting questions about the hypothesis that delusions are idiosyncratic and personal. It also suggests that there is a common etiology for these delusions and that they are minimally created by unique personality features or by factors unique to the patient's culture.

The anomalous experience model of delusion formation may contribute to our understanding of this apparent puzzle. There is evidence that several changes happen at the onset of schizophrenia in the way persons experience reality, as well as their own thoughts. These include experiences of passivity ("my thoughts are not thought by me"), of the personal significance of external objects ("this object directly relates to me"), of the significance of the coincidence of one's thoughts and some external event ("this happened because I was thinking about it"), of disordered thought, or of alienation ("there is a wall of glass between me and everything else"). These experiences are likely to arise from internal, endogenous neuropsychological defects that form from the basic pathology of the schizophrenic disorder.

A parallel set of disturbing experiences arises from the discrepancy between the patient's actual action and the intended action. At one level, this appears to arise from a fundamental disjunction in consciousness between the awareness of the action that is performed and the attribution of the action to the self. This explanation has been elaborated by Frith (1987, 1996), Silbersweig, Stern, and Frith (1995), and others with specific reference to the conscious phenomena of hallucinations.

At another level, the experience of discrepancy between intent and action may arise because associative interference in producing language creates utterances that are not congruent with the intended utterance. At the conscious level, the patients' experience is of speaking or (less commonly) writing something that fails to match what they wanted to say (Maher, 1988c; Maher, Manschreck, Seung, & Tsuang, 1995). Similar misattribution about hand movements has been reported in deluded patients by Daprati, Franck, Geogief, Proust, Pacherie, Dalery, and Jeannerod (1997).

Such experiences are disturbing and they prompt the patient to seek explanations. Thus, the experience of not being able to produce coherent utterances any longer may be interpreted by patients as evidence that somebody else is interfering with their thoughts by some technical device. The experience of not thinking one's own thoughts may become transformed into the idea that someone else is thinking one's thoughts. This, in turn, leads to an attempt to determine who the "someone else" might be. When the patient decides that it must be the FBI, Vatican, or other identifiable agency, the delusional process has begun.

As long as patients focus directly only on changes in their experience—as can be the case for several days or weeks at the beginning of the psychosis—statements that describe these changes should not be defined as delusions but rather understood as veridical descriptions of disordered or anomalous conscious experiences.

Delusions in Affective Disorders

Estimates of the incidence of delusions in affective disorders are affected by the criteria employed by investigators in defining the cohorts of study. Thus some investigators exclude from their definition of depression those patients who have delusions due to depression. Delusions have been reported by Kantor and Glassman (1977) in 20–30% of depressed inpatients; the most common delusions are of guilt, worthlessness, and hypochondriasis. By definition, delusions in mania and in depression are "mood-congruent," that is, their content can be understood in terms of the prevailing mood or affect of the concomitant disorder. Delusions of grandeur are a common feature of mania, whereas delusions of worthlessness, pov-

erty, or guilt, as well as hypochondriac and nihilistic delusions, are features of depression.

Delusions in affective disorders are meaningfully related to the underlying affect, and they also seem to be causally related to the affective changes brought about by the disorder. Clinically, it is well known that a change in the affect brings about a change in the delusions, although this may take some time. Again, the theory of anomalous experiences—in this case affective—can be used to make those changes plausible. In this framework, delusions in affective disorders can be interpreted as a patients' hypotheses of the reasons and consequences of their affective states.

Research comparing deluded depressed patients with nondeluded depressed patients has been done with inconclusive results. Patients with delusional depression do not differ from nondeluded depressed patients with regard to neurochemical variables (Lykouras, Markianos, Malliaras, & Stefanis, 1988). However, the occurrence of delusions does impact the clinical course of a depressive illness. Kettering, Harrow, Grossman, and Meltzer (1987) reported that delusional depressed patients had more mood-incongruent delusions at a 14-month later follow-up, whereas nondeluded depressed patients suffered from more depressed mood and anxiety, thus suggesting two different underlying disorders. Roose, Glassman, Walsh, Woodring, and Vital-Herne (1983) reported a 25-year retrospective study of the suicidal risk of delusional versus nondelusional depressed patients. They found that the delusional depressed patients had a risk of suicide five times higher than nondeluded patients.

The prevalence of delusions during depressive episodes depends on the diagnostic criteria used to define depression and also schizophrenia and paranoia. As the underlying concepts change over time, the range of prevalences is quite broad, and frequencies range from roughly 5 to 50%. A study with 280 patients reported by Beck (1967, pp. 36–39) reported that there is a correlation between the frequency of delusions and the severity of depression. In this study, the delusions of the main depressive themes, namely, delusions of worthlessness, guilt (sin and punishment), or the patients' body being defective or decaying, occurred with frequencies of about 40 to 50% each. Chambers, Puig-Antich, Tabrizi, and Davies (1982) found that delusions were present in only four out of

fifty-eight children with prepubertal major depressive disorder.

Little is known about the exact frequency of delusions of grandeur in mania. Whether other types of delusions are a frequent feature of mania is also not known. As in depression, such figures are highly dependent upon the conceptual boundaries between the affective and schizophrenic disorders.

Specific Syndromes

There are several syndromes in which delusions are the only or the predominant symptom. In general, these are rare conditions and, perhaps for that reason, the concepts used to describe them are somewhat vague.

Paranoid Personality Disorder

In the DSM-IV (p. 634), the diagnostic criteria for this disorder are that patients suspect (without adequate basis) that others are exploiting or harming them, are preoccupied with doubts about the loyalty or trustworthiness of friends or associates, are reluctant to confide in others because of unwarranted fear that the information will be used against them, read hidden demeaning or threatening meanings into benign remarks or events, bear grudges, perceive attacks on their character that are not evident to others, and have jealous suspicions of the sexual fidelity of spouse or partner.

Little is known about this disorder with respect to prevalence, family patterns, and predisposing factors. The relationship of this disorder to other paranoid disorders and to paranoid schizophrenia is unclear.

Delusional Parasitosis

This syndrome is characterized by the delusion that parasites, insects, worms, or foreign bodies are under the skin. The delusion arises on the basis of the patient's sensations of itching under the skin. As a reaction, the patients tend to scratch their skin, sometimes giving rise to severe lesions. At different times, this syndrome has been termed "monosymptomatic hypochondriasis," "epidermozoophobia," "delusion of infestation," "atypi-

cal somatoform disorder," "tactile hallucinosis," and "delusional disorder, somatic type."

Little is known about the prevalence, etiology, predisposing factors, and family patterns of this disorder, perhaps a result of the multiplicity of names under which it has been described. Although the symptomatology is usually circumscribed, delusional parasitosis can lead to considerable impairment. It should be noted that delusions of insects crawling under the skin are a common feature of delusional disorders due to prolonged cocaine abuse. A case of this disorder associated with lesions in frontal white matter was reported by Flynn, Cummings, Scheibel, and Wirshing (1989) and is cited by Benson and Stuss (1990) to support the hypothesis that frontal damage is a critical feature of delusions.

Delusional Misidentification

Capgras

In 1923, J. Capgras and J. Reboul-Lachaux first described a syndrome that consisted of the delusional belief that doubles of significant others or oneself or both exist. For instance, patients may claim that their spouses have been replaced by one or more impostors. The syndrome is not a perceptual problem, an illusion, a hallucination, a misrecognition, or an autoscopic phenomenon; it certainly is a very specific circumscribed delusion. The syndrome is also known under the names of "illusion of doubles" and "illusions of false recognition," and is to be distinguished from autoscopy, prosopagnosia, as well as from defects of perception and memory. Berson (1983) summarized 133 cases of this syndrome in the English language literature. The Capgras syndrome appears in both men and women over a wide range of ages and underlying mental disorders. The most common diagnosis was that of schizophrenia (about 60%), especially of paranoid type, whereas 23% of the patients suffered from organic brain disorders.

Fregoli Syndrome

This syndrome, first described by Courbon and Fail (1927), consists of the delusional belief that familiar persons appear "disguised" in various forms as other people. In one recent case (De

Pauw, Szulecka, & Poltock, 1987), a patient complained that she was being persecuted by a cousin and his friend. She believed that they disguised themselves with false beards, wigs, make-up etc. On this basis, she confronted strangers demanding that they acknowledge their true identity and made complaints to the police. A CT scan revealed a right-sided posterior-temporo-parietal infarct. After recovery from speech slurring, orientation and memory problems, she developed the Frégoli syndrome. It was controllable with trifluoperazine.

Intermetamorphosis

Courbon and Tusques (1932) described a syndrome wherein the physical appearance of some people, animals, or objects changes radically to match that of someone else. They described the case of a woman who reported that animals or objects that she owned changed to take the form of some other animal or object. Bick (1986) reported four such cases, three of whom had temporal lobe epilepsy.

The frequent appearance of organic disorder in connection with the misidentification syndromes lends support to the model of Ellis and Young (1990), who hypothesized that the critical locus of the pathology lies in a complex neural system of facial recognition units and person identity units. This pathology gives rise to conscious experiences of recognition failure or of false recognition which, in turn, generate delusional explanations. The Ellis-Young model is more specific than other attempts to interpret the misidentification syndromes in broader nonspecific motivational terms (De Pauw, 1994).

Erotomania (de Clérambault's Syndrome)

de Clérambault's syndrome is also called erotomania, or, as in the DSM-IV, delusional disorder, erotomanic type. The central theme of this delusional syndrome is that *one is loved by another*. "The delusion usually concerns idealized romantic love and spiritual union rather than sexual attraction. The person about whom the conviction is held is usually of higher status ..." (DSM-IV, p. 297). The patient's efforts to contact this person by phone calls, letters, etc., are common and can be very distressing for the respective person. Although reportedly more common in females than

males, it does occur in males and may take the form of stalking or other activities that conflict with the law. Signer (1991) argued that at least in some patients, the basic pathology is an affective disorder (rather than a "pure" delusional disorder).

Folie à Deux (Shared Psychotic Disorder)

Folie à deux is the most widely used name for a condition which has been given quite a few names, for example, "shared paranoid disorder" (DSM-III; American Psychiatric Association, 1980)), "induced psychotic disorder" (DSM-III-R; American Psychiatric Association, 1987), "induced insanity," "communicated insanity," "double insanity," and "folie simultanée." The diagnostic criteria listed in the DSM-IV (p. 306) are as follows:

- A. A delusion develops (in a second person) in the context of a close relationship with another person, or persons, with an already established delusion.
- B. The delusion is similar in content to that of the person who already has the established delusion.
- C. The disturbance is not better accounted for by another psychotic disorder ... or by substance abuse ... or a general medical condition.

The disorder develops in a person who is involved with another individual who already has a psychotic disorder with prominent delusions. The disorder is more common among females, and the patients usually are less impaired by it, compared to the patient with the primary person. Cases do not always involve only two patients; cases of three (Dewhurst & Ellenberg, 1961), four (Ropschitz, 1957), five (Kamal, 1965), and twelve (Waltzer, 1963) have been reported.

Delusions Associated with Somatic Disorders

Space does not permit a detailed account of the many reported cases of delusions associated with various bodily disorders. A fairly complete review may be found in Maher and Ross (1984). However, it may be noted summarily here that delusions have been found in the disorders listed following. Although the delusions that are reported cover the range of content that we have already described, many of the cases described in published reports present delusions with persecutory features, and many describe feelings of insignificance or puz-

zlement. Unsurprisingly much of the delusional content has a somatic theme. Reported cases include patients suffering from temporal lobe epilepsy; narcolepsy; Huntington's chorea; cerebral malaria; hereditary ataxia; multiple sclerosis; hydrocephalus; systemic lupus erythematosus; encephalitis; traumatic brain injury; scleroderma; chronic liver disease; pellagra; manganese intoxication; porphyria; various disorders of the thyroid, as well as many other syndromes. In the majority of cases, the delusions clear up after the basic somatic disorder has been treated successfully.

Treatment

At the clinical level, a delusion is generally regarded as part of the larger pattern of disturbance that the patient displays. Delusions are generally more likely to respond to appropriate therapeutic action if they are part of a syndrome such as schizophrenia and depression (rather than the only symptoms as in delusional disorder), if they are not systematized (compared to highly systematized delusions that affect almost all realms of a patient's thinking), and if they have not been present for too long. Superior intelligence does not make patients more open to demonstrating the inadequacy of their beliefs. Instead, high IQs may help patients to systematize their delusions, and therefore preserve the disorder against refutation. This is, of course, consistent with our observation that defective reasoning is not a significant causative factor in the genesis of delusions.

Biological Methods

Our knowledge about the response rate of delusions of various types to drug treatment of the underlying disorder is very limited and can be summarized as follows. Delusions are often harder to cure than other symptoms of mental disorder. In schizophrenia, for example, the anomalous experiences of hallucinations, thought control, thought broadcasting, and the like (i.e., purely subjective experiences), tend to respond quickly to neuroleptic substances, whereas delusional systems that incorporate many aspects of a patient's real life have a tendency to persist, even though the delusion may come to seem more alien to the patient.

Neuroleptic drugs may be taken by the patient either on the basis of the presence of other symptoms such as anxiety or agitation in acutely ill patients or on the basis of an already established therapeutic relationship in nonacutely ill patients.

Glassman, Kantor, and Shostak (1975) found that depressed patients with delusions are markedly unresponsive to tricyclic antidepressants such as imipramine. Good results are reported in treating delusional depression with either a combination of tricyclic antidepressants and neuroleptics or ECT (Minter & Mandel, 1979).

Psychological Method: Cognitive and Behavioral

Psychotherapists of the various schools agree that establishing a trustful relationship with the patient is a necessary condition of every psychotherapy of a delusional patient. It has long been assumed that it is unwise to confront patients with their delusions because this does not tend to convince the patients that their beliefs are delusional, but rather makes them angry, suspicious, or even hostile. "Initially, the therapist should neither agree with nor challenge the patient's delusions" comment (Kaplan & Sadock, 1985, p. 233). There is no available empirical evidence that would compel us to reject this advice, at least in the initial stages of interaction with the patient. However, whether the therapist should look for psychodynamic reasons and adaptive purposes of delusions, as Kaplan and Sadock propose, is open to question. Although it may be sometimes possible to conclude that a delusional system conveys some "benefit" to the patient, the general hypothesis that delusions serve any purpose other than that of explaining personal experience is highly speculative.

Behavior Modification. There are several reports of attempts to modify delusional behavior by manipulating the consequences of the expression of the delusion. Beck (1952) employed direct discussion of delusional ideas that had been held for 7 years by a 28-year-old chronic schizophrenic, a procedure that led to eliminating them. Watts, Powell, and Austin (1973) reported successfully eliminating delusions by presenting counterevidence (without direct confrontation of the delusional belief) and encouraging their clients to develop and voice arguments against their delusional beliefs. Alford (1986, 1994) reported successful

outcomes in using a cognitive therapy that centers on helping patients develop the practice of seeking alternative explanations for their experiences. The treatment reportedly reduced the frequency of delusional cognitions and reduced rated levels of confidence in the delusional beliefs of some numbers of patients. Studies using a similar technique were reported by Chadwick and Lowe (1990), Lowe and Chadwick (1990), and Chadwick (1994). In these studies, they were able to obtain substantial reduction in delusional beliefs; the reduction remained in effect at follow-ups carried out for extended periods after the intervention. More extensive reports of these interventions and reviews of behavioral interventions may be found in Kingdon and Turkington (1993); Chambon and Marie-Cardine (1994); and Chadwick, Birchwood, and Trower (1996).

Some behavioral aspects of delusions may respond to cognitive explanation training or to adequate contingency management, but the problem remains of determining whether a belief has been modified on the basis of modifying the overt expression of the belief. Supportive counseling and management of the social aspects of the disorder may be the treatment of choice for the chronically ill paranoid patient. If the condition is fluctuating, it is generally agreed that additional drug therapy should not be withheld in stages of acute exacerbation.

Conclusions

From the material that we have presented, it is clear that our understanding of the etiology, pathology, and therapy of delusions is far from adequate. It is more than likely that the origins of delusional beliefs, as of normal beliefs, are heterogeneous. It is also likely that the factors that give rise to delusions are not the same as those that maintain them over time. With these caveats in mind, we offer the following general conclusions:

1. The criteria by which delusions are to be defined are open to dispute. These disputes center particularly on the ambiguity of concepts of "falsity" and the steps that would serve to establish it. They also include problems with the concept of the "in corrigibility" of a belief and the operational requirements necessary to establish this.
2. There is reason to question the scientific status of the practical distinction whereby culturally accepted, false, and incorrigible beliefs are not defined as delusional, whereas similar beliefs held by one or a few individuals are so defined.
3. After many research studies, there is still no good evidence to support the hypothesis that delusions arise from a cognitive defect in deductive or inductive reasoning or from other processes of inference. Normal individuals employ inferential processes that are indistinguishable from those of deluded patients; the locus of the delusional problem must lie elsewhere.
4. There is no acceptable evidence to support the hypothesis that delusions are reflections of unconscious motives, distorted into delusional form so as to permit entry into consciousness.
5. Given the occurrence of delusions in a very wide range of disorders, it is unlikely that an explanation that is derived from a model of the pathology of a specific disorder will be adequate to explain delusions in general. An adequate model must explain delusions across the spectrum of disorders in which they are found.
6. As an additional comment on the preceding item, it is entirely possible that delusional beliefs have differing etiologies—a possibility that suggests the necessity for fine-grained longitudinal analyses of the origin and development of delusions in clinical populations.
7. The writer has presented a model of delusion formation in which a principal role is played by anomalous conscious experience. As defined in this model, anomalous experience may arise (1) exogenously from the presence of unidentified but genuine atypical and unpredictable features in the external environment or in the somatic functions in the patient's body; (b) from impairment in the sensory and/or information-processing mechanisms involved in attending to, perceiving, and/or processing the redundancies and contexts of an otherwise normal environment; and (c) from endogenous neuropathological states that give rise to conscious experiences such as those of "significance" puzzlement or anomalousness which are in

turn ascribed to undefinable changes in the external environment and/or the patient's bodily functions.

Schizophrenia: Biopsychological Aspects

Brendan A. Maher and Patricia J. Deldin

Introduction

The research literature on the biopsychology of schizophrenia is monumental. Any attempt to cover all of it would require that we write a book. Accordingly, we have opted to focus on the literature that relates biological processes to psychological processes in the population of schizophrenia patients and represents lines of investigation that are currently active. This means that we do not include purely biochemical studies, such as those investigating the effect of medications on neurotransmitter activity or other similar associations between the operation of one biological variable on another. It also means, regrettably, that we will have little space for historical references.

Because of the focus that we have chosen, much of the content of this chapter will focus on the general areas of neuropsychology and psychophysiology. In some cases, the inference that a biological variable is involved may itself depend upon a psychological (i.e., nonbiological) measure. Where this is the case, we will point it out.

General Methodological Issues in the Investigation of Schizophrenia

Heterogeneity

Schizophrenia is heterogeneous. That schizophrenia is heterogeneous has been known since the word “schizophrenia” was created. Bleuler’s classic *Dementia Praecox or the Group of Schizophrenias*, first published in 1911 (in English in 1950), made it clear that he was talking about a group of diseases with some common symptoms and perhaps some common components in their pathogenesis. This being so, it is ultimately more critical to discover the regularities underlying the differences between subgroups of schizophrenia patients than to demonstrate differences between general unselected samples of schizophrenia patients and patients with some other psychopathological classification or nonpatient controls. The task is rendered difficult because seemingly different manifest aberrant behaviors (i.e., symptoms) may arise from the same prior causes and seemingly similar symptoms may arise from different prior causes. Arguing backward from effect to cause is notoriously unreliable, but it is a constant problem for the research psychopathologist who takes heterogeneity seriously.

The investigation of heterogeneity implies a certain model of a group of illnesses that have been traditionally subsumed under a single diagnostic label. An oversimplified version of this

Brendan A. Maher and Patricia J. Deldin • Department of Psychology, Harvard University, Cambridge, Massachusetts 02138.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

model of this might be stated as follows. A set of independent etiologies creates a set of different basic pathologies. These differences may consist of different biological pathologies and/or differences in the proportional roles played by biology and environment. The differences, however, produce overall clinical presentations that have some striking components in common. These common elements lead to the grouping of the patients under a single diagnostic label. Common elements may arise in part as common, secondary, compensatory responses to the handicaps created by different pathologies and in part because different etiological factors have produced different underlying primary pathologies that have, nonetheless, certain common consequences within the central nervous system itself. Where the common symptom/s are largely in the form of defects, this possibility is particularly likely.

Etiological Heterogeneity

We have already commented on the complexity of systems that underlie seemingly simple responses. This is especially the case in which we seek to establish the neural basis of a defect. As we have pointed out, a complex system may fail to operate adequately as a result of quite different kinds of damage to the components of the system. Coupled with this is the fact that the brain does not operate on the basis of simple isomorphic linking of behavior with the activity of a specific region of interest; that functional brain regions may develop in response to environmental input, especially in the early years of life; that when regions of the brain are damaged—again, especially early in life—other regions may take over the functions normally mediated by the damaged area; that there are gender differences in normal brain development; and that the brain changes with aging. All of these considerations point to the immense complexity of the task of developing a comprehensive model for understanding the neuropsychological pathologies in a disorder that is as clinically complex as schizophrenia.

The Concept of Defect

As a general working principle, it may be helpful to consider that human and other organisms rarely do nothing in response to situations in which they find themselves. They may not do,

however, what the observer regards as the correct thing, and what may appear to be normally the most effective thing. When this happens, it is tempting to classify what we observe as an instance of a deficit or lack of capacity to make the normal response. Unfortunately, this is a plausible inference as stated, but this kind of classification tends to distract us from observing what the individual actually does do—an observation that might otherwise have provided a clue to the nature of the active pathological process that determined the “wrong” response. By making this point, we are, of course, simply rephrasing the position of James Hughlings Jackson when he pointed out that much of the disordered behavior seen in cases of CNS damage is produced by the undamaged lower centers (e.g., Jackson, 1887).

A good example of this problem is in the classification of the language utterances of a patient as exhibiting “poverty of content,” “derailment,” or “incoherence.” The very choice of a term such as “incoherent” tells us that we have noticed something that is absent from the utterance, i.e. “coherence,” but it does not tell us what was present in the utterance. In one of our own studies, for example, Maher, Manschreck, Hoover, and Weisstein (1987), we found that the counted repetitions of words and phrases in samples of speech in schizophrenic patients significantly correlated with rated levels of Derailment, Understandability, and Poverty of Content as assessed in the Schedule for Affective Disorders and Schizophrenia (SADS; Spitzer & Endicott, 1977) in the same patients at a different time. What the patients were not doing was showing a richness of content; what the patients were doing, at least in part, was repeating and perseverating in speech. This observation leads us to become interested in the positive determinants of repetition and perseveration. The question, “What factors lead to repetitiousness” seems to us a more manageable definition of the research problem than the question “Where did the content go?”

Investigations of heterogeneity have taken certain approaches. One is the attempt to discern independent patterns or clusters within the global spectrum of symptoms, laboratory performance, case histories, and the like. Cluster analysis, the various forms of factor analysis, and other multivariate analyses are the main tools in this search. In themselves, these approaches create models of the possible complexity of the heterogeneity, that

is, do the data analyses produce results that are plausibly consistent with the conclusion that there is a specific number of separate entities or subtypes, two, three, or more? If so, can these subtypes be differentiated when we turn to another level of inquiry such as brain structure or patterns of brain functioning?

The Sequential Emergence of Manifest Phenomena

The timing and the unfolding sequence of the appearance of the various elements of the manifest pathology do not necessarily correspond to the sequential timing of the underlying biopathological processes themselves. We cannot assume that these causes become apparent before their consequences become apparent. This fact creates fundamental problems in retrospective studies of patients who are now manifestly ill. If we turn to relatives for information about the first appearance of the pathology in the premorbid behavior of the future patient, we encounter serious problems. Veridical recall of the past behavior of others is unreliable even when the recall is unaffected by any dramatic later development in the life of the person whose behavior is being described. It may be particularly unreliable when the patient has already been identified as psychiatrically ill.

In the case of biopsychological factors, we can be reasonably confident that structural anomalies in the central nervous system in young patients predate the appearance of pathological behavior. In older patients, our confidence is somewhat reduced because we know that changes in the brain occur with aging. In the case of neurophysiological anomalies unaccompanied by structural anomalies, we must be more cautious in interpreting cause and effect sequences. Once again, caution is more necessary in older patients than in younger ones.

The preferred solution to this problem, namely, the premorbid investigation of populations believed to be at some high risk of later pathology, is complex and difficult. It requires that we have very shrewd ideas about the kinds of variables that should be examined premorbidly and, of course, good epidemiological bases for selecting high-risk subjects. Furthermore, patients in psychopathological research may show deficits in a wide range of tasks for reasons that do not necessarily provide direct clues to their underlying pathology. Prob-

lems of diminished motivation, medication, general energy level, and the like can all impair performance. Because of this, hypotheses that predict that patients will fail to equal control groups in performing a specific task are quite likely to receive misleading support from the data.

Traits and States

Pathological behavior frequently undergoes episodic changes in severity and composition, sufficient at times to warrant discharge from care or to return to care after a previous discharge because some elements of behavior are states that fluctuate over time and others are more permanent traits. The only reliable way to distinguish between these two alternatives is to employ the method of test-retest stability. It is routinely accepted that this be done with formal psychometric tests, such as those of intelligence, but this has been much less often the case with measures developed specifically for psychiatric populations. The method of group comparisons, made cross-sectionally in single time periods, establishes differences between some aspect of the behavior of a group of patients and a group of controls; it cannot establish that the differences obtained are stable and will be found again in the same sample if the comparison is made some time later. Because of this, we can never be sure that a failure to replicate a previous study is due to some methodological flaw in the original or reflects the fact that the behavior under scrutiny is state-like and hence difficult to replicate on demand.

But even more important than the technical questions is the question of functional brain organization itself. Are categories of response that appear similar at the overt behavioral level necessarily mediated by similar topological regions in the brain? What are the conditions under which one part of the brain may take over the functions of a damaged part? What do individual differences in lateralization mean about the brain organization of left-handed and right-handed patients? It is clear that we are making progress in answering these questions, but it is equally clear that a vast territory of information has yet to be acquired.

Brain-Behavior Isomorphism

Neuropsychological and psychophysiological research in schizophrenia seeks to establish the

association between some direct measure of the structure and/or function of the nervous system, on one hand, and either or both of the overt behavior of the patients, measured clinically or in the laboratory, or the patient's conscious experience as described by verbal report. The methods available for assessing brain structure and function are complex. Inferences based on the data produced by these methods rest on assumptions whose validity is sometimes uncertain.

Methods of Measuring Brain Structure and Activity

The techniques of measurement available for use with the biological side of this link include various methods of imaging and quantifying brain structure and processes: electroencephalography (EEG), pneumoencephalography (PEG), positron emission tomography (PET), magnetoencephalography (MEG), computerized tomography (CT), magnetic resonance imagery (MRI), and MRI images taken while the subject is engaged in a specific activity (fMRI). Brain imaging techniques have their own methodological problems, including, for example, such technical questions as the definition of degrees of level of activity in a specific brain area and how the signal is to be separated from noise. Additionally, the measures vary in their spatial and temporal resolution.

Structural and functional neurophysiological measurements have been used in most psychological paradigms in studying schizophrenia. For example, researchers have attempted to improve differential diagnosis, determine subtypes of schizophrenia, distinguish state versus trait attributes, study abnormal psychological processes, study individual symptoms of the disorder, study populations believed at risk of schizophrenia, examine the environmental factors contributing to the disorder, define the course of the disorder, establish treatment efficacy, understand unique aspects of schizophrenia for special populations (e.g., women and ethnic minorities), and understand associated biological processes. Given the broad nature of neurophysiological research, it would be impossible for us to cover all of their applications in studying schizophrenia. Rather, this chapter will focus on the ability of neurophysiological studies to identify and elucidate possible cortical changes associated with schizo-

phrenia. This chapter will also highlight the psychological constructs associated with the regions of the brain in which abnormalities occur.

