Torrey et al. (1994) reported on twenty-seven pairs of MZ twins discordant for schizophrenia, a research strategy that was potentially revealing about nongenetic causal factors. Perinatal factors were important in at least 30% of affected cases, as were widespread early CNS dysfunctions. Evidence from discordant affected twins sheds some light on the complexity of the genetic evidence from twin studies. Of discordant affected twins, 30% were described as having been different during early childhood (e.g., shy and withdrawn, aggressive, or odd), suggesting possible CNS dysfunction. These twins also showed prominent alterations in brain function as assessed by cerebral blood flow, neuropsychological tests, neurological exam, and smooth-pursuit eye movement. Hypofrontality (reduced blood flow to the frontal lobes), it was demonstrated, is associated with reduced size of the anterior hippocampus. Moderate/severe cognitive impairment in neuropsychological tests was observed in fourteen of the twenty-seven affected twins. The nonschizophrenic co-twins of discordant pairs, though less neurologically impaired than their disordered siblings, were more impaired than a set of control MZ twins where both members of the twinship were considered psychiatrically normal. Comparing schizophrenic persons from discordant and concordant pairs, no significant differences in clinical or potential etiologic variables are found.

What can be made of the findings that changes in brain structure were not correlated with clinical aspects of schizophrenia in the affected twins and that there were significant structural deficits in the

nonaffected twins? It appears that things are more complicated than can be sorted on the basis of this methodology. Although compelling, several shortcomings must be kept in mind. First, despite the apparent robustness of these findings, it remains impossible to predict schizophrenia outcome for individual cases. Second, there are some inconsistencies in these data. In a few cases, the “well” twin appeared more biologically compromised than the affected co-twin. The authors rightly conclude that these data do not sufficiently resolve the most basic questions of the genetics of schizophrenia. However, it does seem that these neurological abnormalities play a role in the chain of causal events that lead to the disorder. We remind the reader of the problems surrounding the definition of the disorder.

Fischer (1971, 1973) extended the twin methodology by reasoning that the genetic influence would rear itself in the offspring of the non-schizophrenic twin, and bore this out in a search of the official records in Denmark. In a follow-up of these offspring, Gottesman and Bertelson (1989) reported age-corrected incidence rates of 16.8 and 17.4%, respectively, for children of schizophrenic and discordant MZ twins. The age-corrected risk for children of schizophrenic DZ twins was of the same order (also 17.4%), whereas that for the offspring of discordant normal DZs was a mere 2.1%. These data constitute, then, a relatively powerful argument that there is some genetic contribution in some instances of schizophrenia. On the other hand, as Gottesman and Bertelson (1989) note, they also show that this presumed predisposition may remain “unexpressed” unless “released” by unspecified environmental factors.

What can be concluded from the twin studies? It must be remembered that if schizophrenia were an exclusively genetic disorder, the concordance rate would be 100%. As we repeatedly emphasize, however, such typological thinking is erroneous when it comes to conceptualizing unfolding biological or genetic influences or factors. As Torrey and colleagues (1994) pointed out, MZ twins are only genetically identical when the original zygote splits. Phelps, Davis, & Schwartz (1997) report that two-thirds of MZ embryos are monozygotic, meaning that they share blood supply, whereas DZ twins never do. Then, it seems plausible that shared pathogens may account for the increased rate. Chronic hypoxia and other obstetric complications are more likely to be shared by

MZ rather than DZ co-twins (Maier et al., 1995). At the very least, the twin studies have provided an important insight that illustrates the lack of clarity between genetic and environmental boundaries. Environmental-biological events that occur during the pregnancy, as will be discussed in greater detail later on, play a role in the unfolding of genetic material and possibly influence CNS development.

Adoption Studies. An additional major approach to examining the genetics of schizophrenia is the adoption strategy. The defining study in this area was carried out by Heston (1966). In a sample obtained from an Oregon state mental hospital, he found a significant difference between the age-corrected incidence of schizophrenia diagnoses among index adoptees (16.6%) compared to controls and a result similar to that for children *not* separated from their schizophrenic mothers. Index adoptees also evidenced an increased range of sociopathic personality disorder, suggesting the possible transmission of a more general sort of psychopathological compromise. Thus, this study provided fairly convincing evidence that enhanced schizophrenia risk was attributable to genetic (or prenatal) causes, and the stage was set to search for genetic causes using the adoption strategy.