The Search for Markers

At the outset we assume that individuals who later receive a diagnosis of schizophrenia have a preexisting vulnerability to developing the disorder. These individuals are defined as "at risk" for schizophrenia. Psychopathologists generally hypothesize that there will be signs of the presence of this vulnerability for some time before the onset of the illness. These signs are the "markers" for possible future schizophrenia. Implicit in this model is the recognition that biopsychological markers indicate the possibility, not the certainty, of future illness. In principle, a valid marker ought to distinguish reliably between patients and controls, ought to be present in patients even when their clinical condition has remitted, ought to be present more frequently in relatives of patients, and ought to be present in individuals who show minor subtle features in their perception and thinking that are similar to the more florid symptoms found in patients.

Several methods exist for identifying markers. One is to study the close relatives of patients, especially younger relatives. Because the range of potential biobehavioral features that might be studied is very broad, the usual strategy is to begin by using measures that typically differentiate between schizophrenic patients and the general population. These include measures of language, attention, memory, perception, and so forth.

One example of this approach is the use of the Continuous Performance Test (CPT). This test requires the subject to watch a screen on which stimuli of various kinds appear. Typically these are single digits. All but one of the targets must be ignored. Whenever the designated target appears, the subject must press a button. Stimuli appear briefly (100 milliseconds) at a rapid rate, generally one stimulus per second. Schizophrenic patients have shown defective performance in several studies. The CPT has been interpreted as a measure of sustained attention. Studies of CPT performance have uniformly shown defective performance in schizophrenia patients compared to normal controls. Positron emission tomography (PET) studies suggest that brain activity in normal

subjects during the CPT centers in the prefrontal, temporal, and inferior parietal regions of the right hemisphere (Neuchterlein, 1991).

The performance of the parents and siblings of schizophrenia patients has shown deficits compared to controls (e.g., Mirsky et al., 1992; Steinhauer et al., 1991). Examination of the findings from these and other studies (e.g., Cornblatt & Erlenmeyer-Kimling, 1984; Rutschmann, Cornblatt, & Erlenmeyer-Kimling, 1986) indicate that impaired performance on the CPT by the relatives of schizophrenia patients depends on the complexity of the features of the target stimulus that is to be identified. Simple identification of digits is less effective as a test than the identification of complex patterns. Certain components of the deficit in schizophrenia patients' performance on the CPT continue even when the patient's clinical condition is in remission, leading Neuchterlein (1991) to suggest that the CPT is tapping a stable measure of vulnerability to schizophrenia.

Other tasks that have been successful in distinguishing the at-risk relatives of schizophrenia patients from controls are backward masking and span of apprehension. Backward masking involves presenting a rapid sequence of two stimuli located at the same point in the visual field. If the first stimulus has a very brief exposure, such as 20 ms, it can be recognized, unless followed by a second stimulus after an interval of 100 ms or less. In this case, the second stimulus "masks" the first and is not recognized. The interference in recognition is more marked in schizophrenia patients than in normal controls (e.g., Braff, 1981; Knight, 1990). Green, Neuchterlein, and Breitmeyer (1997) demonstrated impairment in backward masking in the siblings of schizophrenia patients, suggesting that this is another possible marker for vulnerability.

The span of apprehension is measured by the capacity of a subject to detect which of two letters, such as T or F, are present in an array of letters briefly flashed on a screen. One or other of the two letters will be present in each array. Schizophrenia patients have been deficient in this task (Asarnow, Granholm, & Sherman, 1991). Remitted patients continue to exhibit the deficit (Asarnow & MacCrimmon, 1978, 1981).

Now, we turn to the investigation of so-called schizotypal individuals. The concept of the schizotypal individual hypothesizes the presence of individuals who are more likely to develop schizophrenia than members of the general population.

Such individuals do not necessarily have family histories of schizophrenia. They are normally functioning individuals in the general population who report experiences and beliefs (minor aberrations that resemble hallucinations, delusions, and other conscious anomalies) that are similar to some of the more evident symptoms in diagnosed schizophrenia patients. These experiences are assessed on questionnaires that can be easily administered to large samples of the population, particularly the population of late adolescents and young adults who are approaching the age at which the onset of schizophrenia is most common. Typical studies have tended to use university students.

Studies of the CPT, backward masking, and the span of apprehension have been conducted on schizotypal individuals with the following results. Lenzenweger, Cornblatt, and Putnick (1991) reported that students who scored high on a schizotypy scale performed significantly less well on the CPT than low scoring students. Keefe et al. (1997) report the presence of anomalous eye tracking and schizotypal features in the nonpsychotic first-degree relatives of patients. Backward masking deficiency has been reported in schizotypal individuals by several investigators (Balogh & Merritt, 1985; Braff, 1981; Saccuzzo & Schubert, 1981; Steronko & Woods, 1978). The latter two studies investigated individuals who had been hospitalized with a diagnosis of schizotypal personality disorder. The span of attention has been examined in schizotypal subjects by Asarnow, Neuchterlein, and Marder (1983). They reported poorer performance in high schizotypes than in low scorers.

The general picture with regard to these stable neuropsychological markers in schizophrenia has been well summarized by Green (1998). In essence, the findings are that CPT deficit has been found in all four relevant groups (patients with schizophrenia, patients in clinical remission, their siblings and/or parents, and schizotypal individuals). A span of apprehension deficit has been found in three of these groups but has not been tested in relatives. Backward masking deficit has been found in all four groups. What we do not know from these studies is (1) Are there subgroups of individuals within these four groups whose performance is not deficient, i.e., do the data reflect heterogeneity? and (2) What are the direct correlates of performance in these tasks with aspects of brain structure or activity?

Research on this question has sometimes taken the form of a search for heterogeneity within schizotypal samples from whom a range of measures has been taken. Recent examples of this approach are in Voglmaier, Seidman, Salisbury, and McCarley (1997) and in Gruzelier and Kaiser (1996).

In the first of these, Voglmaier et al. (1997) compared the neuropsychological profiles of ten individuals who met the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition, revised (DSM-III-R; American Psychiatric Association, 1987) criteria for schizotypal personality disorder (SPD) with a group of age-matched normal controls. An array of twenty-four tests covering ten domains (e.g., abstraction, verbal intelligence, semantic memory, visual memory, etc.) was administered. Significant differences were found in two of the ten domains; the SPD group was lower than the controls. The two domains were abstraction, measured by the Wisconsin Card Sorting Test (WCST), and verbal learning, measured with the California Verbal Learning Test (CVLT). In both cases, the difference was at or close to two standard deviations below the mean. The study is suggestive, but the authors point out the limitations of sample size, which includes insufficient power to detect small differences and insufficient size to permit any meaningful assessment of heterogeneity. Additionally, the validity of the study is further limited by the fact that it did not use any biopsychological measure.

Gruzelier and Kaiser (1996) examined the relationship between schizotypy and the onset of puberty. They were guided by the hypothesis that schizophrenia is a disorder related to the termination of the cortical pruning process, whereby synaptic connections are progressively eliminated during adolescence. This process, it is supposed, is terminated by the processes of puberty and maturation into adulthood. Schizophrenia, postulated by Saugstad (1994), is a disorder of late maturity and is characterized, therefore, by low synaptic density, because the pruning process has continued longer than normally. Affective disorders, on the other hand, are attributed to unusually early maturation and its concomitant excessive density of synaptic connections. Sex differences in the major psychoses are consistent with this formulation. Men mature later than women and, according to this model, are therefore more likely to develop schizophrenia. Women on the other hand would be

more likely than men to develop affective disorders (Lewine, 1981; De Lisi, Dauphinais, & Hauser, 1989).

Gruzelier and Kaiser offered a modified version of this model. They began with the concept of a three-syndrome classification of the clinical states in schizophrenia. These are the Unreality syndrome, which in schizotypy would be associated with unusual perceptions, magical ideation, and in the psychotic state would include delusions and hallucinations early and late. This syndrome, they suggest, is associated with both extremes of maturation. The Withdrawn syndrome in schizotypy includes social and physical anhedonia that could be associated with early puberty, if depressive in character, or with late puberty if schizophrenic withdrawal was the primary feature. The third syndrome, the Active syndrome, shares some features of hypomania seen in bipolar affective disorder, but are also found in one syndrome of schizophrenia (Hoffman et al., 1986).

With this background, Gruzelier and Kaiser selected three groups, each composed of men and women. These were classified as early, normal, or late maturers. Maturation was defined by the age at growth spurt and menarche in females. In males, it was defined by the age at growth spurt, the age of the first nocturnal emission, and the age at shaving. Composite scores show the expected difference between females and males; the former reached maturity approximately three years earlier than the latter. Schizotypy was measured with the Schizotypy Personality Questionnaire (SPQ) or Raine (1991). The results of this investigation showed that there were significant interactions between gender, age at maturation, and the syndromal features of the schizotypal responses made by the participants. They concluded that the age of onset of puberty is one of the significant components of the determinants of schizophrenia but that the Saugstad model does not fit the data. At this point, it will be helpful to present a summary of the processes that are measured with these methods.

Electroencephalography

The neurons in the brain are constantly firing and can be recorded as electrical potentials from the scalp or directly from the brain. The recording of such electrical potentials via electrodes is called electroencephalography or EEG. EEG, it is thought, reflects the summation of large numbers of neu-

rons whose synchronous firing from cortical and/or subcortical regions is probably controlled by corticothalamic neurogenerators. The frequency of the electrical activity generally varies according to the degree of psychological arousal. Within this model, it is thought that the more active or aroused a given region of the brain, the faster the frequency of the sinusoidal waveforms; the less active a given region of the brain, the slower the frequency. For example, beta (12–28 Hz) is noted during activation and alpha (8–12 Hz) is noted during relaxation. EEG is generally discussed in terms of the power of a given frequency in a particular region of the brain or in terms of abnormal patterns of response.

Event-related brain potentials are a class of EEG characterized by voltage changes that are time-locked to stimulus presentation or to other relevant events. They are composed of components that, it is thought, reflect specific psychological processes. There are two general types of ERPs, either event-preceding or event-following. Event-preceding ERP components, it is thought, reflect brain activity that is produced in anticipation of an event, and event-following ERP components, it is thought, reflect brain activity that is produced as result of stimulus presentation. Embedded within these temporal categories are psychological categories of ERPs: exogenous and endogenous. Exogenous ERPs, it is thought, reflect changes in the stimulus properties of events. Endogenous ERPs, it is thought, reflect the interaction of the subject with the event. ERPs are generally displayed in a voltage \times time function. Positive and negative voltage peaks represented in voltage \times time functions are usually characterized by differences in polarity, latency, and voltage. For example, the N200 component of the ERP has a negative shift in polarity and a specific voltage that occurs approximately 200 ms after an eliciting event. Before being statistically analyzed, these voltage changes are subjected to mathematical computation, typically averaging, to enhance the signal-to-noise ratio.

It has been suggested that ERP studies can make a unique contribution to the study of schizophrenia (Roth et al., 1988). Relative to positron emission tomography (PET) and function magnetic resonance imaging (fMRI), scalp recorded ERPs have much better temporal resolution and more thoroughly established substantiation of association with specific psychological processes. However,

ERPs have relatively worse spatial resolution. Except for magnetoencephalography (MEG), EEG and ERPs are the only imaging methods that measure neuronal activity directly as opposed to indirect measures of activity of blood flow via PET and fMRI. Nevertheless, because neuroanatomical generators have been proposed—though in most cases not confirmed—for most ERP components, ERPs can be used to localize and categorize abnormalities associated with schizophrenia. For example, if an ERP component distinguishes patients with schizophrenia from controls, impairment in the region generating that ERP component is implied.

Magnetic Resonance Imaging

Magnetic resonance imaging of the brain (MRI) refers to a group of procedures that employs common hardware, but has somewhat different emphases. It applies the principles of what is known about nuclear magnetic resonance (NMR) to human physiology. Initially, NMR was used to study various properties of nonorganic objects, providing information about the structural and chemical attributes of these objects. The details of the procedure can be found in De Lisi (1991) and in Coffman and Nasrallah (1986). When employed in the study of brain activity while the patient is engaged in some activity such as speaking, recalling, or identifying stimuli, it is referred to as functional MRI or fMRI.

Examples of the use of MRI to study schizophrenia are found in investigations of patients brain volume and brain volume ratios (e.g., Andreasen, Nasrallah, Dunn, Olsen, Grove, Ehrhardt, Coffman, & Crossett, 1986), and of the use of fMRI to study patient brain activity during verbal production (e.g., Yurgelun-Todd, Wateriaux, Cohen, Gruber, Camper, English, & Renshaw, 1996).

Positron Emission Tomography

Positron emission tomography (PET) measures blood flow by tracing the movement of radioactively labeled substances (oxygen or deoxyglucose) through the body. Brain activity uses oxygen, so that loci of increased activity are reflected by greater rates of oxygen metabolism in the region of the activity. The major limitations of this method are that it is invasive (the labeled substances have to be injected into the patient), it

requires the nearby availability of the cyclotron to create the labeled substances, it is expensive, and its capacity to detect rapid activity of brief duration is less than that of either EEG or MRI. A simpler method that embodies the same basic principle as PET is single photon emission cerebral tomography (SPECT) which is less expensive, does not require proximity to a cyclotron and, although it gives a cruder image, is adequate to examine activity in various brain regions.

In the ideal study, direct imaging of the brain and neuropsychological measures are combined. Such studies are costly and complex and are typically confined to limited sample sizes. Because of this, it is common to seek associations between neuropsychological tests believed to reflect a specific regional brain function and other behaviors of interest, from gross diagnostic status to performance in specific behavioral tasks. The obvious advantage of this is that neuropsychological tests are easier and much less expensive to administer and that this may compensate somewhat for the question of their validity as measures of the physical aspect of brain structure and function. However, the disadvantage lies in this invalidity because even large validity coefficients between test performance and brain measurements may translate into a significant potential for error.

Raine et al. (1993) provide an example of the first kind of study. The volume of the prefrontal areas of the brain was assessed with MRI in seventeen schizophrenia patients, eighteen nonschizophrenia psychiatric controls, and nineteen normal controls. These groups were also assessed by three neuropsychological measures, the Wisconsin Card Sorting Test (WCST), the Spatial Delayed Response Matching Test (SDRMT), and the Block Design. The results indicated that schizophrenic patients had smaller frontal areas than either of the two control groups. A comparison of differences in the posterior area of the brain revealed no differences among the three groups. Performance on the three neuropsychological tests were partially parallel to the MRI findings. The main difference was that the WCST discriminated schizophrenics from normal controls, but not from other psychiatric patients. The same was true of the SDRMT. Only the Block Design discriminated between schizophrenic and the other two control groups. No correlation was found between the individual MRI measures and the individual neuropsychological measures.

The investigators point to biasing factors such

as the composition of the schizophrenic sample (mainly paranoid schizophrenia), but it is clear that there is a limit to the possible validity of neuropsychological tests as measures of frontal lobe size. Findings of this kind are not uncommon and point to the constraints that exist in trying to establish brain-behavior relationships, using only behavioral measures.

Measurement of brain structure and function may involve many derivative measurements. The absolute size of a brain area may be less predictive of some specific behavior than the ratio of this size to the size of the brain as a whole or to some other brain region with which it is connected. This consideration is complicated further by the hemispheric asymmetry of the human brain, a factor that is discussed extensively later in this chapter in relation to anomalies of cerebral lateralization.

In this general connection we note the problems that exist with a priori assumptions about brain functions that are tapped by a specific test. A simple reaction time task, in which the respondent is instructed to press a key when a light appears, requires maintaining attention in the interval before the light appears, sensory efficiency in detecting the light when it does appear, effectively initiating the central motor program that produces the tapping response, and efficient peripheral motor output of the response itself. This seemingly simple task involves several different brain regions, and it is clear that a defect in any one of them or in the connections between them may lead to a defective response. We now turn to research on particular brain regions in relation to schizophrenia.

Neuropsychological Profiles in Schizophrenia

Studies of neuropsychological functioning in schizophrenia have identified an array of deficits. These include impairment in abstraction, attention, language, verbal learning, and memory, as well as impairment in motor functioning. The relevant studies are contained in a very large and complex literature. Several strategies have been employed to provide a framework for interpretation that would allow us to hypothesize a smaller number of neurological loci for the complex of impairments.

One approach has been to hypothesize a typology of schizophrenia that could be tested against the correlated clusters of symptoms and quantitative measures that are found in the literature. An

example is provided by the work of Liddle (1987) and Liddle and Morris (1991). Liddle proposed that symptom measures in schizophrenia can be subsumed under a three-domain model. The three domains are psychomotor poverty (i.e., poverty of speech, decreased spontaneous movements, and blunting of affect), reality distortion (hallucinations and delusions), and disorganization (thought disorder, inappropriate affect, and poverty of content of speech). To each of these three domains, he assigns a putative dysfunction of brain areas. They are psychomotor poverty—the dorsolateral prefrontal cortex; reality distortion—the medial temporal lobe, and most probably the left medial temporal lobe; and disorganization—the mediobasal prefrontal cortex. Attempts to validate this model have been largely unsuccessful (Liddle, 1987; Liddle & Morris, 1991; Norman et al., 1997). However, the data of Norman et al. did support one component of the model, namely, the relationship between reality distortion and verbal memory. This suggests the possibility of temporal lobe involvement and also of frontal lobe involvement. The other two components of the model received no support.

A second approach begins with the fact that the core neuropsychologies in schizophrenia are difficult to disentangle from the effects of medication, age, length of hospitalization, gender, and other secondary adaptations that the patient makes to the limitations imposed by the illness. In the light of this, there is a promising possibility in the study of individuals at risk for schizophrenia, such as family members, as well as individuals in the general population who meet the criteria for schizotypy. These investigations can be collectively gathered under the rubric of the search for markers of schizophrenia discussed in detail later in this chapter.

General EEG Dysfunction

It has been established that a significant proportion of patients with schizophrenia have abnormal EEG activity. For example, John et al. (1994) reported that the existing literature demonstrates that 10–80% of schizophrenic patients have non-specific abnormal brain electrical activity; epileptiform activity, including sharp waves and paroxysmal episodes, is found in as many as 25% of patients studied. In addition, it has been established that patients with schizophrenia have abnormalities in the frequency distribution of their

brain activity. For example, such patients have increased beta, delta, theta, and decreased alpha, whether or not they were first episode or chronic patients, suggesting that it is a stable characteristic of the disorder (Sponheim, Clementz, Iacono, & Beiser, 1993).

It is important to note that these abnormalities have not yet been correlated with overt psychotic symptoms. For example, Stevens et al. (1979) observed behavior while schizophrenic patients' EEGs were collected and transmitted by radio for analysis. In this study, about 40% of the patients demonstrated abnormal activity such as slow waves and spikes. This abnormal activity did not, however, coincide with episodes of abnormal behavior such as hallucinations, stereotypy, catatonia, psychomotor blocking, and other clinical manifestations of schizophrenia. At the most general level, we consider the significance of cerebral lateralization.

Cerebral Lateralization

Anomalous Lateralization

There has been a long-standing interest in the role of anomalous cerebral lateralization in at least some schizophrenia patients. This interest is consistent with early reports that there is a greater incidence of left-handedness and mixed-handedness as well as left-footedness in the population of schizophrenia patients than in the general population (Boklage, 1977; Chagule & Mater, 1981; Dvirskii, 1976; Gur, 1977; Piran, Bigler, & Cohen, 1982; Shan-Min, Flor-Henry, Dayi, Tiangi, Shu-guang, & Zenxiang, 1985). This is so particularly in male schizophrenia patients (Nasrallah, Keelor, Van Schroeder, & McCalley-Whitters, 1981; Taylor, Brown, & Gunn, 1983; Walker & Birch, 1970). These observations are consistent with the general tenor of those findings, but it should be noted that they properly refer to some schizophrenia patients. Most schizophrenia patients do not exhibit manifest anomalies of lateralization. For this reason, we shall consider the subset of patients with left- or mixed-lateralization as a subtype of schizophrenia with possible specific demographic and prognostic neuropsychological features.

The Measurement of Lateralization

The measurement of lateralization (or the degree of lateral dominance) is a complex matter.

Four different kinds of measures have been employed: preference measures, performance measures, measures of brain structure, and measures of brain activity.

Preference Measures. The crudest form of measurement is the simple classification of individuals by the hand preferred for writing. More sophisticated versions of the preference criterion employ self-report questionnaires asking the respondent which hand is used for each of several different tasks. (Which hand do you write with? In which hand do you hold a scissors when cutting? Which hand do you use to throw a ball?) Examples include the Annett Scale (Annett, 1970) and the Edinburgh Scale (Oldfield, 1971), amongst others. Chapman and Chapman (1987) reported a correlation of .83 between a self-report scale of this kind and the actual behavior of subjects when performing the tasks to which the self-report items referred. This is a substantial coefficient but suggests that self-report measures should be interpreted with caution. In this and other studies, participants who describe themselves as left-handed are likely to turn out to be more mixed-handed than participants who describe themselves as right-handed.

Performance Measures. Any one preference item necessarily divides respondents dichotomously into left or right; in an occasional case, a respondent reports using either hand for a task. In performance measures, the investigator directly measures the effectiveness with which each hand performs a similar task. The measure of lateral dominance is then computed by subtracting the performance score with one hand from the score with the other, and then dividing the result by the sum of the two scores $(L-R)/(L+R)$. This gives the relative difference in performance in percentage terms, corrected for the absolute magnitude of the scores themselves. Examples of measures of this kind include varieties of pegboard tasks, which assess speed and accuracy in placing wooden pegs in sequence in a row of holes, placing dots in printed squares, finger tapping, and accuracy with which straight lines can be drawn with each hand.

Preference and performance measures give a different picture of the distribution of laterality. Preference measures typically produce a J-curve where very few people are mixed-handed and most are highly right-handed or somewhat left-handed (e.g., Borod, Caron, & Koff, 1984; Maher & Manschreck, 1998). Performance measures, in contrast, give a distribution that is approximately

Gaussian, but there is a peak around moderate right laterality. All in all, the data from either type of measure suggests that laterality of manual performance is essentially a continuum stretching from one extreme to the other, and the bulk of cases are somewhere in the middle.

The correlation between dominance measured by the Annett preference scale and the dominance ratio calculated from the line drawing test developed by Maher (Blyler, Maher, Manschreck, & Fenton, 1997) was +.48 (Maher & Manschreck, 1998). Although statistically significant, it is clear that the association between the two kinds of measures reflects only modest common variance and that important relationships between laterality and schizophrenic pathology may not be detected as readily with one as the other.

The intercorrelations between various kinds of manual performance measures are not high, and it is clear that factors specific to the kind of task that is used affect the dominance ratios that are obtained (Borod, Caron, & Koff, 1984). Many questions must be raised about the validity of any of these measures as a valid index of cerebral dominance. The situation has been summed up by Bryden, Bulman-Fleming, and MacDonald (1996), "... handedness is a multidimensional skill. It remains uncertain which dimension is most critical and for what ... if the goal is to predict something about the pattern of cerebral organization, then it is more open to question which aspect of handedness is the most appropriate to measure" (p. 66). However, this question is of lesser concern to psychopathologists who seek to delineate the boundaries of clinically and experimentally measured differences in laterality within the population of schizophrenia patients. Once these are established, their relationship to the putative pathology of cerebral organization becomes the ultimate question.

Manual Laterality and Schizophrenia

Handedness and Thought Disorder

Some investigators have turned to the task of identifying what differences of functions, if any, that are relevant to the diagnosis of psychopathology exist between left-handed and right-handed schizophrenia patients when assessed clinically

and in the laboratory. Language functions are generally chiefly mediated by areas of the left hemisphere, suggesting that disruption of left-hemisphere function is likely to have consequences in disrupting language as well as impairing right-hand functioning. Because of this, attention has been directed to the possible connection between verbal behavior and left-handedness in schizophrenia. Taylor, Brown, and Gunn (1983), Manoach, Maher, and Manschreck (1988), and Manoach (1994) reported significantly greater disturbances of language and thought in left-handed compared to right-handed schizophrenia patients. Handedness in these studies was defined as the hand used in writing.

Perseveration (Verbal Repetition)

The production of repetitive perseveration in an array of activities has long been one of the common elements in describing schizophrenia. In summing up the literature on this topic, Crider (1997) concluded that perseveration covaries with positive thought disorder and disturbances of voluntary motor activity. In a study of dominance ratios in the line-drawing task and language production, Maher and Manschreck (1998) reported that there were positive correlations between dominance ratio and repetitions of word types ($-.605$), repeated words ($-.46$), and repeated phrases ($-.43$) in left-handed (by preference) schizophrenia patients. No such correlations were found in the sample of right-handed schizophrenia patients.

Memory

In an investigation of handedness and verbal memory, Manschreck, Maher, Redmond, Miller, and Beaudette (1996) matched left-handed and right-handed patients for performance on immediate recall in a simple verbal memory task (recall of a list of unrelated words). The two groups showed significant differences in their ability to improve their recall performance for word lists increasingly approximating sentence structure. This difference cannot be readily explained as a general impairment in verbal memory because the groups were matched on this variable, but more plausibly as an impairment in using context as an aid to memory organization. This impairment has been noted in samples of schizophrenia patients not differentiated by handedness (e.g., Gerver,

1967; Truscott, 1970; Williams, 1966). An additional analysis of the same data indicated that the poorer recall performance of left-handed patients was significantly correlated with the presence of thought disorder in the left-handed group, but not in the right-handed group.

Neuropsychological Aspects of Anomalous Lateralization

Underlying the various reports of anomalous lateralization of performance and preference in schizophrenia patients is the assumption that this arises from some neuropathology that disturbs the normal dominance relationship between the two hemispheres. Two broad possibilities exist. One is that there is a group of schizophrenia patients in whom a biological anomaly (possibly but not necessarily of genetic origin) has led to failed development of normal hemispheric asymmetry. The other is that some early exogenous unilateral damage to the brain has occurred. This possibility envisages perinatal injury, infections or toxic insults, and other such factors that play a role in the genesis of disrupted hemispheric dominance.

Crow's Hypothesis

One of the most prominent hypotheses of a possible developmental anomaly was presented by Crow and his colleagues (Crow, 1990; Crow, 1995; Crow, Colter, Frith, Johnstone, & Owens, 1989; Crow, Done, & Sacker, 1996; De Lisi, Sakuma, Kushner, Finer, Hoff, & Crow, 1997). Their model proposes that there is a developmental anomaly of genetic origin whereby the normal processes of the development of cerebral asymmetry are impaired. The second decade of life is the period during which the neurodevelopmental processes occur that lead to the emergence of normal hemispheric asymmetry. These processes include the synaptic pruning that has been discussed earlier. The developmental process is usually completed by the end of adolescence (Buchsbaum, Mansour, Teng, Zia, Siegel, & Rice, 1992b; Feinberg, 1982). Benes (1989) reported that this timing for the maturation of the brain is especially the case for the frontal and temporal areas. Normal asymmetry most often consists of left hemisphere dominance but can consist of right hemisphere dominance. Crow's model proposes that the hypothesized genetic anomaly leads to a failure to

achieve clear dominance by adulthood. At this point, the effects of this failure become manifest in the behavior of the patient, ultimately leading to the diagnosis of schizophrenia. Therefore, such patients would be most likely to have an early onset. Because the failure to achieve dominance involves the failure of left-hemisphere dominance, language disturbance inevitably becomes a major component in the pathology of schizophrenia. Finally, the model suggests that the genetic disorder is sex-linked and males are more at risk.

Postmortem studies of lack of normal asymmetry have been reported by Falkai et al. (1992), and lack of asymmetry in brain activation was reported by Buchsbaum et al. (1982) and Rossi et al. (1992). Maher, Manschreck, Yurgelun-Todd, and Tsuang (1998) report a volumetric MRI study of the brains of a sample of sixteen schizophrenia patients. Substantial lack of asymmetry in the frontal and temporal areas was found in some patients and was also correlated with age of onset. With a frontal volume dominance ratio, the age-corrected correlation with age of onset was .616 ($p = .01$) and with temporal volume .479 ($p = .05$). This finding is clearly consistent with Crow's hypothesis.

We cannot assume a priori that morphological symmetry will necessarily be reflected in performance symmetry. However, lack of normal asymmetry of manual performance at the age of 11 years was associated with the subsequent onset of schizophrenia in a large scale birth-cohort study of 16,980 persons reported by Crow, Done, and Sacker (1996). In this study, no such lack of manual asymmetry was found in individuals who were later diagnosed with affective disorders or with personality disorders.

All in all, it seems reasonable to conclude that the evidence to date pertinent to Crow's hypothesis is predominantly supportive. In saying so, we remind ourselves that many schizophrenic patients in these studies do not show anomalous asymmetry in either preference, performance, or brain structure. This, in turn, echoes our comments at the beginning of this chapter, namely, that schizophrenias are a heterogeneous group of disorders with some common features. Given this, we should not be overly optimistic about the possibility or usefulness of trying to seek a grand, unifying, reductionist model of the biopsychological aspects of this group of disorders.

Other Measures of Asymmetry in Schizophrenia

The preceding discussion has centered on brain morphology and manual preference and performance as the core area in which asymmetry might be found. Other studies examined the laterality aspects of such performance as visual recognition of verbal and spatial information. Studies of normal performance in recognition in these tasks has indicated that the left hemisphere is involved in processing verbal information and the right hemisphere in processing spatial information. Studies of left-hemisphere advantage in schizophrenia patients produced inconsistent findings (Gur, 1978; Colbourn, & Lishman, 1979; Pic'1, Magaro, & Wade, 1979; Connolly, Gruzeliel, Kleinman, & Hirsch, 1979; Magaro & Chamrad, 1983; George & Neufeld, 1987; Merriam & Gardner, 1987). The general tenor of these findings indicates a deficient left-hemisphere advantage which is consistent with findings of diminished left temporal lobe size. These findings are discussed later under the section dealing with the general topic of temporal lobe anomalies. However, there are inconsistencies in the findings of these studies that are related to variations in the subtype of schizophrenia involved, sample differences in gender, and differences in the kinds of tasks employed. In one recent study, Bruder et al. (1995) reported that a sample of thirty-two schizophrenia patients displayed a smaller right-ear (left-hemisphere) advantage in a dichotic listening task, compared to depressed patients. The smaller advantage was unchanged by the presence or absence of neuroleptic administration and did not depend on gender. This study did look at heterogeneity within the schizophrenic sample and reported significant negative correlations with right-ear advantage and the negative symptom of stereotyped thinking and with the positive symptom of hallucinations. This latter finding is consistent with the findings of Barta et al. (1990) discussed later, in which the same result was obtained when correlating severity of hallucinations with the volume of the left temporal gyrus. Performance measures that offer more consistent findings were reported for right-hemisphere processing of spatial information. Gur (1978), Connolly et al. (1979), George and Neufeld (1987), and Ellis, de Pauw, Christodoulou, Papegeorgiou, Milne, and Joseph (1993) all found that the right hemisphere advantage was preserved in schizo-

phrenia patients in processing spatial visual information.

In a recent study, White, Maher, and Manschreck (1998) reported that the expected right hemisphere advantage in a facial recognition task was not present in schizophrenia patients. However, when the patients were differentiated on the basis of the presence of perceptual aberration, there was a strong negative correlation (-0.685) between the perceptual aberration score and a reversal of the normal right-hemisphere advantage. Patients with perceptual aberration showed a left-hemisphere advantage in facial recognition. Patients without perceptual aberration and normal controls showed the expected right-hemisphere advantage. This study underlines once again the importance of seeking the axes of possible heterogeneity in schizophrenic samples.

We turn now to consider general regions of the brain. The division by regions is adopted for convenience in discussion. In dividing our discussion in this way, we remind ourselves that the regions in question are connected reciprocally in many ways. Individual research reports frequently examine multiple regions and report on the interactions between them. Therefore, our decision to cite them under one of the following headings is based on the relative emphasis given to the area by researchers. It is hoped that this organization will have practical usefulness for the reader without distorting the real complexity of the brain structures involved.

The Investigation of Regions of Interest in the Brain

The Prefrontal Cortex

The prefrontal cortex is a collection of areas that lies immediately in front of the premotor cortex of the frontal lobe. Its function has been variously described but can be summed up as the one area of the brain that receives information about the external environment and mediates the exchange of this information with neural connections from the internal structures of the brain. It is clear that this makes the question of neuropathology in the prefrontal cortex particularly critical for maintaining organized adaptive behavior in the human being. This crucial role of frontal processes is sometimes summed up by referring to it as the seat of the "executive functions" in the brain.

There is a plethora of evidence that implicates the frontal lobes in the pathology of schizophrenia. Particular attention has been paid to the prefrontal cortex (PFC) and especially to the dorsolateral component of that area (e.g., Berman, Zec, & Weinberger, 1986; Bogerts, 1993; Buchsbaum et al., 1992; Liddle et al., 1992). Adults who suffer lesions in the PFC exhibit some of the characteristics that appear in some schizophrenics, notably the so-called negative symptoms.

Frontal abnormalities in cerebral metabolism were reported by Buchsbaum et al. (1982) and Farkas et al. (1980). Other studies reported abnormalities in regional cerebral blood flow (Berman et al., 1986; Franzen & Ingvar, 1975a,b; Weinberger et al., 1986). Investigators employing neuropsychological tests reported a broad spectrum of findings of anomalous performance. An extensive review is in Goldberg and Seidman (1991).

Many investigators suggested that frontal dysfunction plays a part in memory defect in schizophrenia. A review of these studies was provided by Goldman-Rakic (1991). In a more recent MRI study, Maher, Manschreck, Woods, Yurgelun-Todd, and Tsuang (1995) examined the effect of the ratio of frontal brain volume to that of the brain as a whole in eighteen schizophrenic patients in a memory task that included context-aided and non-context-aided word lists. Absolute frontal volume was not correlated with performance in either kind of task, but relative volume was strongly correlated with context-aided memory ($r = .637, p < .01$). It was not correlated with non-context-aided verbal recall. Correlations with other brain regions produced no significant associations. The significant correlation was attributable mainly to the relative size of the dorsolateral area; the correlations with dorsomedial and orbital areas were negligible. This study points to the importance of examining brain ratios in both structure and function (as is the case in the studies of laterality already described) and the importance of focusing on correlations within samples of schizophrenic patients, rather than focusing exclusively on mean differences between comparison groups.

Frontal and Prefrontal Dysfunction and ERPs

Three ERP components may be generated in the frontal or prefrontal regions: postimperative negative variation (PINV, e.g., Klein, Rockstroh, Co-

hen, & Berg, 1996), contingent negative variation (CNV, e.g., Rosahl & Knight, 1995), and P3a (Knight, 1990). CNV, it is thought, is made up of an early (O-wave) component that reflects sensory processing and orienting and a late (E-wave) component that reflects expectancy or motor preparation (Loveless & Sanford, 1974). The psychological interpretation of PINV is less clear, though it is probably related to performance and action uncertainty, as well as control and contingency expectation (Klein, Rockstroh, Cohen, Berg, & Dressel, 1996). P3a, it is thought, is related to novelty stimulus processing (Squires, Squires, & Hillyard, 1975) and has not been studied frequently in schizophrenia. As a guide to the reader, the major ERP components and their functions are presented in Table 1.

CNV and PINV have been studied frequently in patients with schizophrenia and have revealed a relatively consistent pattern of frontal CNV decrements, PINV enhancements, and posterior CNV and PINV normality (for a review, see Pritchard, 1986; for inconsistent results, see Strandburg et al., 1994; van den Bosch, 1983). Patients with schizophrenia have shown unusual CNV and PINV topographical distribution over the frontocentral vertex (Eikmeier & Lodermann, 1994) that suggests inefficient information processing where inadequate frontal functioning commands excessive frontal (relative to central) cortical activation (van den Bosch et al., 1988).

PINV enhancement and CNV decrements are associated with an increase in psychotic symptoms such as emotional withdrawal, incongruous affect, hallucinations, ideas of reference, and a decrease in affective symptoms such as depressed mood, anxious depression, and guilt (for a review, see Pritchard, 1986; Chouinard, Annable, & Dongier, 1977; Eikmeier & Lodermann, 1994; Bachneff & Engelsmann, 1980; Dongier, Dubrovsky, & Engelsmann, 1977).

Frontal ERPs are uniquely associated with hallucinations. For example, up to 95% of hallucinating patients with schizophrenia have an enhanced PINV (Dongier, Dubrovsky, & Engelsmann, 1977). Additionally, Turetsky, Colbath, and Gur (1998) found that changes in frontal P300 over time were highly inversely related to the severity of auditory hallucinations.

The role of the frontal lobe in negative symptoms is captured by the fact that the difference in amplitude between Fz and Cz for the PINV and

CNV is related to anergia, Scale for the Assessment of Negative Symptoms (SANS) total and SANS affective flattening, alogia, and anhedonia, but this difference is negatively related to symptoms of depression, hopelessness, and asociality (Eikmeier & Lodemann, 1994; van den Bosch et al., 1988). However, it is important to note that some researchers have found no correlation of negative symptoms with PINV (Eikmeier et al., 1992).

There are some hints in the literature that frontal lobes might be modulating ERP attentional decrements typically seen in patients with schizophrenia, even though the components themselves are probably not generated in the frontal lobes. P200 amplitudes, for example, are reduced over frontal brain regions during performance of the SPAN task (Sponheim & Kodalen, 1998). PNs are reduced particularly at the frontal leads (Ward, Catts, Fox, Michie, & McConaghy, 1991), and bilateral N100 amplitudes are reduced at frontocentral sites (Tenke, Bruder, Towey, Leite, Malaspina, Gorman, & Kaufmann, 1992). The amplitude of these components, P200, N100, and Processing Negativity (PN), it is thought, reflect early stimulus processing and selective attention, and they are probably generated, at least in part, by auditory stimuli in the auditory cortex. As discussed in detail later, the frontal lobe probably plays at least a modulatory role in generating PN (Knight, Hillyard, Woods, & Neville, 1981) and P200 (Picton, Hillyard, Krausz, & Galanbos, 1974; Shenton et al., 1989) that may account for group differences found in the frontal lobes.

In summary, frontal dysfunction in schizophrenia is suggested by reduced early CNV amplitude and enhanced PINV amplitude. These differences are evidence of frontal lobe dysfunction in patients with schizophrenia for two reasons: (1) the greatest differences between controls and patients with schizophrenia tend to be in the frontal region and (2) PINV and CNV are likely to be generated over broad frontocentral regions. Additionally, PINV and CNV abnormalities have been related to hallucinations, negative symptoms, and possibly attentional problems. The conclusion that negative symptoms are related to frontal lobe ERP activity agrees with a recent comprehensive study by Gerez and Tello (1995) that concluded that electrocortical variables associated with frontostriatal abnormalities are most related to negative symptoms. Having affective symptoms provides

Table 1. The Major ERP Components and Their Functions^a

Component	Proposed cortical generator	Psychological or mental operation
Lateralized readiness potential (LRP)	Motor cortex	Motor preparation
Motor potential (MP)		
Readiness potential		
Contingent negative variation (CNV)	Cerebral cortex (when excitatory signal from thalamus depolarized neurons over extensive frontal regions)	O wave = orienting, sensory processing E wave = expectancy or readiness or motor prep.
Early "O-wave"		
Late "E-wave"		
Postimperative negative variation (PINV)	Frontocentral cortical structures	Prolongation of CNV State marker for general psychopathology Performance and action uncertainty Sensory perception, attention, time estimation and processing of control and contingency expectation
Brain stem (ABR or BAER)	I Distal eighth nerve II Proximal eighth nerve III Cochlear nucleus-trapezoid body IV Superior olivary complex V Lateral lemniscus termination in inferior colliculus VI & VII thalamus (medial geniculate body) to auditory cortex or inferior colliculus	Sensory processing of auditory stimulation
P50	Left and right planum temporale or hippocampus	Sensory gating
N100	Primary auditory cortex in temporal lobe	Selective attention (early selective processing and early stimulus encoding)
P200	Inferior parietal gyrus, auditory temporal cortex, temporoparietal junction	Selective attention, stimulus encoding
N200a and MMN	MMN-superior temporal plane—specifically the superior temporal gyrus	MMN-mismatch detector N2a: automatic mismatch detector
N2b (auditory)	Auditory cortex	Deviant stimulus classification (controlled processing)
N2b (visual)	Prestriate cortex of occipital lobe	
P3a	Frontal lobes, prefrontal cortex, amygdala	Mismatch detector Attention switch Orienting
P3b	Hippocampus, temporoparietal junction	Context updating, encoding
N400	Temporal lobes and surrounding areas	Semantic congruity and expectancy

^aIt is important to note that although these generators have been proposed, most are not universally accepted. Rather, the purpose of this table is to provide a reference for the current state of knowledge, and it should be interpreted with caution.

some protection from these types of frontal abnormalities, presumably due to subtyping differences in patients with affective symptoms. The frontal CNV dysfunction provides convergent evidence of a link between the frontal lobe and orienting deficits. Although the exact psychological significance of PINV is unknown, it may be related to sensory perception, attention, control and contingency expectation, all of which, as has been previously shown, are deficient in patients with schizophrenia and are related to frontal lobe functioning.

At this point, it is clear that the frontal areas of the brain are reliably implicated in the group of disorders that constitute schizophrenia. However, although variations in the Coffman structural features already described (relative frontal volume and lack of frontal hemispheric asymmetry) play a part in the pathology of schizophrenia, we have no clear hypotheses about the heterogeneity that underlies these variations.

The Temporal Lobe

Disturbances of language and (by inference, from language) thought provide the core of the clinical phenomena that lead to the diagnosis of schizophrenia. The temporal lobe has a central place in organizing language functions in the brain, and it is here that many biopsychologists have turned in their search for the pathology. Changes in the size of temporal lobe structures are closely connected to changes in the size of the ventricles of the brain. Relative ventricular size is computed by the ratio of ventricle size to whole brain size, the ventricle/brain ratio (VBR).

Results of several MRI studies may be summarized by saying that the left temporal lobe of schizophrenia patients, as has often been shown, is smaller than the right temporal lobe (e.g., Coffman et al., 1989; Crow, 1990; Rossi et al., 1990a,b) and that a parallel enlargement of the size of the left ventricle has sometimes been observed. The question to which this gives rise is whether the enlargement of the ventricle is a by-product of the reduction of adjacent cortical structure (or vice versa) or whether both processes have autonomous pathological origins. However, some studies have found the opposite effect, that is, enlargement of the right temporal cortex, and it appears that different effects may be related to differences in the handedness of the patients. An interesting finding by Barta et al. (1990) is that the volume of the left

superior temporal gyrus was inversely related to the severity of hallucinations. This is consistent with the report of Grove and Andreasen (1991) that patients with enlarged VBRs tended to produce negative symptoms, such as catatonia, and patients with small VBRs produced positive symptoms, such as hallucinations and delusions.

With this exception, neuroimaging studies of temporal lobe and ventricular anomalies in schizophrenia have paid little attention to heterogeneity within schizophrenic samples and have been content to measure gross volume or activity levels in comparison with control samples. At this point, it is reasonable to be confident that with more attention to heterogeneity, we will be better able to understand the significance of these biopsychological findings.

Temporal Dysfunction and ERPs

There has been a flurry of activity examining temporal lobe functioning via event-related brain potential techniques. Components (i.e., P50, N100, P200, N200, and P3b) that are likely to be generated in or near the temporal region have consistently demonstrated reductions in amplitudes of patients with schizophrenia relative to controls. This reduction is not related to general functioning but rather to more specific symptoms of schizophrenia, particularly thought disorder.

P50. The ratio of P50 amplitudes in a conditioning testing paradigm is said to be enhanced in patients with schizophrenia (Adler, Pachtman, et al., 1982). This paradigm involves presenting two brief auditory stimuli in pairs (usually 50 ms apart) with long interpair intervals. P50 is reportedly generated in the hippocampus, superior temporal gyrus (STG) (Freedman et al., 1991), or planum temporale (Reite, Teale, Neumann, & Davis, 1987). Although P50 is usually reported in terms of conditioning/testing ratios, both S1 and S2 are reduced in patients with schizophrenia (e.g., Adler, Hoffer Griffith, Waldo, & Freedman, 1992). Recent work (Zouridakis, Boutros, & Jansen, 1997) has demonstrated that there is a decrease of P50 elicited by S1 in patients with schizophrenia and no further decrease is elicited by S2. The difference in amplitude between the groups is related to the fact that the P50 elicited by S1 is highly synchronized in controls but not in patients. The reduction in P50 elicited by S2 in both patients with schizophrenia and controls results from de-

synchronization of latency. However, patients with schizophrenia may also have higher S1 P50 trial to trial latency variability, whereas the P50 at S2 shows the same increased variability as controls (Jin, Potkin, Patterson, Sandman, Hetrick, & Bunney, 1997). Consequently, single trial averages eliminated P50 amplitude differences between the groups. Others (Clementz, Geyer, & Braff, 1998), however, disagree with this analysis and believe that the P50 reduction is not due to wave shape or the number of usable trials, rather that the reduction is related to poor suppression.

The P50 reduction in response to the first stimulus is possibly related to stress (Johnson & Adler, 1993; White, Yee, Neuchterlein, & Wirshing, 1997), interference (Jim & Potkin, 1996), and attention deficits (Cullum et al., 1993). This effect is not specific to patients with schizophrenia because approximately 50% of a general psychiatric population has this deficit (Baker et al., 1987). The deficit is not related to global measures of psychopathology (BPRS) or negative symptoms but has been linked to specific symptoms such as anxiety, depression and anergia (Adler et al., 1990; Baker et al., 1990; Yee et al., 1998). The fact that paranoid patients are less likely to show the effect (Boutros et al., 1992; White, Yee, Neuchterlein, & Wirshing, 1997) suggests that it may be different for subtypes of the disorder.

The P50 ratio is temporarily normalized by nicotine (Adler et al., 1992), clozapine when administered to clozapine responders (Nagamoto, Adler, Waldo, Griffith, & Freedman, 1991), and slow-wave sleep (Griffith & Freedman, 1993), but not REM sleep (Griffith et al., 1995). In contrast, yohimbine causes significant transient decreases in auditory gating in normal controls (Adler, Hoffer, Nagamoto, Waldo, Kisley, & Griffith, 1994). Even though P50 is generated in both the left and right planum temporale (or possibly hippocampus), patients with schizophrenia once again showed an abnormal asymmetric pattern of response. Source localization by MEG suggests that the left-hemisphere source accounts for the difference between the two groups (Reite, Teale, Zimmerman, Davis, Whalen, & Edrich, 1988).

In summary, P50, which may be generated in the temporal lobes, is reduced in schizophrenia. The S1 reduction is likely to be due to the fact that patients with schizophrenia have a more variable P50 response latency. The difference between controls and depressives seems specific to left

temporal lobes. The reduction is not related to global measures of psychopathology; rather the reduction is more likely to be related to specific symptoms.

P300. P300 is probably the most frequently studied ERP component, and its amplitude, it is almost universally agreed, is reduced in schizophrenia (Souza et al., 1995). P300 is often subdivided into frontal P3a and parietal P3b. Most studies of schizophrenia have studied the classic P3b which is related to expectancy, attention, probability, and stimulus meaning (Duncan-Johnson & Donchin, 1977; Johnson, 1988) and probably reflects encoding or updating of working memory (Fabiani, Gratton, Karis, & Donchin, 1987). There is evidence that P3b (referred to as P300 in the rest of the chapter) may be generated, at least in part, at the temporoparietal junction (Knight, Scabini, Woods, & Clayworth, 1989) or in the inferior parietal lobe (Smith et al., 1990).

The P300 reduction seen in patients with schizophrenia is due to the fact that patients with schizophrenia have fewer, smaller, and more variable latency P300s (Ford, White, Lim, & Pfefferbaum, 1994b; Roschke, Wagner, et al., 1996). And, although P300 amplitude is quite sensitive to schizophrenic psychopathology (e.g., Barrett, McCallum, & Pocock, 1986; Levitt, Sutton, & Zubin, 1973), it has failed to be a specific marker for schizophrenia (Ford, Pfefferbaum, & Roth, 1992). For example, no differences have been found between patients with schizophrenia and borderline personality disorder (Kutcher, Blackwood, St. Clair, Gaskell, & Muir, 1987), substance dependence (Brecher, Porjesz, & Begleiter, 1987), major depression (Pfefferbaum, Wenegrat, Ford, Roth, & Kopell, 1984), and bipolar depression (Muir, St. Clair, & Blackwood, 1991; Souza et al., 1995).

Although patients with schizophrenia who have the smallest P300 amplitudes have earlier hospitalizations (Roth & Cannon, 1972), worse social functioning (Strik, Dierks, Kulke, Maurer, & Fallgatter, 1993), poorer premorbid adjustment, pronounced residual symptoms, low relapse, and male predominance (Hergerl, Juckel, Muller-Schubert, Pietzcker, & Gaebel, 1995), P300 amplitude is more likely to be related to specific, rather than general symptoms of schizophrenia. For example, total Brief Psychiatric Rating Scale (BPRS) (Louza & Maurer, 1989; Souza et al., 1995) and the Present State Examination (PSE) (Barrett et al., 1986) and Mini-Mental Status (Louza & Maurer,

1989) fail to be consistently related to P300 amplitude and latency. However, when a relationship is found, P300 amplitude is negatively related to BPRS score (e.g., Strik et al., 1993; Roth et al., 1980).

P300 is related to formal thought disorder that is both active (e.g., Roth, Pfefferbaum, Kelly, Berger, & Kopell, 1981; McConaghy, Catts, Michie, Fox, Ward, & Shelley, 1993; Shenton et al., 1989; O'Donnell et al., 1993—at T3 and Cz), and residual (Juckel, Muller-Schubert, Gaebel, & Hegerl, 1996). However, P300 and Slow Wave (SW) amplitudes are unrelated to delusions and hallucinations (Roth et al., 1980, 1981). Negative symptoms are associated with decreased P300 amplitude (Pfefferbaum, Ford, White, & Roth, 1989; Strik, Deierks, & Maurer, 1993a; Merrin & Floyd, 1994; Eikmeier et al., 1992; Kemali, Galderisi, May, Cesarelli, & DiAmbra, 1988), or unrelated to P300 amplitude (e.g., Ward et al., 1991; Shenton et al., 1989; Blackwood et al., 1991; Brecher & Begleiter, 1983).

The relationship between positive symptoms and P300 is also inconclusive. For example, McCarley's group reported both positive and negative correlations of P300 with positive symptoms in T3 (Shenton et al., 1989; O'Donnell et al., 1993). Brecher and Begleiter (1983) found no relationship, and Egan et al. (1994) found a negative relationship for auditory (but not visual) P300.

Many experimental factors affect whether the P300 amplitude differences appear. Some studies have suggested that P300 is only consistently reduced in the auditory modality and only when low probability stimuli are presented (Duncan, Perlstein, & Morihisa, 1987). Stimulus discriminability plays a role in the P300 amplitude reduction noted in schizophrenia because discriminability is related to enhanced P300 amplitude and decreased latency in controls, but only decreased latency in patients with schizophrenia (Salisbury et al., 1994a). However, even under conditions of enhanced motivation (\$1 per correct categorization), P300 is reduced in patients with schizophrenia (Brecher & Begleiter, 1983). Many studies have shown that medication status is not related to P300 amplitudes, whereas others have shown that P300 amplitude to visual stimuli, though not auditory P300, is related ($r = -.88$) to the amount of improvement in neuroleptic medications (Duncan, Morihisa, Fawcett, & Kirch, 1987).

P300 latency, it is thought, reflects stimulus

evaluation time (Duncan-Johnson, 1981) and is also probably increased in patients with schizophrenia (e.g., Blackwood et al., 1987; Pfefferbaum et al., 1984), even though it has also failed to distinguish patients with schizophrenia from other groups (Pfefferbaum et al., 1984). P300 latency enhancement in patients with schizophrenia probably reflects slow categorization and decision making (Pfefferbaum et al., 1989). P300 latency has been positively correlated with general functioning, as measured by the BPRS (Blackwood et al., 1987), specific symptoms (e.g., attention; Eikmeier, Loderman, Zerbini, & Gastpar, 1992), and withdrawal (Blackwood et al., 1987).

Some researchers suggested that P300 reduction is particularly sensitive to left temporal lobe dysfunction associated with the illness (e.g., Egan et al., 1994; Morstyn, Duffy, & McCarley, 1982; Salisbury et al., 1994; Heidrich & Strik, 1997; Roemer & Shagass, 1992; Strik, Dierks, Franzek, Sober, & Maurer, 1994). This temporal lobe dysfunction occurs with medicated patients (Ford et al., 1994a; Pfefferbaum et al., 1989) as well as unmedicated patients (Faux et al., 1993). This effect, which appears at the onset of the disorder, is specific to patients with schizophrenia because patients with affective psychosis did not show this reduction (Salisbury et al., 1998).

However, this effect is not universally found (e.g., Pfefferbaum et al., 1989; Kawasaki et al., 1997; Connolly, Manchanda, Gruzlier, & Hirsch, 1985). Proponents of this theory believe that left temporal P300 abnormalities reflect specific left superior temporal gyrus (STG) abnormalities. Indeed, impressive inverse correlations have been found between left temporal lobe structures and left P300 (Egan, Duncan, Suddath, Kirch, Mirsky, & Wyatt (1994) in the auditory but not visual modality (McCarley et al., 1989). The volume of the left STG, in turn, is highly correlated ($r = .81$) with thought disorder (Shenton et al., 1992). T3 is correlated with left sylvian fissure size, both of which are correlated with positive symptoms (CT left sylvian fissure correlates with SAPs .70, delusions, .76, and FTD, .72).

In summary, P300 amplitude, which may have a generator at the temporal-parietal junction, is generally reduced in schizophrenia. This reduction is due to the fact that patients with schizophrenia have fewer, smaller, and more variable P300s. Left temporal P300 is related to specific symptoms such as formal thought disorder but not to hallu-

cinations. The fact that left temporal lobe P300 is particularly sensitive to thought disorder is intuitively appealing, given the proximity of the left temporal lobes to language centers. This effect is particularly robust in response to auditory stimuli and is affected by stimulus discriminability and possibly by medication status (medication enhances P300 under some conditions). P300 amplitude reduction is not related to decreases in motivation. This P300 effect is largest over the left temporal regions perhaps reflecting specific left temporal lobe dysfunction. P300 latency is probably increased in schizophrenia and has occasionally been associated with general functioning, as well as with specific symptoms such as withdrawal.

N100. Although not studied as frequently as P300 in clinical samples, N100, generated in the primary auditory cortex in selective attention paradigms (Woldorff, Gallen, Hampson, Hillyard, Pantev, Sobel, & Bloom, 1993), is also reduced in schizophrenia, even though patients with schizophrenia show normal selective attention effects, that is, larger N100 to attended than unattended stimuli at fast but not slow rates of stimulation (Baribeau-Braun, Picton, & Gosselin, 1983). This is the case whether or not subjects are attending to stimuli (O'Donnell et al., 1994; Roth et al., 1981). N100 has not been specifically related to symptoms of psychosis. For example, PSE was unrelated to N1 amplitude except for affective blunting (Barrett et al., 1986).

The selective attention literature about patients with schizophrenia suggests that hemispheric asymmetries may underlie the N100 differences (Hiramatsu, Kameyama, Saitoh, & Niwa, 1984). ERP (and MEG) topographic differences for N100 (and the MEG equivalent, M100) suggest that the dysfunction resides primarily in the left temporal region (Buchsbaum et al., 1982).

N200. Auditory N200 is a class of ERP components that are also generally reduced in schizophrenia (e.g., Shelley et al., 1991; Javitt, Doneshka, Zulberman, Ritter, & Vaughn, 1993; Ogura et al., 1991; Salisbury, O'Donnell, McCarley, Shenton, & Benavage, 1994a,b; O'Donnell et al., 1993). This effect occurs using both deviant and non-deviant targets (Pfefferbaum et al., 1984), though this finding is also not universal (Barrett, McCallum, & Pockock, 1986; Roth, Horvath, Pfefferbaum, Berger, & Kopell, 1980).