The most prominent and extensive of the adoption studies in schizophrenia were initiated by a group of American investigators who were granted access to the exceptionally thorough census and social services database maintained by the government of Denmark. The initial results of this eventually widely reported study became available in 1968 (Kety, Rosenthal, Wender, & Schulsinger, 1968; Rosenthal et al., 1968). The central finding of the original study (Kety et al., 1968) was that a much higher percentage of the biological relatives of the index cases had a schizophrenia spectrum diagnosis than the nonbiological cases (8.7% versus 1.9%, respectively). These results must be tempered because the range of diagnoses included in the schizophrenia spectrum was broad. In fact, subsequent analyses have shown that the finding of heritability specific to schizophrenia does not hold up when more stringent diagnostic criteria for schizophrenia are employed (Rosenthal, Wender, Kety, Welner, & Schulsinger, 1971). Again, the evidence is more supportive for inheritance of some sort of general compromise, a conclusion that is not so surprising in the light of the diagnostic dilemmas reviewed earlier.

Later reports by Kety (Kety, Rosenthal, Wender, Schulsinger, & Jacobsen, 1978; Kety, 1987) have provided results that generally support the original findings. However, one persistent and peculiar finding in which second-degree relatives are persistently more concordant for schizophrenia than those of first degree seemingly disconfirms the genetic transmission hypothesis. Although such an apparent anomaly might be regarded as an important lead to which to devote further effort to unravel the complexities of transmitted—genetic or otherwise—factors, the report by Kety (1987) suggests in narrative format that the balance of first- to second-degree index relatives who show spectrum disorders was “in accord with expectation,” presumably implying a preponderance of the effect in parents and full siblings. Unfortunately, that report does not contain the data necessary to fully evaluate the claim.

Kendler and Gruenberg (1984) attempted an independent replication of the Kety et al. (1968, 1978) greater Copenhagen family study. Using the record data already assembled, these investigators rediagnosed all subjects, adoptees, and family members according to the relatively precise criteria of DSM-III. Of the various results of the project, two stand out as especially important: First, schizophrenia spectrum disorders (now systematically defined to include paranoid and schizotypal personality disorders in addition to schizophrenia) are significantly more frequent in index than in control biological families, and the difference is especially pronounced among the *first-degree* relatives. Second, the risk for a schizophrenia spectrum disorder also significantly increased in biological relatives of adoptees who have a predominantly schizophrenic type of schizoaffective disorder or schizotypal personality disorder. These data are relatively convincing and highlight the systematic strengths of the DSM-III-type diagnostic approach in bringing order to a confusing data set with conflicting reports, notwithstanding the limitations of that instrument as a research tool (see Andreasen, 1998).

An important variation on the adoption methodology is the approach of cross-fostering (Wender, Rosenthal, Kety, Schulsinger, & Welner, 1974). This method examines biologically normal adoptees who are placed in foster homes in which one of the adoptive parents subsequently becomes schizophrenic. The schizophrenia incidence rate for these “cross-fostered” adoptees is then com-

pared with (1) adoptees whose adoptive and biological parents are normal and (2) adoptees who have a schizophrenic biological parent and are raised by normal adoptive parents. The “purified” group incidence rates for at least borderline schizophrenia among adoptees in each of the above conditions were, respectively, 4.8, 10.7, and 19.7%, a statistically significant variation. However, it has been independently reported that the schizophrenic adoptive parent of a large majority of the cross-fostered children had not become seriously disturbed until the children’s late childhood years (Van Dyke, Rosenthal, & Rasmussen, 1975). Hence, they would not have necessarily presented an unremarkable environmental challenge during the presumably more critical earlier developmental period. In other words, the study basically fails to demonstrate that (adoptive) parental schizophrenia is psychopathologically nonnoxious for children exposed to it (barring the implications of prodromal symptoms).

The adoption method was originally conceived as one that would circumvent the serious problems of other pedigree approaches, such as twin studies, with the hope that the answers provided would be more clear-cut. This was not the outcome, however. Beyond the idea that there is clearly a familial link to the disorder, a proposition that one might reasonably surmise purely by conjecture, evidence that sheds light on the nature of that mechanism is lacking. Evidence does exist, in our view, that whatever is being genetically transferred to the individual lacks specificity to schizophrenia *per se* and more accurately relates to a broader type of compromise, perhaps even beyond the “schizophrenia spectrum.” The idea of some sort of general compromise is also consistent with the more recent idea that the most consistent aspect of schizophrenia is poor functioning.

On the other hand, the lack of reports on the environments in which the adoptees were placed is striking. In largely neglecting the environments, a potentially important source of morbidity has been overlooked. This gap has been filled by the work of Tienari and colleagues (1985, 1987, 1994; Tienari, 1991). The design of their study involves a follow-up of the adopted-away children of all women in Finland hospitalized for schizophrenia, beginning around 1960. As these index children grow into adulthood, they are compared with a matched group of control adoptees whose biological mothers were normal. The trend of the results

is already clear and reaches high levels of statistical significance. There is the familiar finding that the index adoptees have developed more, and more serious (including schizophrenia), psychopathology than the controls. Most of this psychopathology, however, is concentrated in the index group reared by poorly functioning adoptive parents—for example, parents who demonstrated high levels of communication deviance. Index adoptees reared by well-functioning adoptive parents had substantially less psychopathology, and control cases reared in disorganized adoptive families experienced more serious psychopathology as adults than their counterparts raised in “healthy” families. We will recall these results when discussing the relationship of schizophrenia to the subculture of the family.