N200 is a complex component that has been

subdivided into three components; each has distinct but related psychological processes associated with it. Specifically, N200 has been related to (1) automatic mismatch detecting, (2) attentionally mediated mismatch detecting, and (3) classification of stimuli that have been associated with the processing of targets (for a review, see Pritchard, Shappell, & Brandt, 1991). The N2 amplitude is correlated with neuroanatomical abnormalities as well, such as reduced neocortical and medial temporal lobe volumes in schizophrenia (O'Donnell et al., 1993; Egan et al., 1994). Symptomatically, subcomponents of N200 over the left and right temporal lobes are correlated with thought disorder and chronicity (O'Donnell et al., 1993) but not affect/volition (Staffansson & Jonsdottir, 1996).

N200 latency differences have been inconsistently found in patients with schizophrenia (Ogura et al., 1991; Salisbury et al., 1994). This difference has been interpreted as suggesting slower classification process or response selection response. The difference between studies may have been due to the fact that there is a large inconsistency in the latency window corresponding to N200 (Anderson et al., 1995). N200 latency, nevertheless, has been associated with negative symptoms (Staffansson & Jonsdottir, 1996).

In general, the N200 literature also suggests greater dysfunction of left than right temporal lobes. The N200 amplitude difference between controls and patients was greater over the left than right temporoparietal sites. This effect was associated with a right ear advantage for perceiving dichotic syllables. Patients with schizophrenia did not show the behavioral or physiological asymmetry suggestive of left temporal lobe dysfunction (Bruder et al., manuscript submitted for publication).

P200. Roth and Cannon (1972) were the first to note reduced P200 amplitudes in patients with schizophrenia. Auditory P200 is probably an index of early stimulus processing (Polich, 1993), selective attention, and stimulus encoding (Shenton et al., 1989). The major source of P200 is in the auditory temporal cortex (for a review, see McCarley, Faux, Shenton, Nestor, & Adams, 1991). Some researchers, however, have suggested frontal generation (Picton et al., 1974)—or at least frontal modulation—of the component (Shenton et al., 1989).

P200 amplitude reduction in schizophrenia is probably related to task requirements because

P200 amplitude and latency increased with task requirements in controls but not in patients with schizophrenia (O'Donnell et al., 1994). The P200 deficit is most robust for the left temporal lobe in the presence of nontarget stimuli. Nontarget stimuli presented to the left hemisphere tended to produce a smaller T3 P200 in patients with schizophrenia than in controls, whereas there was no difference in T4 P200 to nontarget stimuli. When nontargets were presented to the right ear, mean amplitudes of T3 and T4 P200s were smaller in patients with schizophrenia than in normals. Patients with schizophrenia had smaller T3 P200 than T4 P200 regardless of the side to which they were attending (Hiramatsu et al., 1984).

The negative symptoms of avolition and anhedonia are significantly related to P200 amplitude at left and right temporal and central sites. Affect was also significantly related to P200 in each of those same regions, except for T4 (Shenton et al., 1989). The relationship of P200 to negative symptoms is unanticipated given the general lack of association between putative temporoparietal regionally generated components. The relationship between ERPs and negative symptoms is more typical of frontally generated ERPs and is consistent with the notion that (1) P200 is generated by broad areas of the frontal lobe (Picton et al., 1974) or (2) the frontal lobe's modulation of P200 is responsible for the relationship between P200 and negative symptoms.

Right Temporal Dysfunction

Although less frequently found when viewed across studies and components, right-hemisphere differences appear between schizophrenics and controls in both ERPs components and EEG at temporal sites (Shenton et al., 1992) and are related to emotional processes. EEG asymmetry of left/right-hemispheric ratio scores in patients with schizophrenia was associated with BPRS items of anxiety, hypochondriasis, sadness, and depression (Matousek, Capone, & Okawa, 1981). This right-hemisphere association with emotionality has also been supported by imaging studies where right sylvian fissure size correlated with SANS subscales: *alogia* .67, *avolition-apathy* .63 (Shenton et al., 1992). Additionally, ERP studies (Shenton et al., 1989) have found that avolition and anhedonia were significantly related to P200 amplitude C4 and T4. Other dysfunctions associated with right-

hemisphere component amplitude includes hallucinations, thought disorder, and chronicity with N200 (O'Donnell et al., 1993). Finally, paranoia has been associated with right-hemisphere Nd amplitude (Oades, Zerbin, & Eggers, 1994) and EEG hypoactivation (Gruzelier, 1984).

N400. N400 is an ERP component that is also generated in the temporal lobes and surrounding area (for a review, see Olichney, Iragui, Kutas, Nowacki, & Jeste, 1997). N400 amplitude is related to the processing of semantic incongruity; the more semantically incongruent a sentence ending, the larger the N400 (Kutas & Hillyard, 1980). N400 is an exception to consistent findings of temporal ERP component reductions in schizophrenia. When found, the N400 reduction might be related to asymmetrical dysfunction because greater differences between controls and patients with schizophrenia have been shown over the right lateral leads. For example, Olichney, Iragui, Kutas, Nowacki, and Jeste (1997) found a greater difference between patients with schizophrenia and controls in the right-hemisphere N400. Grillon, Ameli, and Glazer (1991) studied word pairs. Although they found no N400 amplitude differences at left lateral leads, they did report differences at the right lateral leads.

In general, however, N400 results have been inconsistent. Under some conditions, N400 amplitudes are reduced (Adams et al., 1993), equal (Mitchell et al., 1991; Olichney et al., 1997) or enhanced (Andrews et al., 1993; Nestor et al., 1997; Niznikiewicz et al., 1997) relative to controls. These differences emphasize the need to look at clinical symptoms because reduced N400 amplitudes may be related to the severity of negative symptoms, as for example, the correlation of .58 reported by Olichney et al. (1997).

More consistently, N400 latency was reduced in all but one of the studies that reported it (Nestor et al., 1997; Niznikiewicz et al., 1997; Koyama et al., 1991; Grillon et al., 1991; Olichney et al., 1997; Andrews et al., 1993). The exception is Strandburg et al. (1997).

General Temporal Lobe Summary

The vast majority of studies that examined ERP components generated by a brain system that includes temporal lobe structures show a reduction in amplitude in patients with schizophrenia. Psychologically, the components that are reduced

play a role in attention. Left temporal dysfunction may be especially related to thought disorder in schizophrenia. Right temporal lobe dysfunction may be related to the emotional aspects of the disorder. When found, latency reductions in these components are related to negative symptoms of the disorder. It is speculative, but not unreasonable, to assume that schizophrenic temporal lobe ERP reductions recorded at the scalp reflect neuronal pathology such as a general bilateral reduction in temporal volume (for a meta-analytic review of hippocampal volume reductions, see Nelson, Saykin, Flashman, & Riordan, 1998) or less elaborate connections than normal in the hippocampus (for a review, see Weinberger, 1999).

Interestingly, a comprehensive study of ERP components confirmed the specific sensitivity of temporally mediated components in classifying patients according to subtypes and DSM-III-R diagnoses. Boutros et al. (1997) tested five groups of subjects: paranoid schizophrenics (28), disorganized/undifferentiated (22) schizophrenic, schizoaffective (19), bipolar (16) and normal controls (40). Using a standard oddball task, they monitored amplitudes and latencies of P50, N100, P200, and P300. Disorganized subjects could be significantly distinguished from the other groups using N100, P200, and P300 which all may be temporally generated. P200 significantly distinguished all schizophrenic and schizoaffective patients from normal controls. Finally, P300 could differentiate both schizophrenic groups from controls. However, overall, controls had as high a level of misdiagnosis as patients, though the patients with schizophrenia were not often classified as controls.

Brain Stem and Middle-Latency Components

Brain stem evoked potentials, it is thought, reflect initial sensory processing of auditory stimuli that occur in the brain stem. Brain stem functioning is relatively intact in patients with schizophrenia because there were no reported differences between patients with schizophrenia and controls in brain stem evoked potential amplitudes (Pfefferbaum, Horvath, Roth, Tinklenberg, & Koppell, 1980; Brecher & Begleiter, 1985). They also failed to distinguish between patients with schizophrenia and alcoholics and controls (Sommer, 1985).

However, the latencies of wave III and N3 (not wave V or N15) are different. Harell, Engender, Demer, Kimhi, and Zohar (1986) found N3 latency enhancements but no wave V differences. Kimhi, Engender, Zohar, and Harell (1987) found both wave 3 and wave-V differences. Additionally, they found that the N3–N5 and N1–N5 latency increased in patients with schizophrenia. Grillon, Ameli, and Glazer (1990) also found an increase in wave III-I latency in patients with schizophrenia. N15 latency, which is probably related to hippocampal activity, is normal in patients with schizophrenia (Coger & Serafetinides, 1993). The latency effects are probably modified by clinical status because Szelenberger (1983) found a relationship between the psychoticism score and interpeak conduction time of I–II for patients with schizophrenia and controls, but no group differences.

Motor Cortex

Reduced readiness and motor potential in schizophrenia were reported (e.g., Chiarenza, Papakostopoulos, Dini, & Cazzullo, 1985; Kornhuber, 1983). For an inconsistent result see Singh et al. (1992). Readiness and motor potentials reflect motor preparation and, it is thought, are generated, at least in part, in the motor cortex. There is a single piece of evidence that there may be differences in motor potential asymmetry between the groups. Terayama, Kumashiro, Kaneko, Suzuki, and Aono (1985, cited by Koyama et al., 1991) found that ERPs recorded from patients with schizophrenia are smaller in the left than the right hemisphere regardless of which hand was used to respond.

Conclusions

Examination of the research that has been reported in this chapter emphasizes the importance of the heterogeneity of schizophrenia and the complexity of the task of unraveling its components. Some broad themes arise from the neuropsychological evidence. One is the critical role of frontal lobe disturbance in the genesis of many patterns of schizophrenic psychopathology. However, whether the disturbance is due to lack of hemispheric asymmetry, low frontal/whole brain volume, neuronal hypoactivity, neuronal hyperactivity, or any one of a host of other possibilities remains ob-

scure. Nor is it clear that frontal lobe disturbance necessarily brings schizophrenic pathology as an inevitable consequence. Studies of aging, activity balance in the affective disorders, and other disorders implicates frontal functioning in many cases.

It is also clear that the structure and function of the temporal lobes play a critical part in the psychopathology of schizophrenia. The central role of the temporal areas in controlling and mediating language, coupled with the major part that language disturbances play in the diagnosis of schizophrenia, suggests that this link may have more specific significance in schizophrenia than the disturbances of the frontal lobe.

In recent years, particular interest has arisen in the question of anomalous lateralization in schizophrenia. As the present chapter shows, there are now many findings of anomalous laterality in brain volume and in the lateralization of performance. The ramifications of these findings are only now beginning to emerge.

A relatively more coherent story appears when examining schizophrenic symptoms, ERP components, and their neurophysiological generators. Frontally generated ERP components (CNV, PINV, and P3a) are abnormal, and these abnormalities are related to negative symptoms and hallucinations in patients with schizophrenia. Components generated by a brain system that includes temporal lobe structures (i.e., P50, N100, P200, N200, and P300) demonstrate a general reduction in amplitude and are related to decreases in temporal lobe volume. These reductions are most striking in the left temporal lobes. Amplitude reductions in left temporal ERP are not related to global functioning; rather they are related to specific symptoms such as thought disorder. Right temporal reductions are less likely to be observed but might be related to affective symptoms. Early brain stem functioning is relatively intact; later brain stem activity is slowed. Motor cortex functioning has not been studied thoroughly in schizophrenia but has been occasionally reduced.

Hence, ERP and EEG research provides convergent evidence for the frontal and temporal lobe abnormalities in schizophrenia, already mentioned. Additionally, the ERP literature suggests specific relationships between symptoms and these purportedly dysfunctional brain regions.

The picture that is now available gives grounds for optimism about our eventual understanding of the neuropathology of the schizophrenias, but our

progress brings with it recognition of the complexity of the problems that lie ahead before that goal can be reached. As is so often the case in the history of science, technological breakthroughs open up new problems more complicated than those that they had solved. With regard to schizophrenia and psychopathology generally, the heart of the matter is the fact that the brain operates as a total system, not as a federation of semiautonomous discrete areas; the activity of each is insulated from that of the others. It is also evident that the relationship of the activity of specific brain areas to categories of behavior is subject to considerable individual variation. For these reasons we will need to develop the concepts necessary to express complex patterns of activity and the mathematical analyses that will permit us to make convincing comparisons between diagnostic groups.

Genetics and Schizophrenia

Franz Schneider and Patricia J. Deldin

Introduction

Human beings have had an intuitive understanding of the concept of heredity for centuries. In his 1621 book, *The Anatomy of Melancholy*, Robert Burton wrote, "That ... inbred cause of Melancholy is our [temperament], in whole or part, which we receive from our parents ... it being a hereditary disease;" (Whybrow, 1997, p. 106). A century ago, Gregor Mendel deduced how genes function in heredity through his experiments breeding pea plants, even though he had no knowledge of the physiological mechanisms underlying genetics. The discovery of DNA by Crick and Watson in 1953 provided an understanding of the raw material of genes that has enabled the genetic revolution we have since enjoyed (Watson, 1981).

During this century, perceptions of the significance of genetic etiologies to various illnesses have waxed and waned, as much influenced by social and political trends as by the state of scientific knowledge. Recently, astonishing advances have been achieved in the techniques and understanding of biotechnology, for example, the ability to examine genetic material at the DNA level (Dickerson, 1983). This progress during the last two decades has led to a resurgence of interest in

genetic contributions to traits in general and to disease processes in particular.

Genetics and Mental Illness

During this century, views about the balance between the etiologic components underlying mental illness have been in flux between the poles of the "nature versus nurture" debate. There are many shadings of the perceived etiologic balance, and extreme opinions range from the view of totally genetic etiology, as exemplified by the eugenics movement early in this century, to a totally environmental etiology, for example, Theodore Lidz's concept of schizophrenogenic mothers causing schizophrenia (Lidz, 1973). However, this review of the literature will reveal competing evidence supporting both genetic and environmental etiologies. Thus, the first conclusion is that elements of both etiologies are apparent in schizophrenia.

Two distinct models might account for the fact that both genetic and environmental etiologies are associated with schizophrenia. Some suggest that this reflects the fact that there are actually two or more distinct diseases, which share enough common symptoms that each is called schizophrenia. An alternative possibility is that the presence of both etiologies is a manifestation of a diathesis-stress model. Such a model supposes that genetics provides an individual with a degree of predisposition to a disease but that the onset of the disease is triggered by an environmental stressor(s), depending on the genetic predisposition of the individual. The diathesis-stress model has fit circumstances

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

well for other mental illnesses with both hereditary and environmental components, such as alcoholism (Vaillant, 1995).

Some dichotomies between possible multiple diseases will be discussed in the next section, and in reviewing evidence throughout this review, it will be important to keep in mind this overall question of what the appropriate model is. At the outset, the diathesis-stress model seems better supported due to the logic of several critical observations; specifically, in the case of families that are known to be at genetic risk for schizophrenia, only a minority of the family members actually develop the disorder. Conversely, to the extent that whole populations have been exposed to what is an environmental risk factor, only a small minority develop the disease.

Because it is likely that schizophrenia at least in part results from a genetic etiology, the first body of evidence to be examined will be studies that may quantify the degree of heritability. These are observational studies, in particular twin studies. The existence of both monozygotic and dizygotic twins is sometimes called an experiment of nature, and over the years comparison of the concordance rates for a disease between the two types of twins has been used to calculate heritability. This review will examine the limitations of these studies, in particular, some of their significant methodological problems.

Following a review of evidence for familial transmission of schizophrenia, a second area of the literature will examine physiological evidence that may be relevant to the later review of both environmental and genetic factors that contribute to schizophrenia. Such physiological evidence may be of interest for two reasons. To the extent physiological traits exist that are associated with schizophrenia, such features may contribute to developing and understanding possible mechanisms that might explain how genetic or environmental etiologies, or both, are expressed. Of special interest will be several biological markers that are associated with schizophrenic patients, and in some cases, also with the well relatives of patients.

The third area of the schizophrenia literature to be examined will be that suggesting environmental etiologies. Although an important purpose of this review is to come to conclusions about the relative importance of genetic and environmental etiologies, the base case at the outset is the con-

sensus in the field that schizophrenia has a strong genetic component. One way to challenge that predominant view will be to review studies that have produced evidence suggesting that in some circumstances the onset of schizophrenia results from environmental stressors. Examples of reported environmental risk factors that will be examined below include viral exposure, especially to the fetus; other in utero insults; and season and place of birth, not because these are actual risk factors, but because they seem to be proxies for yet unknown stressors.

The fourth and final area to be reviewed will be evidence that has been reported in the literature to support genetic etiologies. Given the enormous interest supporting genetic research, we will focus primarily on three particular issues: what is the most likely genetic model for schizophrenia, how useful have the specific techniques of linkage analysis been, and what techniques might make the application of genetic analysis more tractable. Finally, a review of the results of a number of studies related to specific chromosomes or specific candidate genes considered related to schizophrenia will illustrate the current limitations of genetic analysis techniques.

The conclusions section will summarize the evidence this review has identified that answers the research questions described before. In addition, this final section will look beyond the specifics of the genetic and environmental etiologies to see how they are related through the diathesis-stress model and to examine the etiologies that contribute to the incidence of schizophrenia in the general population. Finally, some comments and suggestions will be offered about the way schizophrenia research priorities might be altered.

Taxonomies of Schizophrenia

Several theories related to the etiologies of schizophrenia have proposed a number of distinctions between the symptoms of schizophrenia and also between possible subtypes of schizophrenia. For some studies, these distinctions have provided a framework for the design of experiments. For this reason, a number of these distinctions will be examined now, and the rationale underlying them will be discussed in the context of the theories they support.

Positive and Negative Symptoms

The dichotomy between the positive and negative symptoms of schizophrenia is perhaps the most frequently employed distinction in studying the disorder. This dichotomy is relevant to a review of genetic research because a number of theories and the studies supporting them suggest possibly different etiologies for these two types of symptoms. This dichotomy has also been important in the history of schizophrenia research.

The work of the two pioneers in psychiatric research, Emil Kraepelin, a German psychiatrist, and Eugen Bleuler, a Swiss psychiatrist, took place in the years bracketing the turn of this century. In 1883, Kraepelin first gave the disorder we now know as schizophrenia the name *dementia praecox*, literally precocious dementia; this reflected his belief that this was a progressive neurodegenerative disease (Kendall & Hammen, 1995). Writing in 1911, Bleuler named the disorder schizophrenia, adding the set of symptoms he called *paraphrenia* (hallucinations and delusions) to the dementia described by Kraepelin. Bleuler considered schizophrenia a thought disorder, and its primary symptoms were emotional blunting and an impaired relationship with the outside world; the more dramatic paraphrenia symptoms were secondary (Tsuang & Faraone, 1997).

Reflecting this early insight, the presence or absence of positive or negative symptoms has become a useful classification system. *Positive symptoms* may be considered acute symptoms seen when patients are in their worst states, thus including the hallmark symptoms of delusions and auditory hallucinations, as well as disorganized speech and grossly disorganized or catatonic behavior.

Negative symptoms, sometimes called *deficit symptoms*, are usually described as affective flattening or emotional blunting, but often include apathy, lack of motivation, lack of pleasure, and impaired social and personal relationships. The negative symptoms tend to be more chronic than the positive symptoms. Although the bizarre nature of the positive symptoms calls attention to sufferers of schizophrenia, they are usually present only during a minor period of time, and they are often amenable to treatment by pharmaceuticals. The negative symptoms are typically stubbornly persistent and therefore harder to treat.

Some have questioned whether a simple dichotomy between positive and negative symptoms represents an adequate framework for describing schizophrenic patients. Reporting on the results of factor analyses performed in three published studies of schizophrenic patients plus a large pooled sample, one group of researchers concluded that "... more than two distinct dimensions are required to categorise symptoms in schizophrenia" (Arndt, Alliger, & Andreasen, 1991). These investigators' additional dimensionality involved splitting the positive symptom domain into more distinct factors.

More recently, data on 114 sibling pairs afflicted with schizophrenia or schizoaffective disorder were examined to determine what correlations might be detected along three dimensions of symptoms: positive, negative, and disorganized (Loftus, DeLisi, & Crow, 1998). There was a more than chance correlation for the disorganization dimension that led the investigators to conclude that this disorganization subsyndrome might be a suitable phenotypic marker for genetic linkage studies.

A Neurodevelopmental or Neurodegenerative Disorder?

Although Kraepelin's characterization of schizophrenia as dementia praecox implied that this is a neurodegenerative disease, Bleuler's experience with the disease was such that although he knew complete recovery was rare, he did not necessarily see the irreversible decline of a degenerative disease. His prescience is demonstrated by the fact that debate continues on this point. In a review, Goldberg, Hyde, Kleinman, and Weinberger set out to evaluate evidence to determine whether the nature of cognitive function in schizophrenia was one of progressive dementia or one analogous to a static encephalopathy (1993). Based on their review of longitudinal and cross-sectional studies, they concluded that the latter, nondegenerative, interpretation was strongly supported. Particular data supporting this conclusion was found in a cross-sectional study that administered tests sensitive to progressive dementing diseases to patients in their third through seventh decades of life.

However, a more recent study was designed to address the issue of whether the ventricular neuropathology in schizophrenia is degenerative or is

fully expressed at onset and stable thereafter (Nair et al., 1997). MRI volumetric analysis was performed during a two- to three-year period on a group of eighteen patients with symptoms of schizophrenia, as well as on a control group. The measured rate of ventricular expansion (RVE) for the patients was bimodally distributed. The RVE for a group of ten patients was $0.9 \pm 0.5 \text{ cm}^3/\text{year}$, a rate similar to that of the controls ($0.7 \pm 0.6 \text{ cm}^3/\text{year}$). The other eight patients as a group exhibited a rate of $3.9 \pm 0.7 \text{ cm}^3/\text{year}$.

These results support a dichotomy between a more common form of schizophrenia that does not feature neurodegeneration and a less common form that does. Such a finding is consistent with the clinical experience that a minority of schizophrenic patients do suffer progressive cognitive deterioration. A stable neuropathy after onset might be accounted for by a neurodevelopmental model under which the damage is done during the developmental period of the brain, and little further damage occurs once that developmental period has ended, a time that typically coincides with the age of onset of schizophrenia.

As evidence from various studies is reviewed here, it may be useful to keep this possible neurodevelopmental–neurodegeneration dichotomy in mind. In examining the relative merits of claims for genetic and environmental etiologies, it is possible that one etiology may fit one side of this spectrum better than the other.

Familial and Sporadic Schizophrenia

As research has increasingly focused on possible genetic causes of schizophrenia, some investigators have proposed making a distinction between *familial* and *sporadic* forms of schizophrenia. The defining principle is simple: familial schizophrenia is seen when the family of a patient has a higher prevalence of schizophrenia than the general population. Because those without this familial aspect of the disease lack a readily apparent genetic etiology, their form of the illness is called sporadic schizophrenia. However, this distinction does not necessarily contemplate the existence of two separate disorders. Rather, this is an attempt to define certain characteristics of schizophrenia that may be seen consistently in the familial form and a different constellation of characteristics seen for the sporadic form.

Unfortunately, to develop a consistent familial–

sporadic dichotomy requires navigating through a thicket of possibly conflicting evidence. For example, a review of this distinction by two authorities in the field reports that schizophrenia resulting from neurodevelopmental problems early in life is more common among sporadic patients than familial patients (Tsuang & Faraone, 1997). However, they also observe that sporadic schizophrenic patients show evidence of brain atrophy, a characteristic typical of the degenerative form of illness. The most distinctive difference in symptoms that Tsuang and Faraone report are in brain function; familial patients exhibit more problems with attention span and distractibility.

The results of a study of the co-twins and first-degree relatives of thirty-one monozygotic and twenty-eight dizygotic twin probands may shed some light on this issue, although in the process the authors suggest yet another distinction, that between paranoid and nonparanoid schizophrenia (Onstad, Skre, Torgersen, & Kringlen, 1991). These investigators reported that nonparanoid schizophrenia was more commonly observed among the monozygotic probands than the paranoid type, thus implying that the type of disease more likely to be transmitted genetically is the nonparanoid. Considering that the delusions typical of paranoia are hallmark positive symptoms, we might reason that familial schizophrenia is more likely to be characterized by a predominance of negative symptoms. Keeping in mind that positive symptoms can be induced (and reversed) by certain psychoactive drugs, we may conclude that the sporadic type of schizophrenia offers a better long-term prognosis, which in fact has been the clinical experience.

The Problem of Heterogeneity

In a scientific context, the word heterogeneity usually refers to the problems introduced into an investigation in which the experimental subjects differ in more than one variable. Ideally, in conducting a controlled study of a trait, the clearest results, and thus the most supportable conclusions, are obtained if all of the subjects are exactly alike, except for that one trait. Of course, the real world does not conform to this ideal, and so scientific research usually has to address the potential confounding effects introduced by the heterogeneity of the subjects used in an investigation.

Heterogeneity also emerges as a research prob-

lem if the disorder under study may be composed of several different forms with common symptoms as an end point. From this discussion, we can see that schizophrenia is quite likely to be a heterogeneous disorder. Reflecting this, a complicated series of rules have been set out by the authors of DSM-IV to determine a diagnosis of schizophrenia. But beyond problems of diagnosis, substantial heterogeneity is encountered in the symptoms displayed (or not displayed) by patients suffering from schizophrenia. For example, as will be discussed in "Review of Physiological Evidence," about 70% of schizophrenic patients exhibit smooth eye tracking dysfunction, as do 45% of the well relatives of the patients. But the remaining 30% of patients and 55% of relatives show no such eye movement dysfunction. In other mental illnesses, for example, mood disorders, the various defining symptoms are usually observed to a greater or lesser extent but are not likely to be either present or absent.

Finally, heterogeneity should be mentioned in the very technical context of genetic analysis. Here, the problem is the human genome, which contains approximately 100,000 different genes, as specified by approximately 2 billion base pairs of DNA. Given the enormous diversity displayed by the human species, a minefield of potential confounds await those who undertake research in human genetics. As will be seen in "Evidence from Genetic Research," a number of investigative techniques have been developed to minimize the impact of these confounds. Specifically, experience has taught that combining the results of genetic testing from diverse racial, ethnic, and geographical groups must be avoided. Conversely, confining an investigation to a pedigree of related individuals has become the most promising path to obtaining usable data in genetic analysis. These topics will be discussed in more detail in "Evidence from Genetic Research."

Review of Evidence Indicating Transmission Within Families

In the first section, four general categories of the research literature on schizophrenia were identified for review: evidence of transmission within families, physiological evidence, environmental evidence, and genetic evidence. Evidence of familial transmission of schizophrenia is the logical

place to start because many of the earliest attempts to understand the nature of schizophrenia were prompted by the observation that the disorder runs in families.

Reflecting the wide variety and combinations of symptoms seen in those suffering from schizophrenia, a number of distinctly divergent mechanisms have been proposed as etiologies for the disorder. That there is a genetic component is certainly not in doubt at this time. Over the years, heritability data have been compiled from many observational studies. One consistent result seen in these studies is that the incidence of schizophrenia in first-degree relatives of schizophrenic patients is typically elevated by roughly an order of magnitude over the 1% incidence in the general population.

Family Association Studies

Family association studies collect data on the incidence of schizophrenia (and sometimes, other mental illnesses) within the families of schizophrenic patients. For example, one study compared the lifetime incidence of schizophrenia in 723 first-degree relatives of schizophrenic patients with the incidence in 1056 first-degree relatives of matched controls (Kendler, Gruenberg, & Tsuang, 1985). A number of analyses were performed using a variety of techniques, and the investigators reported at least an 18-fold greater incidence in the relatives of schizophrenic patients than in the controls. Interestingly, the relatives of schizophrenic patients did not show any elevated incidence for unipolar disorder, anxiety disorder, or alcoholism. This reported elevation in lifetime risk for relatives of schizophrenic patients is somewhat higher than the rates encountered in subsequent studies.

For example, in a study using data from a rural county in Ireland, the relatives of 285 identified schizophrenic patients exhibited a 6.5% lifetime risk for schizophrenia, which can be compared to the generally accepted 1% worldwide lifetime incidence in the general population (Kendler et al., 1993a). In a subsequent report based on additional data from the rural Irish country, the same investigators concluded that a family liability to schizophrenia did not substantially increase the risk to affective disorders, anxiety disorders, or alcoholism (Kendler et al., 1993b). The investigators also concluded that these data did not support a sometimes proposed hypothesis that schizophrenia and

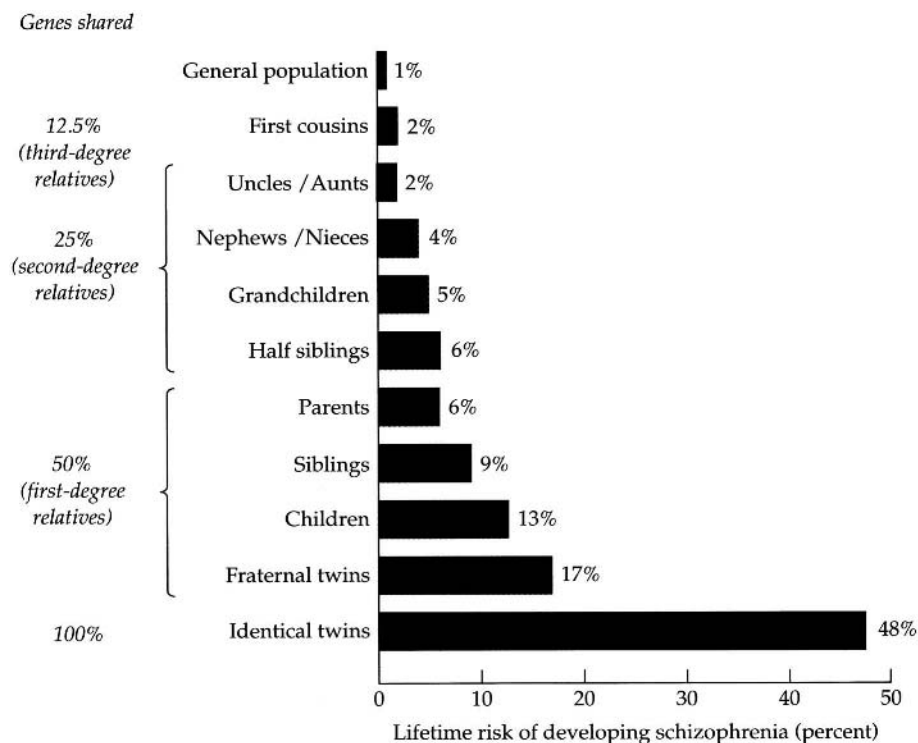

Figure 1. Lifetime risk of developing schizophrenia based on family relationship. From *Schizophrenia Genesis* by Gottesman. Copyright 1991 by Irving I. Gottesman. Used with permission by W.H. Freeman and Company.

affective illnesses are on a single etiologic continuum from a familial perspective.

Figure 1 depicts data adapted from Gottesman (1991, p. 96) that shows the elevation of lifetime risk of schizophrenia for various family relationships, specifically, for first-degree relatives who share half of their genes, second-degree relatives who share one-quarter of their genes, and third-degree relatives who share one-eighth of their genes. Of particular interest are the differing rates for the four types of first-degree relatives.

The apparently lower lifetime risk for parents (6%) probably reflects the fact that those who suffer from schizophrenia are less likely to reproduce, thus creating an apparent reduction in lifetime risk for the parental generation. Conversely, the higher rate for children of schizophrenic patients (13%) probably reflects the opposite phenomenon. The 9% figure for siblings may indicate a lifetime risk that is not biased by either of these generational effects. Because fraternal twins are

literally just siblings that happened to be born at the same time, the relatively high lifetime incidence of 17% is surprising. Reasons for such an elevation in fraternal twins will be discussed later in the context of twin studies.

One final comment should be made to point out that these observational studies cannot discriminate whether genetic or environmental influences are at work. Thus, elevated lifetime risks are not necessarily derived from a genetic etiology; conceivably, these effects may result from common environmental factors.

Twin Studies

Twin studies can be designed so that conclusions about heritability can be drawn. They exploit the fact that monozygotic (identical) twins have exactly the same genetic makeup, whereas dizygotic (fraternal) twins, on average, share half of their genes. Specifically, these studies collect data

from twin sets in which at least one twin has been diagnosed with schizophrenia. Then concordance rates (the percentage of twin pairs in which both have been diagnosed with schizophrenia) are compared between monozygotic and dizygotic sets of twins. If a disease has a purely genetic etiology, we would expect to see a 100% concordance in monozygotic twins; on the other hand, dizygotic twins should exhibit a significantly lower rate of concordance. Indeed, this is exactly the case with Huntington's disease, which features a purely genetic etiology.

Table 1 provides a summary of the concordance rates observed in eight major twin studies. The pairwise figures are the more useful because the proband method double counts individual twins in some cases, although it is often seen in popular literature.

As seen in the two lines at the bottom of the table, the averaged figures are 26% concordance (identical), compared to 8% (fraternal) if the only three studies considered are those which the authors consider were the best executed. Averaging all of the studies results in a 28% to 6% comparison. Of course, the fact that concordance rates for identical twins, who have exactly the same genes, are less than 30% implies that one or more causal

factors other than genetics are also responsible for the disease.

To gain some perspective on the different rates of heritability seen among mental illnesses, Table 2 shows the pairwise concordance rates for twelve disorders. Topping the list is Huntington's disease that is 100% concordant in identical twins, compared to 20% for fraternal twins. This is not surprising because Huntington's disease, it has been shown, results from a single dominant gene. Thus, possession of that gene by one identical twin would make it certain that the other twin would also develop the disease. Schizophrenia is low on the list and has a monozygotic concordance rate about the same as that for multiple sclerosis.

On reflection, there are several issues that imply that results from twin studies may not be entirely applicable to the general population. First, it may be that a twin pregnancy incurs stresses not seen in a normal pregnancy. An additional logical flaw is apparent in the assumption that the concordance rate for identical twins quantifies the genetic component of schizophrenia. This assumes that each identical twin experiences exactly the same environmental effects in utero (Torrey, 1992). But, following this logic, both twins would also be expected to have the same birth weight, which is

Table 1. Twin Concordance Rates for Schizophrenia^a

Study	Identical twins		Fraternal twins

usually not the case. Thus, although it is clear that identical twins are exactly alike at conception, there are significant ways in which one twin may be subjected to stressors that the other twin escapes. For instance, the way in which twins share the womb and their blood supply can provide an environmental stress on only one twin; however, any changed outcome caused by such a stressor will be counted as a genetic effect. Another potential confound is that whether one or both twins are affected by a stressor such as a virus may be a matter of chance. For example, one study of identical twins born to HIV-infected mothers revealed that of six such twin pairs, three were concordant for the virus, and three discordant (Torrey et al., 1994, p. 19).

Nevertheless, despite these methodological and logical issues, twin studies over the years have provided data that strongly suggests some degree of genetic etiology in schizophrenia. However, the previous discussion has pointed out that the interpretation of the data and certain methodological issues have tended to overstate the likely degree of heritability. Given these limitations, it may be that the use of twin studies has reached a limit in its ability to quantify the genetic etiology of schizophrenia.

Adoption Studies

Conceptually, adoption studies are designed to control for a potentially significant confound in twin studies; that twins reared together, in addition to sharing genes, are likely to share many environmental influences. Although a number of different designs have been used, the subjects in many adoption studies have been schizophrenic patients who were adopted shortly after birth; typically, matched controls (who were also adopted) are selected as well. An indication of the relative contributions of genetics and family environment can be assessed by comparing the incidence of schizophrenia in the families of both the biological and adoptive parents of the schizophrenic probands.

Unlike twin studies as discussed before, relatively few adoption studies have examined schizophrenia. Although most of these adoption studies have confirmed some likely genetic component, these studies are harder to compare than twin studies because of significant design differences. Nor have their results uniformly produced statistically significant results (for example, see Wender et al., 1986).

One different design produced particularly interesting results from a nationwide Finnish study in which the adopted-away offspring of mothers diagnosed with schizophrenia were compared with matched controls who were adopted away from normal parents (Tienari, 1991; Tienari et al., 1985, 1987). Although the results supported the hypothesized transmission of a genetic predisposition from mothers diagnosed with schizophrenia to schizophrenic probands, a significant effect related to the adoptive family was also detected. Specifically, no cases of schizophrenia were found in forty-three probands raised in relatively normal adoptive families, whereas schizophrenia was present in fifteen of thirty-nine probands (38%) raised in disturbed adoptive families. This led the investigators to conclude that "this combination of findings supports the hypothesis that a possible genetic vulnerability has interacted with the adoptive rearing environment" (Tienari et al., 1985, p. 227).

Although adoption studies in theory should improve the twin study design by separating the genes of subjects from their family environment, adoption studies also suffer from methodological problems; some of them are unique, and some also

affect twin studies. In particular, the evidence for environmental effects discussed later makes clear that the in utero period is a likely venue for significant environmental effects. Like twin studies, adoption studies are vulnerable to this potentially substantial confound. If there is an in utero effect, both twin and adoption studies will count it as a genetic effect. Given this uncertainty, it must be concluded that neither twin nor adoption studies can prove genetic etiology, nor can these types of studies rule out other types of etiologies.

Review of Physiological Evidence

Making the research problem all the more interesting is that unlike many mental illnesses, the study of schizophrenia has revealed a significant number of physiological anomalies that often accompany the disease, and sometimes precede it as well. However, despite these many anomalies, the only physiological evidence relevant to this review is that which may demonstrate a link to the etiology of the disorder. In this regard, the physiological anomalies of most interest are those observed in schizophrenic patients and also in the relatives of patients. For this reason, two specific physiological phenomena will be reviewed: eye movement dysfunction and the inhibition of certain event-related potentials (ERP) that can be recorded by an electroencephalograph, specifically, the P50, a positive wave that occurs 50 ms after an event.

Eye Movement Dysfunction

It has been known for twenty-five years that eye tracking dysfunction is much more frequently seen in schizophrenic patients than in the general population. In particular, the most consistently seen dysfunction is poor smooth-pursuit eye tracking, that is, in following the track of a moving object, a schizophrenic patient is more likely to exhibit jerky eye movements, rather than the smooth tracking normally seen.

Ten years after such smooth-pursuit eye movement dysfunction had first been noticed, a study was conducted to follow-up on previous studies that found this dysfunction in from 50 to 85% of schizophrenic patients (Holzman, Solomon, Levin, & Waternaux, 1984). Similar smooth-pursuit eye movement dysfunction was found in 34% of

the parents (and 55% of the parent pairs) of schizophrenic patients, compared with the 8% rate of the general population. Interestingly, parental eye movement dysfunction was significantly related to the patient's diagnosis and not to the patient's eye tracking performance. This led the investigators to conclude that eye tracking dysfunction represented a familial marker of vulnerability to schizophrenia.

Writing four years later, Holzman et al. (1988) noted that eye movement dysfunctions (EMDs) were found in a majority of schizophrenic patients and in 45% of their first-degree relatives and reported a study in which eye movements of the offspring of monozygotic and dizygotic twins were recorded. Among their conclusions was the statement "the data suggest that EMDs and at least some schizophrenias can be considered expressions of a single underlying trait that is transmitted by an autosomal dominant gene" (p. 641).

In stark contrast to the results obtained in the studies of Holzman et al. were the results of a later study of four normal control pairs of identical twins and eleven pairs discordant for schizophrenia (Torrey et al., 1994). Although the schizophrenic patients showed elevated rates of EMD, the eye tracking scores of their well co-twins were statistically indistinguishable from the scores of the normals. In addition, no correlations for the affected twins were found between EMD and variables associated with the disorder, such as family history for serious mental illnesses, physiological anomalies, and various indices related to medication status.

Because EMD has been discussed as a genetic marker for liability to schizophrenia and because genomic scans have indicated that the short arm of chromosome 6 may be a possible location for a gene related to schizophrenia, an analysis was performed at the 6p21-23 region of the chromosome to test for linkage between chromosomal markers and EMD as well as schizophrenia (Arolt et al., 1996). Testing five models of EMD inheritance, a logarithm of the odds ratio (LOD) score of statistical interest was found. However, after testing with seven models of schizophrenia inheritance, no significant results were obtained; this raised the question whether EMD is a marker for detecting schizophrenia linkage that is more sensitive than the actual disease status.

Finally, a very recent study examined differences in saccadic eye movements (which are re-

flexive, jerky movements) among twenty-nine schizophrenic patients, fifty of their nonpsychotic first-degree relatives, and thirty-eight unrelated controls (Crawford et al., 1998). They were testing a hypothesis that schizophrenic patients could not reliably inhibit reflexive saccades. Although patients, their relatives, and the controls showed no difference in generating reflexive saccades, the patients showed more saccadic distractibility. Relatives of patients with high distractibility also showed high distractibility. The investigators concluded that the antisaccade anomaly in this distractible subset of patients (and their relatives) might represent a schizophrenia vulnerability marker.

P50 Inhibition

The connection of ERPs to schizophrenia has been studied since the 1980s. Although much of the earlier research focused on the P300 ERP, more recent research on the P50 may be of more interest because a P50 phenomenon is seen in many schizophrenic patients and also in a significant number of their well relatives (Freedman et al., 1997). The abnormality is related to the inhibition of the second of the two P50 responses to closely paired auditory stimuli. Specifically, when normal people hear pairs of sounds presented close together, they will inhibit their responses to the second sounds, evidence of a rapid habituation reaction to the sound. However, many schizophrenic patients will not inhibit the second wave so that both waves are of the same amplitude, as has been demonstrated in a number of studies (e.g., Clementz, Geyer, & Braff, 1998).

A theory may be proposed that this inability to inhibit specific responses, perhaps symptomatic of a generalized inability to inhibit stimuli, may be the source of various schizophrenic symptoms such as distractibility, confusion, or even some of the more bizarre symptoms, such as hearing multiple voices. A recent study, using forty-seven schizophrenic patients for whom complete neuropsychological and clinical data were available, tested for this P50 abnormality, and then separated the subjects into high- and low-P50 abnormality groups (Erwin, Turetsky, Moberg, Gur, & Gur, 1998). A multivariate analysis of variance for the eleven neuropsychological profile scores showed that the high-abnormality group had relatively greater deficits for attentional profile scores than

for the remaining measures. An analysis of the P50 data and the subjects' Scale for the Assessment of Negative Symptoms (SANS) scores revealed one significant difference: the high-abnormality group was also rated as more severe only on the SANS attention subscale.

This review of physiological evidence has identified two anomalies that may have a bearing on the etiology of schizophrenia. We will revisit these anomalies in the review of genetic analysis contained in "Evidence from Genetic Research," when evidence related to several specific chromosomes and candidate genes is examined. The phenomena of eye tracking dysfunction and P50 inhibition described before may be linked to chromosomes 6 and 15, respectively.

Review of Environmental Evidence

Decades ago, before a significant genetic etiology had become generally accepted, the common wisdom was that schizophrenia was caused by environmental factors experienced during the patient's youth. In particular, dysfunctional family settings and styles of parenting were believed to cause the disease. Since that time, such ideas have properly receded to the background, and in addition to evidence of heritability, evidence has slowly been uncovered pointing to environmental influences very early in life, specifically, during pregnancy. This section will examine some of that evidence.

However, at the outset it should be kept in mind that because environmental and genetic evidence are being reviewed separately, does not imply that a dichotomy exists such that any specific case of schizophrenia reflects only a genetic etiology or only an environmental etiology. In the first section, the diathesis-stress model was identified as providing a conceptual framework that can incorporate evidence derived from both genetic studies and from studies that identify environmental stressors. In the Conclusions section, the suitability of the diathesis-stress model will be addressed again in the light of the evidence that has been reviewed. However, during the review of evidence, it must be kept in mind that any environmental stressor identified in this section is very likely to interact with some genetic predisposition. Similarly, any genetic mechanism revealed in the

evidence considered in the next section is likely to interact with the many and varied stressors that are encountered in life, starting at conception.

The Dutch Famine

The most dramatic evidence of an in utero effect was provided by a cruel experience of war. During the last winter of World War II, the Nazi forces imposed a severe but relatively short famine on certain parts of the Netherlands. Because of careful Dutch record keeping at the time, accurate assessments of daily food intake are available for this famine period. In a series of studies carried out by Susser and colleagues during eight years, the amount of food deprivation and its timing have been compared with the incidence of schizophrenia several decades later, as derived from a national psychiatric registry.

In the first study published, a hypothesis was tested that first-trimester exposure to acute food deprivation is a risk factor for schizophrenia (Susser & Lin, 1992). The key finding was that in the famine region, birth cohorts exposed to an average daily ration less than 4200 kJ during the first trimester showed a substantial increase in hospitalized schizophrenia for female offspring but not for males. Relative risks (RR) for these women were 2.56 for "restricted" schizophrenia (an International Classifications of Diseases [ICD] diagnosis comparable to current DSM rules for a diagnosis of schizophrenia), and 2.17 for a "broad" variant that included other schizophrenia spectrum disorders. The investigators also concluded that moderate food deprivation, that is, an average daily ration less than 6300 kJ, was not associated with increased risk of schizophrenia.

In their next published study, Susser and colleagues used more precise data on both exposure and outcome (Susser et al., 1996). By comparing the exposed and unexposed cohorts that had been born in western cities of the Netherlands after the famine, they found that the most exposed cohort, those conceived at the peak of the famine, had a twofold and statistically significant increase in the risk of schizophrenia in both men (RR = 1.9) and women (RR = 2.2). The most recently published study (Hoek, Brown, & Susser, 1998) reported on further examination of data related to the famine and concluded that "early prenatal famine was found to be specifically and robustly associated with each of three conditions: (A) congenital

anomalies of the central nervous system, (B) schizophrenia, and (C) schizophrenia spectrum personality disorders" (p. 373). They found that the greatest increase in the risk of schizophrenia spectrum disorders occurred among men born in the famine cities in December 1945 (RR = 2.7), who were conceived at the absolute peak of the famine in March and April 1945.

Viruses

Consistent with this idea of prenatal vulnerability, in utero viral exposure has been investigated as a possible risk factor for later development of schizophrenia. In one study, psychiatric hospital diagnoses were recorded for all individuals in greater Helsinki who had been fetuses during the 1957 type A2 influenza epidemic (Mednick, Machon, Huttunen, & Bonett, 1988). The key finding was that those who were exposed to the viral epidemic during their second trimester in utero had an elevated risk of being admitted to a psychiatric hospital with a diagnosis of schizophrenia. This was true for both males and females and was found independently in several psychiatric hospitals. Among the investigators' conclusions was that the observed viral effects should be considered just one of many possible perturbations in utero. They suggested that the critical factor in triggering future schizophrenia was the timing, rather than the type, of disturbance.

Another study utilized the extensive medical records kept by Denmark to look for any associations between influenza and schizophrenia (Barr, Mednick, & Munk-Jorgensen, 1990). The investigators ascertained the number of live births, births of future schizophrenic patients, and cases of influenza for each month from 1911 to 1950 from health records at the Ministry of Health. The investigators concluded that in periods when influenza rates were higher than seasonally expected, such elevated rates during the sixth month of gestation were correlated, and birth rates of future schizophrenic patients were higher than seasonally expected. They also concluded that this effect was not attributable to other winter-related factors or to climatic variables.

In a 1994 book that described what had been learned to date in their extensive study of mental illness and twins, the authors report finding antibodies to pestiviruses in the plasma of certain subjects (Torrey et al., 1994). Specifically, among

the twenty-five identical twin pairs that were discordant for schizophrenia, ten of the patients (40%) had these antibodies, whereas none of the well co-twins did. Also, one of the sixteen normal control twins reacted to the pestivirus antigen. As to the nature of the group of viruses, the authors write, "this group of viruses is well known as animal pathogens but has not previously been found in humans.... Pestiviruses are especially interesting to schizophrenia researchers because the pestivirus that infects cattle is known to be transmitted in utero, but most cows do not develop symptoms for several years" (p. 99).

Season of Year Effects

If the developing fetus is vulnerable to viruses, then it should not be surprising that a season of birth phenomenon for schizophrenia has been detected; a slight excess of those who will someday suffer from schizophrenia were born during the late winter months, which presumably reflects the lag time after the peak of "flu season." A study examined this phenomenon in detail and collected data as to season of birth and family history for 561 patients with a diagnosis of schizophrenia (O'Callaghan et al., 1991). Patients with no family history of any psychiatric disorder were significantly more likely to be born in winter than patients with a first-degree relative who was affected with schizophrenia. The investigators concluded, "in comparison with normal population controls, only those without a family history exhibited a significant excess of winter births, suggesting an environmental factor of greater aetiological significance in these patients" (p. 764).

A new study reports on data collected from nationwide databases in Denmark (Mortensen et al., 1999). Specifically, the investigators obtained data on every woman born in Denmark during a 43-year period (1935 to 1978), and their offspring born until the end of 1993. Fathers were also identified for 97.7% of these offspring. Of slightly more than 2 million offspring identified, 1.75 million were followed from the later of their fifth birthday or 1970 until the earlier of 1993, their deaths, emigration, or onset of schizophrenia. The diagnosis of interest for this study population was schizophrenia (defined by ICD-8), and using national psychiatric records, 2669 cases were identified among the offspring. Cases were also identified for parents and siblings.

From this data, relative risks were calculated for

various categories of family history and for other factors. The calculated relative risks are shown in Table 3. Relative risks for those with affected mothers (9.31), fathers (7.20), and one or more affected siblings (6.99) were consistent with previously published studies. The relative risk for having both an affected mother and father (46.90) was notable not just because of its magnitude, but because it is a novel statistic due to its rarity; even in this population-wide study, both parents were affected in only 4 of the 2669 cases. This small number may support the argument that families heavily loaded for schizophrenia reproduce themselves to a significantly reduced degree.

Risk was also significantly associated with season of birth, was highest for those born in February and March, and lowest for those born in August and September. There was also a relative risk of 2.4 for those born in the capital, compared with those born in rural areas of Denmark; this effect was presumably due to a number of risk factors related to urban life, including a higher likelihood of contracting a virus.

The fact that such a large number of participants was tracked by Mortensen is bound to make conclusions about relative risk factors compelling, but the size of the sample also allowed the investigators to calculate population attributable risks, which the authors define as follows: "the population attributable risk is an estimate of the fraction of the total number of cases of schizophrenia in the population that would not have occurred if the effect of a specific risk factor had been eliminated—that is, if the risk could have been reduced to that of the exposure category with the lowest risk" (p. 604). The population attributable risks calculated by Mortensen and colleagues are given in Table 4.

The most surprising statistic is the very low population attributable risk (5.5%) for schizophrenia in a parent or sibling. The fact that these population attributable risks are not additive is illustrated by the fact that even considering all of the variables used by Mortensen, the population attributable risk was only 46.6%. However, it is striking that a family history accounts for only about 10% of the identified population attributable risks. Thus, although family history for schizophrenia creates much elevated relative risks for the disease, such family histories (or at least family histories that have been identified) account for a small minority of the incidence of schizophrenia in the general population. Accordingly, the two environmental factors chosen by Mortensen ac-

Table 3. Adjusted Relative Risk of Schizophrenia According to Family History, Place of Birth, and Season of Birth

Variable	Relative risk (95% CI) ^a
Family history	
Parent	
Father affected, mother affected	46.90 (17.56–125.26)
Father affected, mother not affected	7.20 (5.10–10.16)
Father not affected, mother affected	9.31 (7.24–11.96)
Father not affected, mother not affected ^b	1.00
Father unknown, mother affected	14.18 (8.48–23.70)
Father unknown, mother not affected	2.00 (1.72–2.32)
Sibling	
One or more affected siblings	6.99 (5.38–9.09)
No affected siblings ^b	1.00
Other factors	
Place of birth	
Capital	2.40 (2.13–2.70)
Suburb of capital	1.62 (1.37–1.90)
Provincial city (>100,000 population)	1.57 (1.36–1.81)
Provincial town (<10,000 population)	1.24 (1.10–1.41)
Rural area ^b	1.00
Greenland	3.71 (2.04–6.76)
Other countries	3.45 (2.69–4.44)
Unknown	1.22 (0.46–3.27)
Season of birth (amplitude of sine function) ^c	1.11 (1.06–1.19)

^aThe relative risk was adjusted initially for age–sex interaction, calendar year of diagnosis, and ages of the father and mother (first adjustment) and then for family history or, alternatively, other factors as well (second adjustment). The third adjustment (full model) was for all the variables listed. CI denotes confidence interval.

^bThis was the reference category.

^cFor all three adjustments, the estimated peak of the sine function was March 6 (95% confidence interval, February 6 to April 5).

Note. From Effects of family history and place and season of birth on the risk of schizophrenia by P. B. Mortensen, C. B. Pedersen, T. Westergaard, J. Wohlfahrt, H. Ewald, O. Mors, P. K. Andersen, and M. Melbye, 1999, *New England Journal of Medicine*, 340(8), 605. Copyright 1999 Massachusetts Medical Society. All rights reserved.

count for the majority of schizophrenia cases. Perhaps retarding the realization that environmental effects are major contributors to the etiology of schizophrenia is the fact that factors like place of birth and season of birth are not the true risk factors, but rather are proxies for environmental agents that are yet unidentified.

Obstetric Complications

Complications at birth as a risk factor for schizophrenia might seem like a logical extension of the prenatal risks discussed before, but evidence for such a risk factor is less compelling. One Irish

study used as a sample population sixty-five patients who had diagnoses of schizophrenia, and their previously born same sex siblings were used as controls (O'Callaghan et al., 1992). Maternity hospital records were evaluated (blindly), and the main outcome measure was the presence of one or more obstetric complications recorded in maternity notes of patients and controls. By using siblings as controls (who share on average 50% of their genes), presumably, any confounding genetic influence would be reduced, thus helping to establish an environmental risk.

The primary finding was that patients with schizophrenia were significantly more likely than

Table 4. Population Attributable Risk According to Family History, Place of Birth, and Season of Birth^a

Variable	Population attributable risk (%)
Schizophrenia in one or both parents	3.8
Schizophrenia in one or more siblings	1.9
Schizophrenia in parent or sibling	5.5
Place of birth	34.6
Season of birth	10.5
Place and season of birth	41.4
All variables listed above	46.6

^aFrom Effects of family history and place and season of birth on the risk of schizophrenia by P. B. Mortensen, C. B. Pedersen, T. Westergaard, J. Wohlfahrt, H. Ewald, O. Mors, P. K. Andersen, and M. Melbye, 1999, *New England Journal of Medicine*, 340(8), 606. Copyright 1999 Massachusetts Medical Society. All rights reserved.

the controls to have experienced one or more obstetric complication (odds ratio = 2.44). Patients also showed a greater number, severity of, and total score for obstetric complications, although fetal distress was the only complication that occurred in significant individual excess; it was present in five (8%) patients, and was absent in controls. Obstetric complications in patients were unrelated to family history or season of birth but were associated with a significantly younger age of onset of illness (mean difference = 4.5 years).

However, another study, published several months later, came to the opposite conclusion (Buka, Tsuang, & Lipsett, 1993). To test the hypothesis that pregnancy and delivery complications result in increased risk for developing psychiatric disorders, this study examined the records of 1068 pregnancies classified as chronic fetal hypoxia, other complications, preterm birth, or normal pregnancy/delivery. These pregnancies had initially been followed prospectively from birth to age 7, and the subjects were recontacted at ages ranging from 18 to 27 years. The data did not show that rates of psychiatric disorders were higher for those who had experienced obstetric complications. Two trends were noted that did not achieve statistical significance: subjects born preterm had elevated rates of cognitive impairment, and subjects who experienced chronic fetal hyp-

oxia also had elevated rates of both cognitive impairment and psychotic disorders.

Signals From Childhood

One of the mysteries of schizophrenia is why the onset of the disorder does not take place until the late teenage years for most men and until the twenties for most women. However, with hindsight, it is possible to find clues that are usually overlooked. For example, in a grand epidemiological undertaking, the British Medical Research Council tracked every child born in the first week of March, 1946, until they reached the age of 43. Within this cohort of 5362, thirty cases of schizophrenia emerged. A group of investigators was able to access the accumulated childhood socio-demographic, neurodevelopmental, cognitive, and behavioral information that had been collected over the years (Jones, Rodgers, Murray, & Marmot, 1994).