To summarize, the initial promise of the adoption methodology to offer incontrovertible proof of the genetic basis of schizophrenia is now recognized as overstretched. In addition, we would call attention to numerous demonstrations of methodological problems and the erroneously extended conclusions drawn from this evidence (e.g., Benjamin, 1976; Carson & Sanislow, 1993; Lidz & Blatt, 1983; Sarbin & Mancuso, 1980). Aside from methodological concerns, the dichotomization of genetic and environmental components as distinct, assumed to operate in an independent manner *statistically*, overlooks the continual interplay of these factors that actually occurs in reality. It has been established for some time that these methods that treat these components as independent factors are unlikely to elucidate underlying mechanisms of complex traits or disorders (see, for instance, Carson & Sanislow, 1993; Lewontin, 1974; or Wahlsten, 1999). In the light of these limitations, new hope was garnered from the field of molecular biology.

Molecular Genetics. Linkage studies, including the physical mapping of genes, presaged the more prominent contemporary research strategies developed in the biological sciences, leading inevitably to their employment by psychiatric geneticists in attempts to unravel the presumed genetic processes associated with schizophrenia. In the field of genetics, Morgan (1911, 1920) noticed early on that traits could be inherited together, or “linked” on proximal chromosomal locations by the patterns in which combinations of traits were passed on generationally. This idea led to estimating gene distances and locations on par-

ticular chromosomes by triangulation from observed trait coinheritances. More recent advances in gene mapping have occurred at the molecular level with the use of restriction enzymes to "cut" DNA at known repetitive DNA sequences (see Botstein, White, Skolnick, & Davis, 1980), thereby providing a sort of anchoring point for determining relative intergene distances and thus to enable a more direct measurement. The resultant construction of more detailed maps has permitted relatively accurate localization of actual "disease" genes and hence isolation and identification of gene products (i.e., enzymes or other proteins) presumably implicated in various medical conditions. Therefore, it is within the realm of possibility that if certain genes are systematically associated with schizophrenic outcomes, we will one day be able to pinpoint their locations and describe in some detail what proximal effects they have. Bear in mind, however, that it is a long way from there to schizophrenia.

The current consensus is that a "large" and very specific gene effect in schizophrenia is unlikely, and many researchers have recognized for some time that the genetic effects involved with schizophrenia are more likely to involve multiple genes in interaction with idiosyncratic environmental experiences (Moldin & Gottesman, 1997). The result of studies in molecular genetics that intend to establish the loci of genes for complex mental disorders such as schizophrenia and bipolar disorder are consistent with this idea; few of the findings implicating single genes have been replicated. Early results, including the announced identification of a gene location for bipolar disorder on chromosome 11 (Egeland et al., 1987), were seized upon by the popular media and are now known to have been premature (DeLisi & Crow, 1989). In schizophrenia, there has been much interest in a specific region of chromosome 5 that was stimulated by the discovery of a Chinese man and his nephew, both schizophrenic, who displayed a particular chromosome 5 aberration (partial trisomy). Sherrington and colleagues (1988) studied five Icelandic and two British families that have multiple occurrences of schizophrenia and presented evidence for a gene locus on chromosome 5 with a dominant schizophrenic-susceptibility allele. This result, however, is inconsistent with data gathered on American (Kaufman, DeLisi, Lehner, & Gilliam, 1989) and Swedish (Kennedy et al., 1988) families that have high concentrations of schizo-

phrenia. DeLisi and Crow (1989) noted that some data indicated that schizophrenia has higher concordance but milder manifestations in females and suggested that the presumably implicated genes have a sex-chromosome locus, but the argument is entirely inferential. Other studies have examined linkage to a marker on chromosome 6 (Lander & Kruglyzk, 1993; Wang et al, 1995), but other studies of this region that used better samples produced equivocal results (Schwab et al., 1995) or failed to replicate (Moises et al., 1995). In the Irish study of high-density schizophrenia families, there has been some suggestion of a locus on chromosome 8p (Kendler et al., 1996). Other results from the Irish sample suggested a locus on chromosome 6 (Wang et al., 1995). However, those are statistically questionable (Straub et al, 1995; Gottesman & Moldin, 1998). In fact, non-replication for the majority of loci reported is an ongoing problem with linkage studies (Gottesman & Moldin, 1998).