Some of the associations they reported included the following: Milestones of motor development were reached later in patients than in controls. For example, whereas about one-third of the general population was two weeks or more late in sitting up, two-thirds were late among the future patients. Also, when patients were compared to the controls, the difference in means for age of walking was 1.2 months, and up to age 15, patients had more speech problems than controls. Predictors of schizophrenia included solitary play preferences at ages 4 and 6 (odds ratio = 2.1); at 15 years, teachers rated cases as more anxious in social situations. Finally, a health visitor's rating of the mother as below average in mothering skills and understanding of her child at age 4 years was a strong predictor of schizophrenia (odds ratio = 5.8).

In an interesting study of developmental precursors of schizophrenia, home movies of adult-onset schizophrenic patients and their healthy siblings were viewed by judges blind to the psychiatric outcome of the subjects (Walker & Lewine, 1990). The films covered the period from infancy until at least age 5. Although none of the children had psychiatric conditions at the time, the trained viewers could correctly identify the children who would go on to become patients. One investigator cited as an example the fact that at 2 years old, some future patients had "slightly odd hand movements," which although not likely to be noticed by

a lay person, would be discernible to a trained observer as evidence of troubled motor development. The investigators concluded that “this represents the first demonstration that preschizophrenic subjects can be distinguished from sibling control subjects within the first eight years of life by observing their behavior” (p. 1052).

Evidence for a Possible Neurodevelopmental Mechanism

Except for obstetric complications at the time of birth, the various environmental influences discussed before are all in utero exposures, particularly during the second trimester of pregnancy. From a neurodevelopmental perspective, this is a very critical time because it is when the individual cells which will become neurons migrate to their eventual positions in the brain. Thus, any insult—whether it be viral infection, malnutrition, and/or any other trauma—can upset this migratory progress, thus risking the possibility that the infant brain will grow up lacking some of the intricate interconnections necessary for normal functioning.

A possible mechanism for such an adverse neurodevelopmental course is provided by a study that examined the distribution of various cell types in the prefrontal cortex of twenty deceased schizophrenic patients and twenty matched control subjects (Akbarian, Kim, Potkin, Hetrick, Bunney, & Jones, 1996). They identified three types of cells that represented the remnants of the cortical subplate, a structure that appears in the fourth month of pregnancy and guides migrating nerve cells to their proper locations. As part of programmed cell death, most of these subplate cells die within 30 days of birth, although a few remnants survive that become interstitial cells in the brain. The investigators found that in 35% of the brains of schizophrenic patients (but none of the control brains), there was a maldistribution of these interstitial cells toward the deeper white matter. The investigators concluded that the displacement of these interstitial cells in the frontal lobe of schizophrenic patients suggested alteration in the migration of neurons during brain development or in the pattern of programmed cell death. The investigators concluded that either problem could result in defective circuitry in the cortex.

Such an in utero effect might best explain why a monozygotic twin pair that is identical at conception may become discordant for schizophrenia.

Indeed, this adds to the argument that the heritability of schizophrenia derived from twin studies is overstated. Is it possible that for some monozygotic twin sets concordant for schizophrenia, rather than resulting from a genetic etiology, there was an in utero environmental insult strong enough that it impacted both twins? Keeping in mind schizophrenia's 1% lifetime risk, how much of this relatively low risk derives from genetics and how much from in utero environmental insults?

However, such neurodevelopmental theories do not necessarily exclude a genetic etiology. Given our knowledge of the elevated risk for those with a family history of schizophrenia (roughly an order of magnitude over that of the general public), one avenue of research must be to identify which genes may provide the substrate for increased susceptibility to such developmental influences. We will return to this question of the relationship between genetic and environmental etiologies at the end of “Conclusions.”

Evidence from Genetic Research

In less than two decades, the techniques of molecular biology and genetic analysis have become sophisticated enough that powerful tools are now available to tease out genetic inferences from analysis of the DNA taken from members of a sample population. By using restriction enzymes, it has been possible to map the entire human genome, and in the process, thousands of reference markers spread over all of the chromosomes have been identified. These markers are the guideposts from which a potential disease gene's locus can be triangulated. Thus, to the extent the family members in a pedigree who suffer from schizophrenia may have a common marker in their DNA, it may be inferred that a gene related to schizophrenia may be located someplace physically close to the known position of the marker.

The mathematical model used for the extensive calculations needed for such an analysis gives a result that is expressed as the logarithm of the odds that a finding could have occurred just by chance; this is the LOD score. Thus, if the probability that a result is due to chance is one in ten, the LOD score would be 1.0; the LOD score of a one in a hundred probability would be 2.0, and so on. Because of the vast number of calculations made in a linkage analysis, statistical artifacts are not un-

usual, and the practical result is that LOD scores less than 3.0 are often not considered noteworthy (Hamer & Copeland, 1994).

Like all mathematical models, the linkage analysis requires making certain assumptions to specify the algorithm used in the calculations. One important input is what the assumed mechanism of inheritance is; for example, is the gene being looked for assumed to be dominant or recessive? For some disorders, definitive empirical evidence on this point is available. For example, Huntington's disease is unusual in that over the years clear evidence accumulated that the disorder is likely to be controlled by a single gene and that the allele that gives rise to the disease is dominant (Barondes, 1998). Although one might expect that a dominant Mendelian disease would lead to the extinction of families carrying that allele, Huntington's has been around for more than 300 years because typically it does not strike until middle age, after the childbearing years.

Given the power of the linkage analysis tools, researchers in this field have become increasingly conscious of the problems caused by heterogeneity. Therefore, in finding the Huntington's gene, the research focused on an extended family in Venezuela with a high incidence of the disease. Linkage analysis of data collected in 1982 found a linkage of very high statistical significance on chromosome 4, although it would take another 10 years of effort and the development of new technology to actually identify the exact gene responsible for Huntington's disease (Huntington's Disease Collaborative Research Group, 1993).

Another critical input necessary for linkage analysis is a concise definition of the disorder so that the members of a pedigree whose DNA is being examined are properly classified as affected by the disease or not affected. Therefore, rigorous, clinically derived diagnostic tools, such as DSM-IV, are typically applied to the population studied. Because the quality of a statistical analysis is only as good as the quality of the underlying data, subtle shifts occasioned by varying disease definitions can create widely varying results.

An example of a linkage analysis that produced exciting results followed by disappointment was one undertaken on a number of Amish pedigrees, who exhibited extensive mood disorders, all, it was thought, derived from a small number of founders. Because another study had developed two DNA probes that could be used on chromo-

some 11, the Amish linkage analysis was initiated on just this one chromosome. Nevertheless, in 1987, this study produced powerful initial results that linked manic-depressive illness with a gene on that chromosome; the initial statistical analysis indicated that there was only a one in two hundred probability that the results were due to chance (Egeland et al., 1987). However, when two previously healthy members of one extended family exhibited mania and depression, respectively, the recalculation of the statistics to incorporate these new data points reduced the results below the one in twenty odds of chance that are the threshold of statistical significance (Kelsoe et al., 1989).

This ultimate disappointment reflects the fact that LOD statistical analysis is much less effective for more complicated genetic inheritance patterns, even though it is a very effective technique in analyzing Mendelian traits. LOD analysis for disorders resulting from more than one gene may be a high-tech and dangerous version of the old problem of "data dredging," that is, when a large number of variables is examined, some seemingly significant relationships may appear, which turn out to be just chance artifacts.

Another study at about the same time was also affected by these problems (Baron et al., 1987). Several large Israeli families with a high incidence of mood disorders were analyzed; the analysis in this case focused on the X chromosome because no male-to-male inheritance was apparent in the pedigrees in question; evidence suggested an X-linked trait. Here again, the exquisite sensitivity of the LOD technique to small changes in the underlying data was shown. When just two subjects, whose disorder was relatively mild cyclothymia, were reclassified from affected to not affected, the LOD score for linkage dropped from as high as nine (one in twenty million odds that results were due to chance) to scores that indicated a lack of statistical significance.

The point of this discussion is to set out some of the problems presented when attempting to use linkage analysis to locate "schizophrenia genes." An important threshold question is whether a possible genetic liability to schizophrenia is caused by just one gene or by multiple genes. Irving Gottesman first proposed a polygenic theory of schizophrenia in a seminal paper (1967). Almost 20 years later, Gottesman and two coauthors described the results of their goodness-of-fit analysis of pooled data for morbid risks of schizophrenia among the

relatives of schizophrenic probands in nine different classes of relatives with five different degrees of genetic relatedness (McGue, Gottesman, & Rao, 1985). They concluded that a pure polygenic threshold model fit the observed risks, although the fit of the model to the data was significantly improved if environmental sources of familial resemblance were also allowed for.

As a result of the extensive genetic analyses performed since, there is a widely accepted consensus that a polygenic model is most likely, with one notable exception, which will be discussed later. One empirical tool argues for such a conclusion as well. In a single gene inheritance model, the gene in question can either be dominant or recessive. If it is dominant, then we would expect that the concordance rate among monozygotic twins would be 100%, which is exactly the case for Huntington's disease, which is determined by one dominant gene. If the single gene is recessive, then we would expect to see that the monozygotic concordance rate would be twice that of the dizygotic concordance rate. However, based on the data reviewed earlier, we have seen that the ratio of monozygotic versus dizygotic concordance rates for schizophrenia is typically between three to five times, depending on the studies considered.

If liability to schizophrenia is likely to be a polygenic phenomenon, one analogy to consider is the existence of another polygenetically determined trait, human height. Common sense tells us that it is not likely that there is a single gene controlling height, but rather that each of us is the result of the influence of many genes that may affect our height. However, even this simple analogy points out possible complications when you consider that in rare cases, one gene may cause pathologies that dramatically affect height, for example, achondroplasia, which includes the symptom of dwarfism.

In addition to the problems occasioned by using linkage analysis to look for genes that are part of a polygenetic process, we must also keep in mind that any input assumptions as to genetic model and penetrance are educated guesses at best. Finally, there is the very legitimate question of how broad a definition of the disorder should be applied to the sample in classifying which pedigree members are affected and which are not. Should the sole criteria be a DSM-IV diagnosis of schizophrenia, or should a schizoaffective diagnosis also merit classification as affected? Or perhaps, family mem-

bers who exhibit schizotypal personality disorders should also be included as affected. The actual problem created by such choices motivated one author who wrote a review entitled "The maddening hunt for madness genes" to observe that "Some investigators have obtained their most compelling data by using a broad definition of illness, while others prefer to use a narrow one; a narrow definition of schizophrenia resulted in linkage to [chromosome] 5p, a broad definition resulted in linkage to 6p and a still broader one, to 8p in the same pedigree set" (Moldin, 1997, pp. 127-128).

Genome-Wide Scans

Armed with the caution that the previous discussion should engender, the first step in assessing genetic evidence should be to see what results have been obtained from genome-wide scans. This is the application of the linkage analysis techniques at the macroscale of all of the chromosomes that make up the genome to identify regions that may be worthy of more detailed analysis. A set of markers is chosen (typically numbering in the hundreds), and then the DNA for all members of a pedigree is typed for these markers.

Given the consensus that the heritability of schizophrenia is a polygenetic phenomenon, perhaps not much should be expected from genome-wide scans looking for likely schizophrenia gene sites, and so far, that has proven to be the case. For example, during the past year, several such projects have been reported. The Genetics Initiative of the National Institute of Mental Health reported on genome-wide scans performed on both African-American and European-American pedigrees. The African-American scan comprised thirty nuclear families and ninety-eight subjects, of which seventy-one had received diagnoses of schizophrenia and eight diagnoses of schizoaffective disorder (Kaufmann et al., 1998). There were a total of forty-two independent sib-pairs. The analysis revealed no regions that reached the level of significance that had been previously suggested in the literature (Lander & Kruglyak, 1995), although regions on chromosomes 6, 8, 9, and 15 "showed evidence consistent with linkage" (Kaufmann et al., 1998, p. 282).

The NIMH group reported similar results from their genome scan of forty-three European-American nuclear families with 146 subjects (schizo-

phrenia diagnosis = 82, schizoaffective disorder diagnosis = 14) and fifty independent sib-pairs (Faraone et al., 1998). Once again, no region showed statistically significant evidence for linkage, although evidence that suggested linkage was found at two markers on chromosome 10.

Also in 1998, a California group reported on its genome-wide scan of seventy pedigrees containing three phenotype classifications: schizophrenia only (48 pedigrees, 70 sib-pairs), schizophrenia plus schizoaffective disorder (70 pedigrees, 101 sib-pairs), and a broader category that also included various schizophrenia-related personality disorders plus a number of types of psychoses (70 pedigrees, 111 sib-pairs; Shaw et al., 1998). Using allele-sharing tests, twelve chromosomes had at least one region with a nominal p value less than .05, and of these twelve, two (chromosomes 13 and 16) had nominal p values less than .01. Using two-point LOD score analysis, five chromosomes (1, 2, 4, 11, and 13) had at least one marker whose score was higher than 2.0.

Looking at these three analyses as a group, the African-American scan identified four chromosomes of potential interest (6, 8, 9, and 15), the European-American scan identified just one (on chromosome 10), and the California project pointed to either two chromosomes (13 and 16, if you believed the allele-sharing model) or five chromosome (1, 2, 4, 11, and 13, using LOD score anal-

ysis). No doubt it is more than just a coincidence that these three genome-wide scans identified three mutually exclusive groups of chromosomes that merited further investigation. This certainly suggests that the heritability of schizophrenia is polygenetic, or perhaps even nonexistent!

Linkage Analysis of Specific Chromosomes

Rather than jumping into a review of the scores of studies of linkage analysis for schizophrenia that have been published, a good place to start is with a table contained in a 1997 review article that assessed the current status of this quest and was written by a skeptic (Crow, 1997). To prove the point implied by the review's subtitle, "Polygenes of vanishingly small effect or multiple false positives?," Table 5 was compiled by Crow and lists each of the chromosomes or "candidate genes" for which a successful linkage analysis once reportedly achieved statistical significance (p . 100).

One column in the table gives the author and date for the study that reported such significance, and another column lists at least one, and usually several, studies that failed to replicate a finding of significance. Crow may be a skeptic, but on the question of whether linkage analysis has been successful in locating genes related to schizophrenia, the literature is on his side. Indeed, in

Table 5. Claims for Linkage and Association in Schizophrenia^a

Locus/gene	Claim	Examples of discordant findings (usually the first and/or most salient discrepancy)

^aFrom Current status of linkage for schizophrenia: Polygenes of vanishingly small effect or multiple false positives, by T. J. Crow, 1997, *American Journal of Medical Genetics*, 74, 100. Copyright 1997 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

commenting on his position as a collaborator for one of these studies, Crow writes "however in contributing to the discussion and writing of the paper I found myself in a small minority in my interpretation of the findings, and in particular in dissent from the widely held assumption that a large number of genes contributing to susceptibility to psychosis are to be found, and that some linkages have already been established" (Crow, 1997, p. 99).

In fact, Crow uses the confusion of so many contrary studies to conclude that just as likely an explanation would be his long-held belief that there is one gene (yet to be discovered) that determines brain asymmetry, and for some individuals, causes schizophrenia. This is the one exception to the polygenic consensus alluded to previously.

The information in Crow's compilation is intended to demonstrate that the mechanisms by which genetics impacts schizophrenia are complex and subtle, and are likely to be the result of more than one gene, and probably many genes, Dr. Crow notwithstanding. There is a large literature reporting on various efforts at genetic linkage analysis for many genes of potential interest located on a number of chromosomes.

However, rather than chronicling the specific results of the many linkage analyses that have been reported, the goal in reviewing this literature will be to look for what this research can tell us about the interaction between genetics and the physiological and environmental evidence discussed earlier.

Chromosome 5. Table 5, from Crow's article, listed chronologically the chromosomes for which an association with schizophrenia was claimed at one time. From that table, we see that the earliest linkage claim for schizophrenia, involving chromosome 5, was reported by Sherrington et al. in 1988. Subsequently, a number of failures to replicate this association were reported, and interest waned in chromosome 5 in terms of schizophrenia.

However, several years ago, there were two new reports of possible linkage to chromosome 5; although still on the long arm, the sites were in a different region of the chromosome. In one study using 265 Irish pedigrees ($n = 1408$), a genome scan highlighted this region as the second most likely for linkage (Straub et al., 1997). More detailed work by the same group identified a locus with a LOD score that exceeded 3. Interestingly, a

significant LOD score was obtained only with a narrow definition of phenotype (schizophrenia only), in contrast with the same group's experience with two other chromosomes, for which broader definitions, applied to the same pedigrees, produced the strongest result. The investigators estimated that the putative vulnerability locus on chromosome 5 was segregated in 10 to 25% of the families. Another study, reported at the same time, found weak indications of an association near the same site, using fifty-four German and Israeli families (Schwab et al., 1997).

Chromosome 6. Ironically, the same set of Irish pedigrees was the subject matter of the linkage analysis that produced the strongest indications of linkage to schizophrenia seen to date, but had a locus on the short arm of chromosome 6 (Wang et al., 1995). A LOD score of 3.9 was obtained, although a study published later, which augmented the same pedigrees with more families, found a reduced significance (Straub et al., 1995). Subsequently, a number of published studies was unable to replicate these findings; for example, a 1996 study, which used data from 211 families that had affected sib-pairs, concluded that "the present findings together with the published literature fail to find consistent evidence of a linkage for schizophrenia to a single locus on chromosome 6" (Garner et al., 1996, p. 595).

A more recent study was also unable to confirm these findings, although the investigators obtained LOD scores just over 3 for two markers on the long arm in the region 6q21-q22.3 (Cao et al., 1997). It should be noted that 6q21-6q24 was one of the four regions that demonstrated evidence of significant linkage in a genome-wide scan of African-Americans reported several years later (Kaufmann et al., 1998). This finding will also take on increased relevance later when trinucleotide repeats are discussed.

Among the many studies involving possible linkage with chromosome 6, two stand out because they add dimensions beyond the technicalities of the linkage model and LOD scores. As discussed earlier, eye tracking dysfunction (ETD) has been identified as a trait seen in a significant number of schizophrenic patients and also in their relatives. A German group that has done research into ETD as a marker decided to undertake a linkage analysis focused on the short arm region identified by others (i.e., 6p21-23), using members of the families they had assessed in their ETD

research (Arolt et al., 1996). Using schizophrenia as the identified disorder, seven different models failed to detect significant results. However, when the specified disorder was ETD, their work identified two markers with high LOD scores: 3.51 for marker D6S271, and 3.44 for D6S282. Including these markers in a multipoint analysis yielded a LOD score of 4.02. Significantly, these two markers are very close to the three markers (i.e., D6S296, D6S274, and D6S295) that gave the strongest results in the 1995 study of Irish pedigrees that caused the initial excitement about chromosome 6 (Straub et al., 1997).

Another unique approach was taken in a linkage analysis that used twenty-eight markers on chromosome 6 to scan 183 people from ten moderately large Canadian families, for which schizophrenia had been diagnosed in about a quarter of the sample (Brzustowicz et al., 1997). Using various permutations of parametric analysis as well as sib-pair analysis based on categorical disease definitions yielded no significant evidence for linkage. However, the investigators then carried out a sib-pair analysis using three different quantitative traits as the disease input, specifically scores on a positive symptom scale, a negative symptom scale, and a scale for general psychopathological symptoms. The positive symptom scale found significant evidence of linkage, regardless of the disease diagnosis; nominal p values were 1.2×10^{-5} under two-point and 5.4×10^{-6} under multipoint analyses. These values corresponded to simulation-calculated empirical p values of .034 and .0085, respectively. For this study, the use of quantitative data rather than categorical disease input greatly increased the detection power of linkage analysis. The field awaits further testing of this approach.

Chromosome 13. A study published last year reportedly found evidence from a genome-wide scan for schizophrenia susceptibility loci that suggested associations with chromosomes 8 and 13, although only the chromosome 13 data rose to the level of significance (Blouin et al., 1998). Using a dataset that consisted of fifty-four cases of diagnosed schizophrenia and 309 relatives from European backgrounds and a narrow definition of schizophrenia, LOD scores as high as 4.18 were obtained. When the analysis was performed on another data set consisting of fifty-one cases and 248 relatives, a LOD score of 2.36 was obtained, although a finding of significance was possible only when the definition of the disease was broad-

ened to include categories such as schizophrenia spectrum personality disorders or mood disorder psychoses.

A contemporaneous news report stated that this result was consistent with the findings contained in an unpublished study by S.D. Detera-Wadleigh of the National Institute of Mental Health, in which the same chromosome 13 sequence was found often in family members diagnosed with bipolar disorder (Bower, 1998). In the same account, Detera-Wadleigh opined that schizophrenia and bipolar disorder may share some susceptibility genes.

Chromosome 15. In the same way that the Arolt study described before focused on a physiological marker (eye tracking dysfunction), a Denver group undertook linkage analysis on members of nine families that exhibited a significant incidence of P50 inhibition. This phenomenon, discussed before with other physiological evidence, is associated with attentional disturbances in schizophrenia (Erwin et al., 1998). The sample population consisted of thirty-six diagnosed cases of schizophrenia; thirty-five of them (97%) exhibited P50 inhibition, and 104 relatives, twenty-two of whom (21%) also displayed this trait (Freedman et al., 1997). The results of a genome-wide scan linked the P50 trait to a dinucleotide polymorphism at chromosome 15q13-14, and yielded a LOD score of 5.3. This site is the same as, or very close to, the site of the gene for the alpha 7-nicotinic receptor, a type of acetylcholine receptor found throughout the brain, which also responds to nicotine. Long-known anecdotal evidence of the extremely high smoking prevalence among schizophrenic patients certainly hints that this may be more than a coincidence.

A later study supported these findings. Using the marker with the highest pairwise LOD score (D15S1360), twenty families, with at least one sib-pair concordant for schizophrenia, were tested for linkage (Leonard et al., 1998). Because these families had not been tested for P50 inhibition, the affected phenotype used for the analysis was a DSM-III-R diagnosis of schizophrenia. The sib-pair analysis showed a significant proportion of D15S1360 alleles shared identically by descent.

Chromosome 22. Findings involving chromosome 22 would probably not merit mention if judged only by the history of claims of significance followed by nonreplication (see commentaries by Crow, 1997, and Moldin, 1997). A 1996 study by the Schizophrenia Collaborative Linkage

Group (Chromosome 22) reported on their combined analysis of genotypic data from eleven independent research groups, which focused on marker D22S278, the marker of most interest in three of these studies (Gill et al., 1996). Using the affected sib-pair method, the combined data set showed 252 alleles shared compared to 188 alleles not shared where parental genotype data was completely known and gave a chi-squared value of 9.31. The chi-squared statistic dropped to 6.12 when the other sib-pairs were added using parental data assigned according to probability.

As will be discussed later under its own heading, chromosome 22 contains a recently discovered gene that specifies a potassium ion channel. This ion channel is of interest because its function could provide a plausible mechanism for a number of the positive symptoms of schizophrenia.

Candidate Genes

Most of the linkage analyses described before focused on a particular chromosome because it had been identified in a broader, usually genome-wide, scan. However, another logical approach is to focus on certain genes that control structures or functions that might play an important role in the origin or course of the disease in question. By selecting such a candidate gene for investigation, there is the possibility of confirming or rejecting a hypothesized link between the gene and the disease. Of course, the opportunity to discover linkage to sites in the genome unrelated to the candidate gene is foregone, but then again perhaps the chances are also reduced of falling into the type of false positive situation discussed so often before.

Dopamine. Until the early 1950s, Western medicine had not found an effective pharmacotherapy for schizophrenia. Then, at about the same time, two drugs were found that were efficacious in treating the positive symptoms of the illness (Veggeberg, 1996). One of these, reserpine, was derived from a plant called *Rauwolfia serpentina*, which had long been used to treat insanity in India; when first administered to schizophrenic patients in 1954, it had a significant calming effect. At about the same time, another drug, chlorpromazine, which had been developed in France as an anesthetic, was similarly effective. These drugs and their successors became the wonder drugs by which a large majority of the mentally ill could be released from mental institutions, which until that time had been considered the only appropriate

forum for treating serious illnesses like schizophrenia.

Until the relatively recent acceptance of *atypical* schizophrenia medications, these first two drugs, and virtually all of the antipsychotic drugs developed subsequently, had their primary effect on dopamine neurotransmission in the brain. Specifically, they reduced dopamine activity in the brain, particularly in the limbic region, the seat of emotions. Not surprisingly, a *dopamine hypothesis* became popular, which considered schizophrenia a disorder characterized by excessive dopamine activity in certain regions of the brain. By reducing dopamine activity, the new antipsychotic agents often dramatically reduced positive symptoms such as hallucinations and delusions. Because these drugs, especially the early ones, were somewhat indiscriminate in terms of which parts of the brain experienced reduced dopamine activity, serious side effects often posed problems. In particular, because dopamine is an important neurotransmitter in the execution of movements, impairment in movement was frequently seen, and symptoms were similar to those seen in Parkinson's disease.

During the last decade or so, improvements in technology at the molecular level have led to the discovery of several subtypes of dopamine receptors. With this new knowledge, it has become harder to support the relatively simple hypothesis that schizophrenia is caused by hyperdopaminergia. It has now been determined that a blockage of the D2 subtype of dopamine receptors is the primary mechanism of action for the older antipsychotic drugs. Presumably the dramatic reduction in positive symptoms which is brought about by these drugs results from decreased activity at D2 receptors. However, the clinical experience was that D2 antagonists had little efficacy in reducing the negative symptoms of schizophrenia, suggesting that negative symptoms may not be related to hyperdopaminergia. Also, a new and more powerful antipsychotic drug, clozapine, has only one-tenth the binding ability to D2 receptors compared to chlorpromazine, even though it has some efficacy in reducing negative symptoms.

Given this history, the likeliest schizophrenia candidate genes are those related to dopamine function. As the number of known types of dopamine receptors has increased, so has the number of dopamine candidate genes. A number of studies during the past decade investigated the D2 receptor with mixed results. One study examined the

DNA of 253 unrelated subjects (106 with schizophrenia, 113 with alcoholism, and 34 controls) to determine which alleles of the D2 receptor gene were present (Gejman et al., 1994). Based on their results, the investigators concluded that no abnormalities in the DRD2 gene were associated with schizophrenia or alcoholism.

However, at about the same time, a study determined the frequency of one variant of the D2 gene (Ser311 → Cys) in 156 Japanese schizophrenic patients and 300 controls (Arinami et al., 1994). They found that the frequency was significantly higher in the patient group (0.054), compared to the control group (0.018). Also within the patient group, the frequency was increased in the before 25 age of onset (0.090), and family history (0.135) subgroups. They also commented that the patients with Cys311 showed significantly less severe thought disorder and negative symptoms. The same group later reported on case control studies with 291 schizophrenic patients, seventy-eight patients with affective disorders, and 579 controls (Arinami et al., 1996). The frequency of the S311C allele was elevated for patients with an absence of negative symptoms (17.1%), compared to both the other patients (5.7%) and the controls (4.1%). The frequency was also significantly higher in familial schizophrenic patients from one local area, but not in those from other areas. Finally, the S311C allele was frequently present in mood-incongruent psychotic affective disorders (33.3%), but not in the other affective disorder patients. The investigators concluded that the S311C allele might be a genetic factor for symptomatic dimensions of delusions and hallucinations.

A recently published study tested eight candidate genes related to dopamine transmission in fifty-nine families from Germany and Israel for association (Schwab et al., 1998). This analysis detected a CA-repeat marker near G-olfalpha on chromosome 18p, which had a corrected *p* value of .0044. This value decreased to .0007 when nine siblings with recurrent unipolar disorder were included. A two-point LOD score of 3.1 was also obtained for this marker. The investigators concluded that this marker on chromosome 18p represents a potential susceptibility locus for functional psychoses.

An Ion Channel Gene. A series of articles by a group from the University of California at Irvine were published last year that created interest in a newly discovered gene for a calcium-activated

potassium ion channel (hSKCa3) found in neurons. This type of ion channel plays an important role in determining the firing rate of neurons. The new gene was first discovered in a rat model, and when the human version was identified, it was found that it contains CAG repeats (Chandy et al., 1998). CAG repeats have been implicated in other psychiatric disorders, such as Huntington's disease, in which the number of CAG repeats exceeds a certain level for those with a disease condition. This trinucleotide codes for the amino acid glutamine so that, as the number of CAG repeats increases, more glutamines are added to the ion channel, perhaps affecting its function in the case of the hSKCa3 gene.