Overall, there has been a general failure to replicate results that identify specific regions in independent samples, and results that implicate a specific chromosomal area are at best suggestive (Moldin, 1997). In the context of these inconsistencies, it has also been pointed out that molecular-linkage strategy simply lacks the necessary statistical power when it comes to testing for anything but large gene effects. We applaud recognition of this limitation, but it seems to us that stacking the deck to detect a small effect size that might be associated with "weak" genetic effects will not ultimately pay off, as in applying alternate strategies such as association analyses (e.g., Risch and Merikangas, 1996). Before leaving this topic, one remaining problem, the fundamental idea of the phenotype, deserves careful consideration.

The Problem of Phenotype. It might be reasonably argued that the cardinal factor limiting the acquisition of knowledge of the "genetics of schizophrenia" is a pervasive blurriness of the concept of phenotype. Definitional problems and the diagnostic heterogeneity that surround the schizophrenia diagnosis notwithstanding, the problem of the phenotype is more basic and involves the intricate complexities of the interaction of genes and environment. To illustrate this fact, the "phenotype" (i.e., the resulting expression of the genotype) in schizophrenia can broadly range from the disorder itself, to features associated with the disorder, to some more basic gene product

involved with structural development that, it is hypothesized, is related to the disorder. Nowhere in the literature can we find any clarity on this matter, although Scher (1999) succinctly stated the problem when discussing the issue more generally:

Phenotypic psychological mechanisms surely arise through a complicated process. The role of genes is likely to be rather far away and indirect. Certainly, our current understanding of the relationship between mind and body limits our ability to understand how genes—which code for physical structure—contribute to psychological development. (p. 436)

We have stressed that genes and environment continually interplay as the process of development unfolds. In this light, the phenotype is an elusive concept. Is the phenotype the disorder? Or is the phenotype one of the hypothesized components of the disorder such as a manifest neonatal complication? The phenotype might also be related to temperament, to neuronal development of receptor sites, or to the language centers. The “genetics” of schizophrenia will be handicapped until there is consensus on the phenotype. Even with some agreement on a meaningful phenotype, there will still be complications inherent in the level at which the phenotype is implicated in the disorder. Consider, for example, that an aberrant gene for a defective receptor site will be limited by our understanding of the way pathological synaptic transmission is implicated in the disorder, something that is, as will become clear shortly, far from settled.

To complicate matters further, exactly what constitutes a gene has varying conceptions that depend on one’s approach. In Mendelian (i.e., in pedigree or family) studies, a gene is a hypothesized construct that is related to a particular phenotype and is isolated based on observed patterns of inheritance. In more modern molecular methods, a gene is the smallest sequence of nucleotides in a strand of DNA that codes for the production of a protein. From a molecular point of view, genes are not necessarily unique; they can be overlapping. In other words, genes produce products that undergo programmed biochemical modification to serve their ultimate function, and sometimes these functions include regulating other genes, sometimes the modification of gene products. Such effects are among intricate, interrelated constellations of events that are complex even for the most straightforwardly seeming diseases. For instance, insulin is originally produced as a protein strand that folds back on itself due to the attraction of

branched amino acids within the protein sequence. Related enzymes cleave off the resulting “folds” to produce the final structure. These related enzymes are coded for by other genes, and the final product is produced by a complex system of interdependent regulation and feedback loops. So what causes diabetes? There is no one sole cause, and at least several mechanisms, more or less “genetic,” can lead to this disorder. These include problems in the synthesis pathway of insulin either blocking the conversion to the final product or leading to a defective final product, abnormal receptors for insulin, or the intercellular insulin-receptor complex that facilitates insulin binding. These varied mechanisms end with the common final pathway of diabetes that appears isomorphic at the level of clinical pathology. Is diabetes a hereditary disease? Some understanding of the mechanism will undoubtedly aid in determining the best treatment. Unlike schizophrenia, however, there is a clear understanding of the pathophysiology in diabetes, thus enabling meaningful study of genetic aspects at the molecular level to determine various gene influences. In schizophrenia, molecular genetic strategies will not be of full benefit until the pathophysiology of the disorder is clearly understood.

The dearth of knowledge about the pathophysiology of schizophrenia obviates the specification of the layers involved in the regulatory processes and their interactions with environmental insults that result in the disorder. In other words, there is not a clear understanding of what bridges the “nature and nurture.” We know that schizophrenia runs in the family and that there is a biological constitution that enhances (creates?) vulnerability to the disorder. It appears that some sort of sequence of traumatic events in the context of development opens the vulnerability, but the role of the timing of such environmental traumas is less clear. It also appears that individuals can undergo traumas similar in magnitude and nature and come out seemingly unscathed, and that not all this can be chalked up to a genetic difference. This has led one of the major thinkers and researcher of the disorder, Paul Meehl (1989), to declare that developing schizophrenia is a matter of “bad luck” in that some idiosyncratic as yet unspecified sequence of traumatizing events opens the vulnerability to the disorder. Finally, evidence also suggests that certain neural pathways function abnormally, but the exact manner of this dysfunction is not entirely clear. Hence, there are many

gaps in the knowledge required to understand the “genetics” of the disorder.

The best illustration of this is MZ twins, where one can assume that the genetic material is identical only when the zygote splits. Subsequent to that time, a multitude of levels between the extremes of “nature” and “nurture” exist, and recognition of these levels underscores the artificial aspect of bifurcating developmental events as either genetic or environmental. Seen in this light, adoption and twin methods are obsolete, or as Meehl (1972) had the good foresight to put it, “we have skimmed the cream; we are near the research asymptote” (p. 368). There can be little doubt that now defunct dichotomous positions traditionally taken in the nature/nurture debate which have for many years effectively driven the research on schizophrenia, have reached a point of obsolescence, and it is likely that without a more complete theory of schizophrenia pathology, the same is true for more modern molecular methods.

In the search for the biological, biochemical, or genetic solution, we believe it will someday be accepted that it was simply asking the wrong question. Is schizophrenia genetic? Of course it is—how could the disorder be devoid of genetic influences? We would go so far as to suggest that, for the most part, there are no inherent flaws in the data. Rather, forces driving the conceptualization and interpretation of the science have been obscuring real progress. As it turns out, current views (e.g., Harrison, 1998) clearly recognize the failure of the promise of molecular genetics—the last bastion for a “genetic solution”—to solve the schizophrenia puzzle. Presently, the new emphasis is on its pathophysiology. We will return to review that area shortly.

Schizophrenia and the Intrafamilial Subculture

Research on the family subculture and interpersonal processes within the family that might contribute to the development of schizophrenia reached its zenith in the late 1950s and, with some exceptions, has been in decline ever since. There appear to be five principal reasons for this decline:

1. Such research is very difficult to carry out in a precise and controlled way, far more so than the high-technology-driven research into biological processes so prevalent today.
2. Relatedly, some early but insufficiently controlled findings of apparent familial aberrancy (e.g., double binding) have proven nonspecific for schizophrenia and indeed somewhat routine in families that have exclusively normal offspring.
3. Dysfunctional behavior in family members, it has been shown, is reactive to the presence of a disturbed family member rather than antecedent to such disturbance; indeed, such circularity in cause–effect sequences in patient–family interaction may be the norm.
4. Research on the possible intrafamilial origins of some schizophrenias has, perhaps understandably, not been popular among parent groups who have (probably accurately) sometimes perceived that they are summarily and unfairly blamed for the disorders of their children.
5. The so-called “decade of the brain” (i.e., the 1980s), for the most part, obviated thinking and research along these lines in mainstream psychiatry.

In the light of the sensitive nature of this topic, we want to be clear about our own position. We find that assigning blame in this area is both counterproductive and based on an oversimplified notion of the way persons become schizophrenic. Parenting is at best an inscrutable task laden with pitfalls throughout the course of child development, and most of the parents we have known, whether they have had the “bad luck” to have raised a son or daughter who became schizophrenic, have done the very best they could to ensure the happiness, health, and success of their children. We have the greatest sympathy for the difficulties faced by the mothers, fathers, and siblings, of schizophrenic persons. Many of these relatives harbor unjustified guilt feelings; we have no wish to induce or augment such feelings—quite the contrary. Nevertheless, we think open inquiry into the developmental process, which necessarily involves attention to the intrafamilial environment, is essential in any comprehensive attempt to discover the sources of schizophrenic outcomes.

Does schizophrenia as a biological disease somehow soften the blow? Admittedly, there seems to have been an impact on destigmatizing the disorder for those afflicted *and* their family members. The downside of the wholesale version

of this view is that personal responsibilities are minimized, thereby creating a steadfast system that excludes that examination of family dynamics, including expressed emotion (EE), and calls into question the contributions of this view to real progress. On the other hand, it is curious that the notion of blame is contingent on the biological–environmental dichotomy. We are skeptical that the biological disease metaphor provides lasting meaningful relief to those exposed to the suffering of schizophrenia. Moreover, it is appalling that the field (either psychiatry or psychology) has yet to find a way to address more kindly the issue of problematic family communication patterns in a direct manner that would foster a posture of curiosity rather than a defensive reaction. We understand that families with a schizophrenic member may well be emotionally volatile, but one only need pay attention to the pejorative nature of many of the family-related concepts about to be discussed for evidence of this shortcoming.