The initial study showed that the number of CAG repeats found in the various alleles ranged from twelve to twenty-eight in samples of both schizophrenic patients and controls (Chandy et al., 1998). However, the overall distribution of alleles was significantly different in the patients compared to ethnically matched controls; CAG repeats longer than the modal value were overrepresented in patients. A similar, but nonsignificant, trend was also seen for patients with bipolar disorder. A news account at the time reported that several of the investigators speculated that extra repeats might lead to abnormally active potassium channels, which could suppress NMDA receptors. They also pointed out that when NMDA receptors are inhibited by the drug of abuse PCP, schizophrenia-like symptoms can be induced; conversely, some antipsychotic drugs activate these receptors (Travis, 1997).

Some months later, the same investigators reported that when their hypothesis was tested in another case control study, the results provided modest support; schizophrenic probands had a higher frequency of alleles with more than nineteen repeats than controls (Bowen et al., 1998).

A Chinese group reported on a study in which they tested the hypothesis in ninety-seven family trios with schizophrenia from Southwest China (Li et al., 1998). Based on tests of haplotype relative risk and transmission disequilibrium (TDT), they found no evidence for an excess of longer CAG repeats in patients, although they did find a deficit of transmission of the (CAG)₂₀ repeat allele to affected offspring when this allele was considered individually by TDT. A German group also reported on a family-based association study to test the hypothesis in fifty-nine parent/offspring

trios (Stober et al., 1998). Contrary to expectations, their findings indicated that short CAG repeats (less than or equal to nineteen repeats) were transmitted at an *increased* frequency to offspring diagnosed with schizophrenia, particularly among familial cases.

Repeat Trinucleotides

The ion channel gene discussed before is just one example of possible trinucleotide repeat polymorphisms that may have a role in the genetics of schizophrenia. Such a possibility is attractive for several reasons. As mentioned before, such repeat polymorphisms, especially CAG repeats, it has been demonstrated, cause neurodegenerative diseases including Huntington's disease and Alzheimer's disease. From a biological viewpoint, CAG repeats provide a plausible and understandable mechanism, that is, the addition of glutamine amino acids to the ion channel protein affects its functioning.

Finally, repeat polymorphisms also provide a plausible physiological substrate for the phenomenon of genetic anticipation, where the age of onset decreases and/or the severity of a disease increases from generation to generation, presumably because each succeeding generation contains more repeats at one or more critical genes. Such a hypothesis was tested using thirty-three families with at least two affected members in successive generations (Johnson et al., 1997). The disease definition was broad, including schizoaffective disorder, psychoses, and schizotypal personality disorders; various indices measuring age of onset and severity of disease were also used. Anticipation was demonstrated for age of onset regardless of the index used, but anticipation for disease severity was not supported.

Another study used the repeat expansion detection (RED) method to investigate the occurrence of repeat polymorphisms in a group with childhood-onset schizophrenia (COS), as well as in a group with childhood-onset psychosis (Burgess et al., 1998). The difference observed in the CAG/CTG RED product distribution between the normal and the COS samples was only marginally significant. However, the male COS group had a RED product distribution significantly different from the male controls, and longer repeats were detected in the COS group; no significant difference was seen among females. The investigators also reported

that some of the detected trinucleotide repeats in all three populations (COS, childhood-onset psychosis, and control) correlated with expanded alleles found at the CTG18.1 locus on chromosome 18.

A recent study reported on an investigation designed to identify additional candidate genes which might be affected by trinucleotide repeats (Kleiderlein et al., 1998). In this case, complementary DNA (cDNA) libraries (i.e., synthetic DNA without material that may be irrelevant to an analysis; e.g., introns) from the human brain were probed for repeats of a family of six trinucleotides known collectively as the CCG repeats. The cDNA libraries were also compared with the thirty-seven human genes with eight or more consecutive CCG triplets in GenBank. The study reported mapping the repeats to fifteen specific loci, including the following of interest for this review: *6q22*, which was the locus identified by Cao et al., discussed before under the heading Chromosome 6; *18p11*, which may be pertinent to the Burgess et al. study discussed in the previous paragraph; and *22q12*, which is the locus of the gene discussed before in the section Ion Channel Gene. Each of these possible sites for genetic linkage might deserve extra consideration because of the possibility that repeat polymorphisms might also be detected there.

Conclusions

Like most diseases, both genetics and environmental effects are etiologic factors in schizophrenia. Because of long-standing knowledge that schizophrenia "runs in families," it has been known as a genetic disorder. One of the purposes of this review has been to examine the widely held view that a strong genetic component is a major feature of the disorder. However, when schizophrenia is examined on a societal level, some of the more recent evidence has identified environmental stressors, such as viruses, as significant in the etiology of the disorder.

Diathesis-Stress Model Favored

At least two models can account for the contribution of both environmental effects and genetics to schizophrenia. One approach might conclude that there are really two separate and distinct disorders that happen to share a number of common

symptoms as end points. One disorder would be a familial type that exhibits genetic transmission, and a second disorder would be a sporadic type, caused by environmental stressors. Although these two diseases might share many symptoms, they need not. Indeed, an important aspect of a two-disease model is the research effort to identify symptoms that may be used to distinguish between the disorders. In the review of evidence before, a number of taxonomies were discussed that create dichotomies as an aid to understanding the nature of schizophrenia, for example, positive and negative symptoms and a neurodevelopmental disorder compared to a neurodegenerative disorder. As summarized at the end of "Taxonomies of Schizophrenia," research focused on such distinctions has not produced compelling evidence that multiple disorders exist. Furthermore, results have not been consistent from study to study.

An alternative to a multiple-disease model is a one-disease process that can encompass both genetic and environmental etiologies: the diathesis-stress model. This model explains that the disease results from a genetic predisposition to the disease and environmental stressors that trigger the expression of the disease. A number of common diseases, such as coronary artery disease, fit such a model because it can incorporate the many contributing factors that are observed clinically. Thus, the occurrence of heart disease can be viewed as the confluence of some degree of genetic predisposition with various environmental risk factors, such as obesity, lack of exercise, and improper diet.

Although arguments have been made for both approaches in understanding schizophrenia, the evidence reviewed herein makes a more convincing case for the diathesis-stress model. In particular, in both presumed genetic and environmental situations, the logic of what has been observed strongly supports the diathesis-stress model. For example, when a strong genetic risk factor is likely, such as family loading for schizophrenia, only a minority of the family actually develops the disorder, that is, only a portion of those with the genotype develop the phenotype. Because well relatives may share a number of physiological markers, such as eye tracking dysfunction, we know that some well relatives may also have a genetic risk factor for the disease. Therefore, environmental effects are likely to be the agency by which only some of the family develop the illness. Indeed, if every family member contracted the disease, schizophrenia would quickly become

much more rare by reducing reproduction because it strikes in childbearing years.

Conversely, examples of environmental stressors, such as flu epidemics, also provide a logical argument for the diathesis-stress model. The evidence has shown that even if a large population is exposed to an environmental stressor, such as was the case with the 1945 Dutch famine, most of those in utero do not develop schizophrenia later. Rather, the result may be a rate of schizophrenia for those in utero at the time that is elevated from the small 1% lifetime risk to a less small, but still low, several per cent. Unless there is a chance phenomenon at work, it may be argued that the disease occurred in that additional several per cent due to their genetic predisposition.

The Degree of Heritability

An orthodoxy has developed as to the heritability of schizophrenia. It typically begins with the observation that a number of twin studies demonstrated a concordance for schizophrenia in monozygotic twins of slightly more than 50% (on a probandwise basis), compared to a concordance rate for dizygotic twins of about 15%. This ratio of roughly three to one leads to conclusions that calculate the heritability of schizophrenia as somewhat in excess of 50%.

However, as the evidence reviewed in "Review of Evidence Indicating Transmission within Families" revealed, such logic ignores the fact that behind these average numbers there is great variability in the data collected by different studies. Taking numbers from the eight studies contained in Table 1 (Torrey et al., 1994), we see that monozygotic concordance rates range from 26 to 68%, and the range for dizygotic twins is 4 to 18%.

This lack of consistency reflects important methodological problems that are often encountered in twin studies. Frequently the classification of zygosity has not been determined scientifically, especially where the twins have not actually been examined. Similarly, because many studies predate the development of uniform criteria such as DSM, diagnosis of the subjects is questionable, especially if one or both of the twins have not actually been observed. These are examples of the types of problems that are bound to occur when comparing studies conducted at different times and under different circumstances.

The discussion of Table 1 identified another source of confusion: that concordance rates for

schizophrenia have typically been stated on a probandwise basis, rather than the pairwise basis used for many other diseases. However, even allowing for this procedural difference, the higher than 50% rate of concordance for monozygotic twins typically cited is overstated. Using the figures from Table 1, the average probandwise rate for monozygotic twins is 40% if all eight studies are included, or 39% if the only studies counted are the three studies that Torrey considers the least methodologically impaired. Average probandwise concordance rates for dizygotic twins are 15 or 14%, respectively. Translating these numbers into pairwise statistics gives a comparison of either 28% (all studies) or 26% (three studies) for monozygotic twins, compared to either 6 or 8% for dizygotic twins.

But aside from these methodological concerns, the magnitude of heritability that is calculated probably also suffers from a significant confounding factor. In reviewing the evidence for environmental effects earlier, most studies pointed to the in utero period as the most likely time frame for exposure to environmental stressors that may trigger schizophrenia. As discussed in the section "Evidence for a Possible Neurodevelopmental Mechanism," the in utero period also makes sense from a biological perspective, because we can contemplate a plausible mechanism, that is, perturbation during the time when neurons are migrating to their eventual location in the developing brain. However, to the extent that any such environmental stressors occur between the conception and birth of a pair of monozygotic twins, their impact will be counted as a genetic effect in a twin study, further contributing to an overstated heritability.

These types of problems indicate that the usefulness of twin and other observational studies may have reached a limit as to what they can reveal about the etiology of schizophrenia. If that is the case, then genetic analysis may be the approach that offers the most promising potential for studying heritability.

Problems with Genetic Analysis

The evidence reviewed before indicates that the genetic etiology of schizophrenia requires a complicated model. There are three primary reasons for this: probably more than one gene is involved; there is incomplete penetrance, that is, the disease is not expressed in all those at genetic risk; and there are several definitional problems.

The genetics of schizophrenia almost certainly involves more than one gene. In fact, the more appropriate question is how many genes are involved. The evidence we have reviewed points to a model with multiple genes of small effect. One consequence of each gene's small effect is that these effects become difficult to detect. Given this situation, it is not surprising that in the review of genetic studies earlier, many cases were seen of a specific locus on a given chromosome that demonstrated an effect in some studies, but not in other studies.

Even in a family with relatively heavy loading for schizophrenia, only a minority of family members express the disease, which is evidence of the genetic phenomenon of incomplete penetrance. The conclusion that there is incomplete penetrance is bolstered by the fact that several physiological markers have been identified which are present both in schizophrenic patients and in some of their well relatives. The fact that the degree of penetrance is currently unknown and unpredictable and that it may vary from pedigree to pedigree makes attempts to fit observed data into mathematical models of genetic transmission problematical, and perhaps even an impossible task.

An important issue in creating a genetic model is the approach taken in defining the disease. A narrow definition has the virtue of offering a set of quite distinct symptoms (for example, hallucinations, delusions), so that the presence of such a constellation reduces the risk that various symptoms are present by chance or are due to another disorder. However, a broader definition may better reflect the genetic reality. For example, if they are related to the same gene(s), perhaps a related disease, such as schizoaffective disorder, or even usually distinct disorders with a common feature such as psychotic affective disorders, should be included.

The three difficulties in developing a genetic model for schizophrenia described before also have a major impact on linkage analysis. Looking at a converse situation, this technique is most powerful in working with a disorder like Huntington's disease, when it is known that the genetic effect derives from one gene; the genetic model is precisely known, dominant Mendelian in the case of Huntington's; and the outcome measure is binary; either an individual suffers the disease, or does not.

For schizophrenia, to the extent that the number of genes involved in the disease process increases, the mathematics underlying the linkage model is

strained in its ability to detect linkage, and the production of false positives that reflect artifacts is increased. Uncertainty about the genetic mechanism forces investigators to test many sets of assumptions, and even then the calculations may not be productive because the penetrance issue is such an unknown in the process. Finally, the issue of the way the disease is defined has a much larger impact on the results produced by linkage models, compared to questions of definition in the real world. In the review of genetic evidence before, investigations were encountered in which the best results were obtained by using narrow, intermediate, or broad definitions. Judgments as to the appropriate broadness of definition for any particular study have to balance the precision gained from a narrow definition against the possible need for a broad definition to reflect genetic realities.

The review of evidence before highlighted several techniques that may increase confidence in using linkage analysis: identification and use of biological markers, the use of quantitative rather than categorical data, and the use of repeat expansion detection techniques.

The use of biological markers may enhance the efficacy of linkage analysis. However, markers that are present only in patients may not help much. For example, according to the most plausible mechanism proposed to explain problems in the neurodevelopmental process (in utero perturbations to migrating neurons), deficits in prefrontal cortex blood flows may be observed only in patients—and not in their well relatives—because such deficits are likely to be markers of an environmental, not genetic, effect. Thus, the utility of markers probably depends on whether they can be found in well relatives, as well as in patients.

Markers in both patients and well relatives may also present an opportunity to overcome the penetrance problem. To the extent that markers such as eye tracking dysfunction (Holzman et al., 1988) can be objectively measured, the issue of how broad a disease definition to choose may be resolved in favor of a narrow definition. The other marker identified in the review of physiological evidence above was an abnormality in P50 inhibition (Freedman et al., 1997).

Another promising technique is that employed by Brzustowicz and her colleagues (1997), in which quantitative data were used as the disease input into the linkage model, rather than categorical judgments. By inputting patients' scores for

positive symptoms, a linkage finding of statistical significance was produced, whereas the usual categorical variable could not. This demonstrates the possibility of adding statistical power to the analysis of effects that are so weak that the variables currently being used cannot detect them. There are several other benefits to this approach. By definition, quantitative measures are more objective than an investigator's subjective choice of a disease category. It is possible that significant quantitative data can also be collected from well relatives. For example, relatives with certain personality disorders may exhibit subtle negative symptoms that could be detected by a scale for negative symptoms, even though such relatives would otherwise be categorized only as affected if the broadest possible disease definition had been chosen for the linkage analysis.

Finally, knowledge about mechanisms that involve trinucleotide repeats in genetic transmission, which has been culled from the study of a number of psychiatric illnesses, is accumulating. This is another instance of a phenomenon in which the mechanism is plausible from a biological perspective, that is, including the additional amino acids coded by triplet repeats may impact the structure or function of the protein coded by a particular gene. This developing body of knowledge should spur the use of repeat expansion detection methods. As increasingly refined results are achieved, this may enable identifying more genes that are subject to trinucleotide repeat expansion. Potentially this could powerfully corroborate results obtained by ongoing linkage analyses.

These three relatively new techniques can dramatically increase the productivity of the many scientists wrestling with the genetics of schizophrenia. From the large literature describing linkage analysis efforts that are ongoing worldwide, we know that significant amounts of money and scientists' efforts are being allocated to this question. However, these expenditures may be approaching the point of diminishing returns. Perhaps more research attention should be focused on environmental etiologies.

Environmental Etiologies in Schizophrenia

Many of the studies reviewed herein have used pedigrees with a history of schizophrenia as the

subjects of their research because this increases the ability to detect factors that may contribute to heritability. However, it is important to address the question of the way the phenomenon of family heritability is related to the incidence of schizophrenia in the general population. In other words, can the heritability model that has resulted from the genetic research account for a major portion of the cases of schizophrenia that are seen?

The recently published study of a large Danish cohort, discussed in the section "Season of Year Effects," offers important insights into this question (Mortensen et al., 1999). A major strength of this study is that it considers an entire population by drawing on the thorough health statistics maintained by Denmark. The investigators reported the elevated relative risks that would be expected for those with a family background of schizophrenia; the data in Table 3 display the calculated relative risks. Not surprisingly, relative risks for non-family history factors were much lower, for example, 2.40 for birth in the capital city and 1.11 for season of birth. Once again, these relative risks were significant and consistent with several previously published studies.

However, the most interesting statistics calculated by Mortensen and his colleagues were the population attributable risks, which are given in Table 4. The low population attributable risk from a family history of schizophrenia (5.5%) is overshadowed by the two environmental factors chosen by Mortensen, which account for the majority of schizophrenia cases. Thus, although a family history for schizophrenia creates high relative risks for the disease, such family histories (or at least family histories that have been identified) account for a small part of the incidence of schizophrenia in the general population.

The revelation that family background, as defined by Mortensen and colleagues, accounts for a relatively small minority of schizophrenia cases in the general population might argue that genetic factors play a relatively minor role in the etiology of the disorder for the great majority of the population, that is, those without any evidence of family history. However, such an argument unwittingly adopts the assumption that unless the disease is actually exhibited in one or more relatives, a person has zero genetic risk of schizophrenia.

In previously concluding that the diathesis-stress model best fits our understanding of the etiology of schizophrenia, there is an acknowledg-

ment that even in the case of an environmental effect that broadly affects a population, such as the Dutch famine, the genetic predisposition of the members of the population will trigger the relatively small number of cases. Thus, although the readily apparent genetic risk of a family loaded for schizophrenia is a small contributor to the population risk, the currently undetectable genetic predisposition of the rest of the population remains important to the etiology of schizophrenia.

Future Schizophrenia Research Priorities

Because the most significant role of genetics in population attributable risk is in the subtlety of the broad population's genetic predisposition, an interesting question is whether current genetic analysis, which typically focuses on families loaded for schizophrenia, will also provide insights for the much larger population without apparent family loading. The results of linkage analysis among families loaded for schizophrenia may ultimately yield techniques useful for the desirable goals of predictive genetics and/or genetic intervention. But it may be a reasonable question as to whether such techniques will prove useful in evaluating the much less apparent genetic predisposition of the general public.

Genetic research is often viewed as a triumph of high technology and the acquisition of exotic knowledge about the human genome. But, by its nature, it is a very expensive research field and consumes huge resources, measured both in dollars and human effort. Writing in 1992, E. Fuller Torrey, an unabashed advocate for increasing the amount of schizophrenia research focused on environmental effects, made the point that at the time genetics remained the only clearly defined etiological factor for schizophrenia (Torrey, 1992). However, he went on to point out that this might be because genetics is the most important factor in the disorder, but, it might also merely be because other etiological factors are yet to be identified. Certainly, research reported in the six years since Torrey offered these comments demonstrated that there are undeniable environmental effects, even if the mechanisms underlying these effects may still not be known. Studies reviewed earlier that support environmental etiologies include evidence of season of birth effects (O'Callaghan et al., 1991),

evidence of delayed childhood motor development (Jones et al., 1994), evidence of in utero effects during periods of famine (Hoek et al., 1998), and flu epidemics (Barr et al., 1990).

Thus, priorities for research funds and efforts should be directed more toward examining the science underlying environmental etiologies of schizophrenia. Specific areas in which such efforts may prove productive include additional epidemiological studies like that of Mortensen et al., especially using data from countries with well-organized health statistics.

Research attention directed at generating new knowledge about in utero risk factors may prove particularly rewarding by adding to our understanding of schizophrenia and also because of its relevance to many other disorders that shatter lives and absorb huge societal resources.

In a comment related to Mortensen's recently published study, it is pointed out that unlike other mental illnesses that affect multiple cognitive systems (e.g., Alzheimer's disease), once the impairments seen at onset stabilize, schizophrenia usually does not exhibit progressive deterioration over time (Andreasen, 1999). This argues for considering the majority of schizophrenia cases as a neurodevelopmental disorder, in which damage to the brain, by definition, occurs during the developmental period between conception and late adolescence. Thus, our revised priorities should include increased research on the processes of brain development and the impact of various stressors on those processes. To the extent that mechanisms can be found that explain such neurodevelopmental problems, our understanding of schizophrenia will be enhanced, and broader gains in medical knowledge can also be achieved.

Schizophrenia: A Critical Examination

Charles A. Sanislow and Robert C. Carson

Introduction

The editors commissioned us to write a chapter that challenges the notion of schizophrenia, thus providing the “other” viewpoint. It seems that the admittedly provocative view taken in the preceding edition of this chapter (Carson & Sanislow, 1993) has earned that request. At once, however, we find ourselves bewildered about what that “other” might be. Are we to represent the antithesis to the prevailing biological zeitgeist of psychopathology? Is this goal to keep alive the epistemological perspectives that have been issued by those of a Szaszian stripe? Or, are we plainly missing the boat? We are, to say the least, uncomfortable with any of these possibilities. However, the mere suggestion that “schizophrenia” may not be a viable construct inspires expectations consistent with at least one of these propositions. We warn against such expectations.

All provocation aside, there is reason for alarm in the light of the lack of progress during the past century. Hegarty and colleagues (1994) conducted an ambitious and rigorous quantitative analysis of worldwide long-term outcomes in schizophrenia

over what roughly constitutes the entire span of the construct’s existence. The results they found were not good. Overall, the social recovery rate was 40.2% for the period 1895 through 1991. When comparing the contemporary time frame (years 1986–1991) to the period with the most stable plateau (1926–1955), there was no significant difference. Following the introduction of neuroleptics in 1955, the social recovery rates rose to about 50%, but curiously, these rates fell back again around 1975. The authors attributed this drop to the more stringent diagnostic criteria of recent years, a hypothesis related to one of the major impediments of meaningful progress in this area.

On the other hand, the primary focus in this era appeals to the bewildering array of biological correlates in defense of the modern “disease” concept of schizophrenia (because of the lack of progress made during the last century?). In the context of a seemingly endless array of positive results, Crow (1997a) commented as follows on the resultant incoherence of the evidence:

The problem is that many changes in many different anatomical structures are reported. Which of these is reliably associated with the disease process? If, as seems likely, there is more than one such change, which is primary and which is secondary?... We need to find changes characteristic at least of a subtype of psychopathology.... But there is an embarrassment of riches. (p. 521)

Despite our concerns that the present approaches to biological aspects of the disorder provide resolution that is far less than satisfactory, our position

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

should not be mistaken as antibiological. Modern biotechnological methods offer potentially enormous contributions, but there are some serious problems that will be given due consideration later on. Foremost among them, the usual and customary bifurcation of biological and environmental variables lends itself to a dichotomous style of thinking that is at odds with a developmental understanding of psychopathology. We hope that our presentation here will suggest a more productive approach.

Beyond this issue, however, there remains a more fundamental problem: It is still not known exactly what schizophrenia is (this assertion should not be mistaken for deconstruction; we hold the premise that an adequate taxonomy of psychopathology is fundamental to the advancement of knowledge). Noted schizophrenia researcher Nancy Andreasen (1998) pointed out that schizophrenia is a supposed disorder with no visible neuropathology and has warned that, in the light of this fact, the withering dearth of clinical research in this area is a gaping liability. In the absence of a clearly demarcated disorder, advancing research is likely to be accompanied by substantial confusion, thereby undermining the potential knowledge acquired. This, in fact, is the predominant pattern. As will be shown in our review of the multiple changes in the diagnostic approaches, a shifting core without a firm footing is a perennial problem for schizophrenia research.

Having set an appropriately skeptical tone, we remind the reader that the behaviors conventionally associated with the term schizophrenia have been seen for many years and quite properly so, as the most stubbornly opaque, perplexing, frustrating, and in certain eras professionally demoralizing in the entire domain of mental health disciplines and in all probability, of the priestly forebears of the latter. We hope that we have prepared the reader for the idea that much of what can be said for this class of disorder does not cohere in a neat and tidy way, and some of it may be quite disconcerting in its refractoriness to satisfactory conceptualization. Major revisions in the way that the disorder is thought about and studied will be necessary for real progress.

In this chapter, we will address the following areas: The identification of the core, if any, of the disorder(s) (Taxonomic Issues), how genetic and environmental variables are thought about in a developmental context (Etiologic Considerations),

and consideration of the treatment process (Treatment Perspectives). In short, we think that much of what follows will demonstrate that this is not a domain in which simple answers—for example, that schizophrenia is a definite, unitary, but as yet imprecisely localized brain disease—have even a minimal likelihood of achieving convincing confirmation in the foreseeable future.

Taxonomic Issues

Background of the Schizophrenia Diagnosis

In 1860, Belgian psychiatrist Benedict Morel described the case of a 13-year-old boy whose functioning severely deteriorated from that of a brilliant pupil to an increasingly withdrawn, lethargic, seclusive, and delusional boy with substantial intellectual decline. Morel hypothesized that the deterioration was the result of irrecoverable brain degeneration of hereditary origin. He used the term *démence précoce* to describe the condition and to distinguish it from the dementing disorders associated with old age. Based on this early belief of intellectual deterioration—a belief that, as will be shown in more detail later, is not well-supported—Kraepelin subsequently adopted the Latin form of this term to refer to a group of conditions that all seemed to have the feature of mental deterioration beginning early in life.

Bleuler (1911/1950) objected to the term in part because he believed that both of its elements were erroneous and misleading. He reportedly observed numerous patients who otherwise met the descriptive criteria for dementia praecox but whose disorders did not progress inexorably into profound cognitive deterioration and did not first appear at a young age. Bleuler felt that he had identified by careful observation a theretofore unrecognized set of “fundamental symptoms” that were invariant and basic properties of the disorder. He believed that these should be its defining features as well as the criterial specifications for rendering the diagnosis. For Bleuler, the central feature of the disorder was that of the “splitting” of different psychic functions, and therefore named the disorder schizophrenia. However, he issued the important caveat (and one that we would submit still holds true today): “For the sake of convenience, I use the word in the singular although it is ... apparent

that *the group includes several diseases*” (Bleuler, 1911/1950, p. 8, emphasis added). Indeed, persons who earn the designation “schizophrenic” are an extremely heterogeneous lot both behaviorally and biologically, far more so than “normals” in many dimensions of comparison. The recognition of such heterogeneity has spawned a variety of proposed subtypes of schizophrenia over the years and has led some investigators (e.g., Bellak, 1979) to conclude that “schizophrenia” is merely a final common pathway of varied ego dysfunctions produced by numerous distinct causal patterns. Such a view raises questions about the need for an overarching and potentially misleading construct such as schizophrenia. At the same time, evolving diagnostic systems make zeroing in on the core of a disorder like trying to hit a moving target.

Developmental History of the DSM-IV Criteria

To fully understand the modern diagnosis of schizophrenia, according to the most prominent system (i.e., DSM), requires a careful look at the history of the ways by which the disorder has been defined. Bleuler was the first to coin the term schizophrenia, but Kraepelin—at least as it appears by the current climate in psychiatric diagnosis—has been credited the status of father of the disorder.

Early Formulations by Kraepelin. In outlining the following symptomatology for dementia praecox, Kraepelin noted that the “... disease picture appears so varied that upon superficial observation the fundamental symptoms are not recognized” (Defendorf, 1902, p. 154). He went on to note the moderate effects of what we would now term anxiety (i.e., “clouding of consciousness”) and the presence of hallucinations early in the course of the disease, suggesting a source for the distress. It seems that, for Kraepelin, a perplexing aspect of the disorder concerned the fact that those in the throes of it were apparently unaffected in their abilities to perceive the majority of their surroundings and orientation in accurate terms, although delusional states could impose major distortions of specific aspects of the patient’s surrounding reality. The other major symptom areas concerned attentional difficulties, primarily the inability to control attentional processes, and disturbance of “emotional field” which referred to a loss of interest or pleasure in routine daily activ-

ities. Finally, in some cases, there was a disturbance of conduct, or a “disappearance of voluntary activity” that also appeared on occasion at the other extreme in the form of impulsive acts (e.g., outbursts of smashing things such as breaking dishes).