In any event, the heyday of family process research in the 1950s saw the emergence of the double-bind hypothesis of the Palo Alto group (Bateson, Jackson, Haley, & Weakland, 1956), the transmission of irrationality hypothesis of the Yale group (Lidz, Cornelison, Terry, & Fleck, 1958), and the pseudomutuality notion developed by NIMH investigators (Wynne, Ryckoff, Day, & Hirsch, 1958). These and other contributions have been extensively reviewed by numerous scholars (e.g., Goldstein & Rodnick, 1975; Goldstein & Strachan, 1987; Hirsch & Leff, 1975; Jacob, 1975; Mishler & Waxler, 1968; Wynne, Toohey, & Doane, 1979), so we will not repeat the effort here. Suffice it to say that these specific process notions have tended to give way over time to more general ideas that gross intrafamilial communication deviance and a negative affective climate encourages the emergence of schizophrenic behavior. The altered perspective was attributable in no small measure to the success achieved by Singer & Wynne (1965a,b; Singer, Wynne, & Toohey, 1978) in demonstrating that they could postdict the schizophrenia status of offspring from amorphousness and fragmentation in the Rorschach protocols of parents. Subsequent use of a highly similar assessment system in the UCLA high-risk longitudinal sample showed that it could predict schizophrenia spectrum disorders in offspring (Goldstein, 1985). The latter study is particularly significant because the samples of deviant parental communication

were obtained years before the onset of schizophrenia in children, thus ruling out the possibility of parental reactivity to the disordered communication that schizophrenia normally entails.

A nonreactive research design was also employed by Roff and Knight (1981) in a study that related outcomes in diagnosed cases of adult schizophrenia in males to family variables obtained during patients' preschizophrenic childhood years. Data on the latter were obtained from child guidance clinic records that had been prepared at the time these children and their families were seen for various nonpsychotic childhood adjustment difficulties. Particularly interesting was the finding that poor adult outcome was associated with a mothering style remarkably similar to the classic "schizophrenogenic" pattern (Fromm-Reichman, 1948) of rejecting, impervious overconcern, an etiologic concept that had been all but abandoned by researchers by the 1970s. Also in line with the classic notion was some evidence that the effects of such mothering were especially noxious where fathers had been described as critical and noninvolved with their sons. A final instance of this study's rich yield was the confirmation of an association of poor outcome with two particular patterns of parental marital dysfunction that had been described by earlier investigators, in particular, by Lidz, Cornelison, Fleck, and Terry (1957) under the rubrics *marital schism* (extreme distance and hostility between the parents) and *marital skew* (wherein the family subculture is pathologically tilted in the direction of accommodating to serious disturbance in one of the parents).

The notion that familial subcultural aberrancy might promote the development of schizophrenia in offspring must confront at the outset the fact that siblings of the disordered member are usually normal. How have they escaped harm from these presumably relatively constant pathogenic conditions? The answer from proponents of this view is that the subculture of a family is not constant, that it changes appreciably over time, and has its own unique developmental pattern. The early development of the preschizophrenic child just happens to come at a time (Meehl's "bad luck" factor?) of maximum familial pathogenicity. There is some evidence to support this construction.

Taking a direct approach, Stabenau and Pollin (1968; Stabenau, Tupin, Werner, & Pollin, 1965) studied families in which siblings were discordant for schizophrenia and for juvenile delinquency.

They found, in brief, that seventeen of their nineteen "psychopathology siblings" (for schizophrenia alone, nine of ten), compared to only two of twenty-nine controls, encountered periods of maximum family crisis in early childhood identified by the families themselves. The "bad times" included such things as financial disasters, maximum parental strife, and depressive episodes in one or the other parent. A variety of collateral findings confirmed the general picture that these disturbed individuals experienced a world of far less reassuring character in their formative years than their more functional siblings.

Essentially the same type of explanation for normal siblings was offered in the Lidz–Yale family studies (Lidz, Fleck, & Cornelison, 1965). In fact, a criterion for selecting the original families to be studied was that at least one sibling was available who showed no evidence of psychological disturbance. In a series of compelling descriptions, the investigators in this project illustrated how the inherent pathogenicity of a marital dyad can become especially concentrated on a single sibling (owing to gender, concurrent stage of family development, etc), thereby confronting that child with insoluble conflicts and contradictions about the nature of reality that are not necessarily inflicted on other siblings or, if so, at lesser intensity.

As a final entry into this very contracted overview of the extensive literature on family influences in schizophrenia, recall the unique, ongoing project in which independent assessments of child-rearing adequacy were the focus of study by Tienari and colleagues (1985, 1987, 1994; Tienari, 1991) mentioned earlier in the adoption section. There is the familiar finding that the index adoptees have developed more, and more serious (including schizophrenia), psychopathology than the controls. Most of this psychopathology, however, is concentrated in the index group reared by poorly functioning adoptive parents—for example, parents who showed high levels of communication deviance. Index adoptees reared by well-functioning adoptive parents had substantially less psychopathology, and control cases reared in disorganized adoptive families experienced more serious psychopathology as adults than their counterparts raised in "healthy" families. Consistent with their earlier work, these results show a moderate genetic effect—the differential "healthy" and disorder rates of index versus control adop-

tees, irrespective of adoptive family context. However, parental inadequacy and disturbed communication has a substantial impact on the outcome for both index and control cases. Thus, the findings indicate a strong interaction between genetic vulnerability and an unfavorable family environment in the causal pathway leading to schizophrenia. Unfortunately, we cannot be certain that the emergence of odd or psychotic behavior in adoptees did not precede and cause, in whole or in part, the disorganization of their adoptive families. Analyses to examine this possibility are in progress (e.g., Wahlberg et al., 1997), but so far they provide no definitive support for this alternative interpretation. Some independent work reported by Kinney et al. (1997) also fails to show diminished mental health in adoptive parents raising children who became schizophrenic. Despite additional modest evidence for genetic transmission from these studies, the level of integration of the adoptive family into which the child is placed looms as an extremely critical variable. The most disastrous outcomes occur where children whose mothers have been schizophrenic are placed in chaotic adoptive homes.

Because expressed emotion (EE) has usually been seen as related to the course rather than the causes of schizophrenia, we will postpone discussion of it in families until a later section.

Soft Neurological Signs, At-Riskness, and Brain Anomalies

Although we find the genetic evidence pertaining to schizophrenia extremely modest in relation to the amount of "play" it gets and, perhaps excepting the case of monozygotic twinning, by itself virtually useless in predicting individual morbidity (as in so-called genetic counseling programs), we do not discount the possibility that other forms of biological compromise may convey a more substantial risk of schizophrenia. Indeed, it is conceivable that much of what appears "genetic" in the etiology of schizophrenia is mediated in some other biological manner. As it turns out, there is no compelling evidence of progressive brain degeneration in the natural course of the disorder (Cannon, 1998a,b; Russell, Munro, Jones, Hemsley, & Murray, 1997). In those instances where progressive degeneration has been observed, it sometimes appears to have resulted from the iatrogenic effects of antipsychotic medications

(Cohen, 1997; Gur et al., 1998). In other instances, it does not seem that reduced volume in at least some brain areas (i.e., hippocampus) is specific to schizophrenia (Velakoulis et al., 1999). In the light of these findings, it is interesting to note that some studies have suggested that deficits associated with the schizophrenias are the most stable element of the disorder (e.g., Amador et al, 1999; Nakaya, Suwa, Komahashi, & Ohmori, 1999).

Among the good candidates is a somewhat ill-defined syndrome consisting of multiple soft neurological signs detectable in early childhood that has possible fetal or perinatal origins (Lyon, Barr, Cannon, Mednick, & Shore, 1989). Obstetrical complications, such as an unduly short gestational period, in the histories of people who later become schizophrenic are well above normative expectations (Cannon et al., 1997; Gureje, Bamidele, & Raji, 1994; Jones, Rantakallio, Hartikainen, Isohanni, & Sipila, 1998; Torrey et al., 1994), although it is possible that resultant early brain injury contributes to schizophrenic outcomes only among genetically predisposed persons (see Marcus, Hans, Auerbach, & Auerbach, 1993; Mednick et al., 1998). The identification of such a syndrome may turn out to be among the most important contribution of longitudinal high-risk research in schizophrenia. First, we examine the more general aspects of neuroanatomical factors.

The advent of modern computer-dependent technologies, such as computerized axial tomography (CAT) and nuclear magnetic resonance imaging (MRI) have made possible research on the structural properties of the brain in living subjects, and the area of schizophrenia research is no exception. The resulting—and rapidly growing—body of research supports the implication of developmental insults and the possible resultant effects on later cognitive development in the pathway to schizophrenia. The nature of this new thinking is by no means completely developed or uniformly expressed, but essentially it involves the idea that the disorder arises from variable aberrations in brain circuitry. Most forms of the idea include the hypothesis of an early, likely prenatal, insult to the brain that may have detectable neurological effects in early childhood but will not necessarily result in the later development of schizophrenia (e.g., Lyon, Barr, Cannon, Mednick, & Shore, 1989). The latter arises where the initial injury somehow interferes with normal brain synapse development during a period of intensive synaptic

reorganization; for most people, it occurs during adolescence or early adulthood. Conceivable candidates here include neuronal cell “pruning,” cell migration, and programmed cell death, all processes that occur normally during postnatal phases of brain development (see Harrison, 1999, and Weickert & Weinberger, 1998, for overviews).