Kraepelin noted several areas of progressive deterioration associated with dementia praecox. These, he noted, were primarily in the areas of memory and judgment. For the former, Kraepelin noted that it was the memories formed after the onset of the disorder that were in fact impaired; memories before the onset of the disorder remained intact. The worsening of judgment was largely attributed to behavior that was performed in response to persecutory delusional states. Finally, Kraepelin noted the absence of a definite external cause and the limitation of the methods of the time to establish an anatomical pathological basis for the disease. Indeed, his way of thinking about the disorder has been increasingly embraced in more recent times (i.e., the assumption of a discrete anatomical cause and also, his emphasis on the deterioration feature of the disorder). Kraepelin outlined a clinical description of dementia praecox, but it was somewhat lacking in diagnostic specification, and there was at least some implication of a manic component. For instance, “The whole disturbance can be very gradual ... and the symptoms so ill-defined that relatives see them only as a weakness in character... He may still show the same or even greater industriousness, apply himself tirelessly to his books, engage in massive, inappropriate and indigestible reading ...” (Kraepelin, 1896/1987, p. 13). It was left to Bleuler to attempt to better isolate the clinical entity in more discrete clinical terms.

Bleulerian Criteria. The “splitting” that Bleuler believed characterized the essence of schizophrenic mentation was said to be manifest in three “altered simple functions”: association, affectivity, and ambivalence. The other “simple functions”—those of sensation, perception, orientation, and motility—were said to be unaffected in schizophrenia. Certain “compound functions” were also regularly involved in the schizophrenic process, but the only deficit of this type uniformly present was a splitting in the person’s relation to reality, termed *autism*. Bleuler’s “four A’s,” as they came to be known, were considered the bedrock characteristics of the disorder for many years, and therefore deserve close attention.

The splitting deficit in *association*—in modern parlance variously termed formal thought disorder, loosening or derailment of association, incoherence, and cognitive slippage—was considered by earlier generations of clinicians the sine qua non of the schizophrenia diagnosis. In severe cases, the phenomenon is very striking and can be utterly baffling to listeners, but its subtler forms are far from obvious and may be detected only post hoc, if then, when clinicians realize on reflection that they have understood hardly anything of prior conversations with patients. The main difficulty is a failure to organize the elements of ideas into linear sequences; the patient's train of thought gets interrupted by intrusions and blockages, and the result is that verbalizations are at best imprecise and at worst mere "word salad."

Bleuler considered that the deficits of affectivity fundamental to schizophrenia are manifold. Often a profound indifference is the most striking feature of the patient's emotional life. Where emotions, even seemingly intense ones, are displayed, they often lack convincing depth and tend to be highly labile. In general, according to Bleuler, there is a discontinuity (splitting) between emotions and the remainder of the patient's mental life, such that thoughts and feelings may seem orthogonal. Unprovoked mood swings are common, as is a certain "blunting" with respect to matters of taste and social propriety. Bleuler gave as an example of the latter a patient's response (conveyed with blissful expression) to being reprimanded for drinking his own urine: "*Herr Direktor*, if you should taste it but once, you would never want to drink anything else" (p. 52). Bleuler (1911/1950) termed as "ambivalence" the tendency of the schizophrenia psyche to endow the most diverse psychisms with both a positive and a negative indicator at one and the same time" (p. 53). Three forms of schizophrenic ambivalence are discernible: (1) affective ambivalence, in which a particular concept or object simultaneously elicits pleasant and unpleasant feelings; (2) ambivalence of will, where the patient experiences co-occurring motives of an opposite or incompatible nature; and (3) intellectual ambivalence, involving the simultaneous maintenance of logically contradictory ideas.

Finally, Bleuler (1911/1950) noted that schizophrenia was always accompanied by a greater or lesser loosening of ties to reality (another type of splitting): "This detachment from reality, together

with the relative and absolute predominance of the inner life, we term *autism*" (p. 63, emphasis added). It is interesting that Bleuler, who had been influenced by psychoanalysis, considered that autism was essentially in the service of protecting the patient's "complexes." In other words, the patient's sense of reality tends to fail mostly in matters that have substantial personal import. However, Bleuler doubted that emotional complexes were *etiologically* significant in schizophrenia.

Schneiderian First-Rank Symptoms. Notwithstanding Bleuler's extraordinarily detailed and perceptive effort to refine the dementia praecox entity, it had become apparent by the 1950s, at least in the United States, that the distinctions he had proposed were either insufficiently understood (the English translation of Bleuler's major work did not appear until 1950) or too subtle to be adeptly applied by frontline mental health personnel. Interdiagnostician agreement in recognizing the presumed entity, as was shown in repeated studies, was unacceptably, even embarrassingly, low as a general rule, and a tendency had developed to employ idiosyncratic local conventions. The awesomely hopeless prognosis for the unfortunates who acquired the label only complicated matters.

These problems were temporarily alleviated somewhat with the widespread introduction of chlorpromazine, the first of the phenothiazine neuroleptics, in 1955. Now a person could be said to have probably been schizophrenic if he or she responded with notable symptom reduction to a trial on chlorpromazine. But this diagnosis by outcome was still (for various practical and theoretical reasons) a very unsatisfactory gambit. The time was ripe for a new approach to the diagnosis of schizophrenia, one that would permit drawing conclusions upon completion of relatively brief clinical evaluation, but might also yield a reasonable level of interdiagnostician agreement. The work of the German psychiatrist, Kurt Schneider (1959), fit the bill and was seized upon by a number of influential investigators in the United States.

Schneider's approach was organized around eleven pathognomonic signs or "first-rank" symptoms, any one of which, if present, was considered a strong indicator of the presence of a schizophrenic process. In contrast to the subtleties of the Bleulerian criteria, the plainness of Schneider's behaviorally described signs were terms that clinicians have relatively little difficulty in assessing.

1. The patient hears voices speaking his or her thoughts aloud.
2. The patient is the subject of a discussion or argument among hallucinated voices.
3. Hallucinated voices describe the patient's ongoing activity.
4. Delusional percept (a normal perception is interpreted as having special and highly personal significance).
5. Somatic passivity (the patient is a reluctant recipient of bodily sensations imposed by an external agent).
6. Thought insertion (an outside force puts thoughts in the patient's mind).
7. Thought withdrawal (an outside force removes the patient's thoughts).
8. Thought broadcast (the patient experiences his or her thoughts being magically and involuntarily transmitted to others).
9. "Made" feelings (the patient experiences feelings as imposed and controlled by an external agent).
10. "Made" impulses (the patient experiences impulses as similarly imposed from outside).
11. "Made voluntary acts (patients experience their motor activity as similarly imposed from outside).

Schneider's approach to identifying schizophrenia differs fundamentally from that of Bleuler. Whereas Bleuler's criteria focus almost entirely on the formal properties of mentation independent of mental content, Schneider makes distinctive mental content in the form of certain types of delusional and hallucinatory phenomena the central defining property. In fact, Bleuler would have regarded every one of Schneider's signs as having mere "accessory" and inconstant status in instances of true schizophrenia. In any event, Schneider's approach has had a somewhat greater influence in determining the present diagnostic criteria than Bleuler's, as will be seen in what follows.

Whether such prominence is deserved is open to question. Findings from a variety of pertinent studies (e.g., Carpenter, Strauss, & Muleh, 1973; McCabe & Stromgren, 1975; Newmark, Falk, Johns, Boren, & Forehand, 1976; Wing & Nixon, 1975; World Health Organization, 1973) indicate that Schneider's signs show up with distressing frequency in patients for whom a primary diagnosis of schizophrenia would seem on other grounds to be inappropriate. We would also sug-

gest that it seems unwise to employ as a cornerstone of diagnosis alleged mental phenomena that have the status of private experience (e.g., the patients' voices) and can never be directly observed by the diagnostician or, for that matter, by anyone else. The standard scientific requirement of interobserver reliability is impossible to satisfy (in fact, meaningless) in such a context, unless it is specified that the focus of inquiry is exclusively on what the patient reports *about* mental happenings of this sort—in which case the observation itself loses much of its intrinsic force.

Other Diagnostic Systems. In the early 1970s, several other efforts were made to develop more precise criteria. These efforts were primarily by research investigators. Movements began in some research centers to eschew entirely the often vague, abstract, and theory-driven official criteria in favor of definitions stated in very concrete observational language (i.e., so-called operational criteria). Two proposed sets of such criteria—those of Feighner, Robins, Guze, Woodruff, and Munoz (1972) and a modified version by Spitzer, Endicott, and Robins (1975) that included definitions of schizophrenia—rapidly gained ascendancy among investigators, and it soon became commonplace in the method sections of research reports to read that subjects had been selected according to one or the other of these sets of fairly similar criteria. It was inevitable that the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III; American Psychiatric Association [APA], 1980) would strongly reflect both of these efforts, especially the more current one of Spitzer et al. That is what happened pretty much across the board and particularly in relation to the diagnostic criteria for schizophrenia, which turned out to be largely a reproduction of the Spitzer et al. (1975) Research Diagnostic Criteria rules for making the diagnosis.

Endicott and colleagues (1986) reported in a study in which a given group of patients, after careful clinical study, was diagnosed according to seven different (but considerably overlapping) proposed systems for rendering the schizophrenia diagnosis and obtained results that were not encouraging. They found an eightfold variation among the systems in their rates of applying the diagnosis. *None* of the systems did very well in predicting patient status a mere 6 to 25 months later, although the DSM-III was comparatively among the least inadequate in this respect.

DSM-IV. Since the introduction of DSM-III, the changes in subsequent versions have been relatively minor (compared to the changes from DSM-II [APA, 1968] to DSM-III). The primary change concerns the duration of symptoms. From DSM-III to DSM-III-R (APA, 1987), a specification of at least a 1-week duration for the psychotic-delusional (criterion "A") symptoms was added, allegedly to exclude transient psychotic disorders. When DSM-IV (APA, 1994) was introduced, this specification was increased to 1-month, again to "reduce false positive diagnoses" (p. 779). A primary goal of the revisions made in DSM-IV included the provision that "... revisions that would result in substantial reclassification of patients relative to DSM-III-R were to be avoided" (Flaum, Andreasen, & Widiger, 1994, p. 1008). This suggested a recognition of the way changing conceptions of the disorder have stilted progress.

The introduction of the DSM-III began a persistent trend to narrow the schizophrenia diagnosis. There are at least two studies in the literature, those of Winters, Weintraub, and Neale (1981) and Harrow, Carone, and Westermeyer (1985), in which a group of DSM-II-diagnosed schizophrenics was rediagnosed according to DSM-III criteria. The proportions of patients who survived the "cut" (i.e., retained the diagnosis) in the two studies were, respectively, 51 and 41%. Needless to say, such instability renders it uncertain to what extent volumes of pre-1980 research findings apply to the schizophrenias of today. The increase in the duration specification for criterion A, first to 1 week in DSM-III-R, and then to one month in DSM-IV, would be likely to further exclude subjects and perhaps select for a more chronic form of disorder.

To summarize the problems of the main criteria set for DSM-IV schizophrenia, it is neither Bleulerian nor Schneiderian, but a rather complex mixture of both, and considerably favors the latter. Moreover, if there is a clear and unifying concept underlying the various constituent criterial signs, it is not revealed in the accompanying DSM-IV commentary, nor have we been able to discern it on our own. Therefore, the list seems to be something of a hodgepodge of indicators traditionally associated with the concept of schizophrenia, where for the most part each makes an independent contribution to the diagnostic outcome. Certain of the quantitative rules (e.g., "two of the following"; why not one, or three?) are almost

entirely arbitrary. Moreover, for criterion A, only one (not two) of the characteristic symptoms is required if "... delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on a person's behavior or thoughts, or two or more voices conversing with each other" (APA, 1994, p. 285). As can be seen, hallucinatory phenomena are strongly represented and entail the perplexing problems of intersubjective reliability discussed earlier. The naturally occurring overlap with mood disturbance is managed in an artificially exclusionary manner in a cosmetic attempt to enhance diagnostic reliability at the expense of clinical realities. Finally, despite "operational" pretensions, much room remains for subjective judgment in applying the criteria. For example, what is a delusion (see, e.g., Oltmanns & Maher, 1988), and at what intensity level does a phenomenon become "marked"?

No discussion of the schizophrenia diagnosis would be complete without considering the various schizophrenia subtypes that have been proposed, to which we now turn before wrapping up diagnostic issues.

Schizophrenia Subtypes

Given the pluralistic evidence of schizophrenias, it should be no surprise that the proposed subtypes have existed since the inception of the disorder. We will argue here that given the demonstrated elusiveness of the main category, it would be surprising if any of the subdivisions proved to have extraordinary robustness at the empirical level. Indeed, a major criticism of many of these studies is that too broad a spectrum of psychotic disorders is typically employed, so that it is not necessarily "schizophrenia" that is being subtyped (McGorry, Bell, Dudgeon, & Jackson, 1998). We describe the classical subtypes and also consider the more recent "positive" versus "negative" symptom differentiation.

The Classical Subtypes. Kraepelin described hebephrenic, catatonic, and two paranoid subtypes of the disorder (Defendorf, 1902). Later, Bleuler (1911/1950) described simple, hebephrenic, catatonic, and paranoid forms of the basic schizophrenic disorder, but it is clear that he considered that these qualitative distinctions related merely to varying profiles of "accessory" symptoms among different patients who shared the same fundamental deficits. He was not very impressed with them

in terms of their prognostic or predictive significance, and a wealth of evidence accumulated over subsequent decades indicates that he was largely right about this. It is, in fact, not uncommon for schizophrenic patients to display mixtures of these symptom clusters and move among them during the course of an episode.

Therefore, it is somewhat puzzling why the practice of applying formal classical subtype diagnoses has persisted, with only minor modification, to the present. From DSM-III on, the "simple" subtype, basically a symptomless personality description, has evidently (and wisely) been relegated to one or another of the Axis II personality disorders, but the other subtypes remain as originally described, and the "hebephrenic" is now called the "disorganized" subtype. The subtype "undifferentiated" was added to the DSMs long ago to apply to the many instances of mixed and/or highly unstable clinical pictures one sees in any psychiatric inpatient setting.

If there is any justification for retaining this seemingly outmoded system of classic subtyping, it resides in a distinction between the paranoid and the remaining subtypes. As a group, paranoids seem different (Magaro, 1980). Schizophrenic patients who remain persistently paranoid often do not show the kind of striking cognitive and/or attentional deficits seen in other forms of the disorder (Rabin, Doneson, & Jentons, 1979). As a group they tend to have a more benign course and outcome (Ritzler, 1981), and they show less evidence of familial concordance (genetic loading?) for schizophrenia (Kendler & Davis, 1981). On the other hand, many patients originally subdiagnosed as paranoid later acquire alternate designations (Kendler & Tsuang, 1981), and it is a venerable item of clinical lore that some paranoid disorders prove extremely intractable and chronic. There is sufficient reason in all of this to maintain a distinction between paranoid and nonparanoid forms of schizophrenia in selecting subjects for research; the groups can always be collapsed if the data prove that the distinction is irrelevant.

Positive- and Negative-Symptom Schizophrenias. The changing terminology associated with this distinction has made the long history of these subtypes less obvious than the classical subtypes. This dichotomy can be traced back to the process-reactive distinction forms of schizophrenia. Discrimination between the two was a matter of estimating case characteristics in four bipolar

dimensions: (1) slow and insidious versus abrupt onset; (2) absence of identifiable precipitating stress versus severe stress experienced immediately prior to onset; (3) socially shut-in and withdrawn versus socially engaged premorbid functioning; and (4) flat, blunted affect versus volatile, intense affect expression. For each, the first refers more to a *process* pattern, whereas its opposite was said to be associated with the *reactive* one. As these terms suggest, extreme process schizophrenia was considered an endogenously determined pattern of inexorable deterioration, not in concept unlike Kraepelin's dementia praecox, whereas the more reactive variety was seen as induced decompensation in the face of overwhelming life challenge (and therefore had a far more favorable prognosis). Unfortunately, however, the circumstances of many schizophrenic patients were such that they could not definitely be allocated to one or the other of these categories, and some "reactives" showed a distressing tendency over time to drift toward the process end of the continuum.

A later but conceptually similar effort along these lines focused more exclusively on the general competence and adequacy of the person's social functioning before obvious breakdown; the distinction here was "poor premorbid" versus "good premorbid." This strategy yielded a more reliable allocation of patients to the pertinent subtypes, but it too eventually succumbed to a variety of puzzling and contradictory research findings; some of them were undoubtedly attributable to the poorly understood effects of newly introduced phenothiazine drugs. Before its demise, however, this subtyping strategy had modest success in achieving, for the first time, a measure of order in attempts to conceptualize rampant schizophrenic heterogeneity (e.g., Garmezzy & Rodnick, 1959).

The newest version of the presumed underlying dichotomy addressed in these efforts is the currently popular distinction between "negative" and "positive" schizophrenia. These terms refer, respectively, to behavioral characteristics that constitute a deficit relative to normal performance and to those that involve some added element not normally present. Thus, flat affect and social withdrawal are negative symptoms, whereas hallucinations and delusions are positive ones (see Andreasen, 1985, 1988; Andreasen et al., 1995, for a more extended discussion on these subtypes). Therefore, negative schizophrenia is roughly

equivalent conceptually to the old “process” or “poor premorbid” designations, whereas positive schizophrenia bears the same relationship to the “reactive” or “good premorbid” subtypes. A related differentiation that emphasizes biological variables and speed of onset more refers essentially to these same patterns as Type I (positive) and Type II (negative) schizophrenia (Crow, 1985). Although most patients exhibit both positive and negative signs during the course of their disorders (Breier et al., 1994; Guelfi, Faustman, & Csernansky, 1989), a preponderance of negative symptoms in the clinical picture, it has increasingly been shown, has relatively grave prognostic significance (e.g., Fenton & McGlashan, 1994; McGlashan & Fenton, 1993). Finally, there has been some suggestion that the negative symptoms bear some relationship to medication side effects (Kornhuber et al., 1989; see also Miller and Ereshefsky, 1997).

Disorganized schizophrenia is an independently discerned subtype of schizophrenia that has more recently gained recognition partially independent of the positive and negative subtypes (Ratakonda, Gorman, Yale, & Amador, 1998; Toomey et al., 1997). This subtype is characterized chiefly by chaotic and seemingly directionless speech and behavior, and it has been recognized as the classic hebephrenic subtype of schizophrenia. **Subtypes in the DSM-IV.** The DSM-IV retains subsequent versions of the classic subtypes, including paranoid, disorganized, catatonic, undifferentiated, and residual, despite the criticism that these subtypes evidence poor reliability, poor stability over time, and poor prognostic value (McGlashan and Fenton, 1994). It seems that these subtypes were left in mainly on the basis of “clinical tradition” and the belief that they do possess some prognostic value, despite evidence to the contrary (Flaum, Andreasen, & Widiger, 1994). Interestingly, Appendix B of DSM-IV (APA, 1994) contains a section on “Alternative Dimensional Descriptors for Schizophrenia.” These are shown in Table 1.

Commentary on the Current Diagnostic State of Affairs

In leveling these criticisms, we are in the awkward position of having nothing better to offer (and neither does the field). Debates about ways to

Table 1. Alternative Dimensional Descriptors for Schizophrenia from the DSM-IV (APA, 1994)^a

Dimension	Description
Psychotic	Hallucinations or delusions
Disorganized	Disorganized speech or behavior, or inappropriate affect
Negative	Affective flattening, alogia, avolition (exclude the effects of medication, depression, and positive symptoms such as hallucinations or delusions)

^aThe extent to which each dimension is present is rated as absent, mild, moderate, or severe, and ratings can be made for the present episode, and/or the past 6 months, or for the lifetime course of the disorder.

interpret findings from nosological studies of psychosis derived from DSM criteria sets continue along the lines of how many forms of psychosis actually exist. As many as six subclasses have been suggested (e.g., Kendler, Karkowski, & Walsh, 1998; McGorry, Bell, Dudgeon, & Jackson, 1998), and other investigators have provided evidence that suggests four factors (e.g., Dollhus et al., 1996). More parsimonious models have identified criteria sets corresponding to Bleulerian negative symptoms and Schneiderian first-rank systems, results that are not especially surprising in the light of our review of the development of the DSM diagnostic systems.

In any event, the field is presently plagued with debates about where to draw the line on the number of schizophrenic disorders, and the blurry boundary between psychotic and affective disorders has yet to be adequately resolved. We submit that these debates will largely turn out to be fruitless, mainly on the grounds that a multitude of diagnostic approaches drive the interpretation of the data in ways that are not necessarily empirically or theoretically grounded. We further suggest that the current diagnostic system needs a complete overhaul (see Carson, 1997, for careful consideration of this argument). We restrain ourselves from repeating those criticisms here, but it must be mentioned that progress in taxonomy would be better served by a move in the direction of parsimony, with the explicit goal of abandoning

the categorical format in favor of a dimensional one (e.g., Bell, Dudgeon, McGorry, & Jackson, 1998; Crow, 1997b). Thus, we view the “alternative” diagnostic scheme presented before as favorable and a step in the right direction.

Where is the field to go from here? An indispensable requirement is that we recognize an urgency to the taxonomic/diagnostic dilemma presented by those diverse aberrations of behavior that are traditionally and somewhat casually allocated to the schizophrenia rubric. In an article often cited in the field of psychiatry, Robins and Guze (1970) suggested minimal requirements for developing validity in psychiatric diagnoses. The basic requirements they put forth have not been adequately followed, and, in particular, a need remains for much neglected basic clinical research (Andreasen, 1998). The haphazard array of diagnostic criteria illustrate the slow progress in this area, and these limitations all but assuredly hamper research efforts aimed at etiology and treatment. In the most basic manner, the DSM system is plainly inadequate for these purposes. Andreasen (1998) made this point in a straightforward manner: “DSM was developed as a clinical manual to serve as a diagnostic ‘gatekeeper.’ Its descriptions of many disorders are intentionally sparse, simple, and incomplete. (*This is especially true for schizophrenia*)” (p. 1659, emphasis added).

Is the situation hopeless? Perhaps not. The compromise position is simply settling for a definition of the disorder that is more or less acceptable to practitioners and researchers but that is arbitrary in some sense. In fact, this is the strategy adopted by contemporary nosologists such as the authors of the DSMs (i.e., DSM-III and beyond). With such an approach, it is conceivable that systematic and meaningful patterns will be identified over time. And as understanding increases, the defining diagnostic criteria can be sharpened to reflect what might eventually become a valid construct. There is abundant evidence that a program of this sort, “bootstrapping” (Cronbach & Meehl, 1955) our way haltingly toward an understanding of the nature of these disorders, is already in place among mental health researchers. Alas, there is no better alternative, provided that we do not fool ourselves into thinking about “schizophrenia” in unduly reified terms and provided that we continue to seek a much-needed refinement of this *open construct*

in an informed and rigorous manner. This is the sense in which we shall be using the term in the remainder of the chapter.

Etiologic Considerations

There has been tremendous effort over the years to isolate or otherwise identify a genetic cause of schizophrenia. The process of this research is one that deserves at least parenthetical comment. An answer to “the question” (i.e., What is the cause of schizophrenia?) is never quite obtained, despite intermittent promises that loom on the horizon. The potentially promising results entice researchers, offering hope that the answer to the schizophrenia puzzle will soon be solved. Often, such findings are seized upon by the media, further encouraging simplistic answers to a very complex problem. This is a curious pattern, and one that we speculate is at least partly influenced by the desperation naturally associated with working with such a devastating and disabling disorder in the absence of any truly effective interventions (recall the lack of progress during the last century). Those entering the field should be warned against such potentially seductive claims.

If, as we would anticipate, schizophrenia turns out to be a variety of separate and distinct disorders that happen to share some similar properties at the level of behavioral output (and the class “psychotic,” after all, has finite boundaries), it would seem unrealistic to search for some primary etiologic factor that controls a large proportion of morbid outcome variance. Another implication of the multiple-pathway notion is that the search will prove very difficult because such heterogeneity will impede the establishment of reliable commonalities of background across persons who acquire the diagnosis. As will be seen, both of these expectations are amply confirmed in the findings of etiologically relevant research.

It has become customary in discussions of this sort to treat separately purported biological and psychosocial causal influences in schizophrenia, as though it were reasonable to conceive that such influences somehow contribute to the outcome independently of one another; that is, in the merely additive, orthogonal fashion suggested by a simple version of the diathesis-stress model (Zubin & Spring, 1977). It is increasingly clear, however,

that some sort of combinatory function that operates between these two broad sources of causation is at least frequent and quite possibly routine in the development of schizophrenia. Accordingly, we will not employ the common but potentially misleading format of biological/psychosocial causation in what follows but will rather try to convey something of what we judge is the enormous complexity of relationships between the two as our discussion of distinct causal factors proceeds.

We have deliberately used the somewhat cumbersome expression *combinatory function* in the preceding paragraph, where in this context the term interaction is doubtless far more commonly employed. But the latter term may suggest a particular kind of joint determination of outcome, whereas we typically do not know the specific form in which the two classes of variables (biological and psychosocial) conjoin in contributing to the schizophrenic outcome. Hardly anyone doubts that some sort of "interaction," loosely defined, occurs among the variables so far identified and that they are probably implicated in producing schizophrenic outcomes. Indeed, the direct and indirect evidence pertaining to the operation of potent modifier variables with respect to essentially every factor suspected of having etiologic significance is so multifaceted and compelling that the task of finding one's way around in the thicket can be stupefying. It is precisely for this reason, we surmise, that investigators generally manifest strong propensities to focus on and treat genetic, other biological, and psychosocial factors as separable entities, even though it makes only limited sense to do so in light of the evidently convoluted etiologic pathways involved. An additional complicating factor is that these pathways will probably turn out to be highly idiosyncratic for individual instances of disorder (Meehl, 1978), thereby seriously compromising the research value of aggregating observations over subjects.

We have little choice but to follow the leads investigators have laid down, but in doing so, we should bear in mind that the strategies employed mask to a great extent the central fact of pervasive and developmentally continuous interplay among the contributory influences. The general problem here is well illustrated in connection with the suspected role of genetic variables in the intergenerational transmission of a propensity to develop schizophrenia. We turn now to a discussion of the evidence supporting this hypothesis.

Genetic Variables in Schizophrenia

The concept of interaction held by most psychologists derives from the ANOVA statistical model—where, for example, outcomes are allocated to cross-cutting genetic and environmental factors, to their interaction ($G \times E$), and to "error." This conception of interaction can be quite misleading because the constituent elements are erroneously considered independent and the natural events that unfold in the process of development are removed from the temporal sequences in which they occur. Variance components are extracted and treated as though they were distinct entities unaffected by one another over time. But discrete factors do not occur as such in nature, and the statistical model of necessity ignores the extent to which genes and environment covary over time; in fact, the variable of time, crucial for any developmental process, is discarded. What we are suggesting, then, is the necessity for a decidedly more fine-grained analysis of genetic-environment interaction if there is to be any hope of achieving a true understanding of the contribution of either component to schizophrenic outcomes. With these caveats in mind, we proceed to review the genetic evidence.

Inquiries into the genetics of schizophrenia can be roughly divided into two strategic approaches; each is a function of the progress of knowledge and methods available to scholars and scientists who work in this area. The first approach is based on the traditional Mendelian understanding of genetics, where the occurrence of traits (phenotypes) are identified and observed across generations for trends that will shed light on underlying genetic mechanisms. Working from the other direction, more modern techniques have been developed since the molecular elucidation of DNA and the subsequent development of biochemical techniques to study the encryption and expression of heritable information. The family (including twin and adoption methodologies) belongs to the traditional approaches, though what is in only some ways a less inferential examination of genetic processes is possible in the realm of molecular biology. Either approach faces an extreme limitation: A significant gap remains between what is observed at the behavioral level and that which is observed at the molecular—or inferred at the genetic—level. That gap, partly framed by the nature of the questions asked, will have to be

bridged to improve the present rate of progress. More on that later, but first a summary of the currently accepted knowledge.

Twin Studies. It is well-established that there is a higher concordance rate among monozygotic twins (MZ) than among dizygotic twins (DZ), a finding that is often cited in defense of the argument that schizophrenia is a “mostly genetic” disease. In a review of the worldwide literature on twin studies, Torrey and colleagues (1994) report an overall pairwise concordance rate of 28% for MZ twins, and 6% for DZ twins. Thus, it seems clear that sharing 100% of the genes with a schizophrenic twin greatly increases the risk (almost fivefold) of developing the disorder. Furthermore, sharing 50% of the genes, as in DZ twins, provides a risk that is substantially greater than in the general population.