Pioneering work in this area was done by Fish (1957, 1977) and by Sobel (1961), both of whom stressed that subtly compromised CNS functioning, possibly attributable to birth complications, predisposed to schizophrenia. Fish (1977) describes the pathogenic pattern as one of “neuro-integrative defect” (see Meehl, 1962, 1989, 1990), which leads to “pandepvelopmental retardation” in persons who eventually become psychiatric casualties, especially in the schizophrenia range. The notion of premorbid neurological anomalies has been demonstrated by the high-risk studies (e.g., Mednick & Schulsinger, 1968; Mednick, Schulsinger, & Schulsinger, 1975; Mednick et al., 1978), including the suggestion that obstetric complications may factor in as well. Other support has come from the Israeli high-risk study where two neurological assessments carried out 5 years apart showed that index children (offspring of schizophrenic mothers) were markedly more likely than controls to have various neurological anomalies, most of the soft variety (Marcus, Hans, Byhouwer, & Norem, 1985; Silberman & Tassone, 1985).

Ironically, early twin research made a major contribution along the line of compromising neurological events that had pernicious effects later on. Pollin, Stabenau, and Tupin (1965) intensively studied a group of monozygotic twins and their families who were discordant for schizophrenia. Because heredity is a constant in such a sample, it was hoped that thorough investigation of environmental factors that differentiated the members of the discordant pairs would unearth clues as to the causes of schizophrenia in those twins affected. In virtually every instance, the twin who was to become schizophrenic had a relatively unfavorable intrauterine environment, manifested in lower birth weight at the outset and consistent relative retardation in biological developmental milestones. A significant preponderance of soft neurological signs such as praxis difficulties, abnormal reflexes, and abortive clonus, was found in the index twins. In short, the latter were less “competent” than their co-twins over a broad range of behaviors. These indications of compromised

functioning were of sufficient magnitude to evoke noticeably differential parenting behavior and to lead to a constellation of personality characteristics best summarized as excessive submissiveness in index co-twins, possibly adding a psychosocial impediment to the biological one.

Fetuses or newborns who sustained the earlier insult, according to the developmental view, are at elevated risk for missing or misconnected circuitry that arises during cell reorganization and thus are more vulnerable to developing schizophrenia (Walker & Diforio, 1997). Such deficiencies in neural circuitry would not be directly observable by currently available methods of brain scanning. Certain research findings of recent years are consistent with this type of etiologic scenario.

The so-called "season-of-birth effect" notion is relevant here. Although there is some controversy on this issue (see Bradbury & Miller, 1985; Lewis, 1989a,b, 1990; Lewis & Griffin, 1981), it has been documented and is largely accepted that people who become schizophrenic are more likely than people in general to have been born in winter and early spring months—about an 8% elevation (DeLisi, Crow, & Hirsch, 1986a). This peculiar observation, although possibly open to dispute on the grounds of statistical artifact (see Lewis, 1990), has given rise to a variety of hypotheses including the question of compromised brain integrity in schizophrenia, an idea suggested early by Bradbury and Miller (1985). Accumulating evidence supports these possibilities. For example, Wright, Takei, Rifkin, and Murray (1995) found that maternal influenza in the second trimester of pregnancy is associated with impaired fetal growth, enhanced obstetrical complications, and later-developing schizophrenia. Several studies have suggested that, historically, influenza epidemics are associated at a higher than chance level with the gestation periods of fetuses who later become schizophrenic. The latest of these studies reported by Takei and colleagues (1996) identifies the supposedly critical peak infectious period as the fifth gestational month. Here, risk of influenza exposure in the critical period was associated with enlarged ventricles and sulci among a group of eighty-three schizophrenic patients, relative to controls. Seemingly important and possibly related findings, reported by Torrey and colleagues (1993), establish a strong correlation between the occurrence of stillbirths and schizophrenia risk, presumably some infectious agent; in one of the

cases, according to this hypothesis, it leads to death of the fetus, and in the other to brain changes that enhance vulnerability to schizophrenia.

More recent work using the Finnish registry also demonstrated a relationship between prenatal exposure to polio virus infection during the second trimester and the later development of schizophrenia (Suvisaari, Haukka, Tanskanen, Hovi, & Lonnqvist, 1999). The idea of a virus causing schizophrenia is not new, and simply taken as that, lacks explanatory power in and of itself. However, the relationship between a viral compromise and the subsequent chain of effects in the course of development that might be initiated is something that we find more plausible. On the other hand, work by LaMantia (1999) points to the possible importance of an early insult during the third trimester of pregnancy. This approach focuses on the way the genetic code might be derailed as it unfolds while directing the development of brain areas, including the basal ganglia and hippocampus demonstrated as deficient in schizophrenia.

Despite the promise of findings in this area, it is incumbent on us to conclude this section with a cautionary note. The wealth of findings in this area as an emergent pattern illustrates an impending danger in this promising area of research: Without a clear theory on the way that these neurological insults affect the developmental processes in a manner that relates to identified pathophysiological processes and eventually to the expressed behavior of a taxonomic entity, it is likely that these findings will be merely added to many documented associations with the disorder and will add no real insight to the etiology.

Traumatizing Events

Clinicians who expend the energy and patience necessary to fully understand the developmental background of schizophrenic persons—and, regrettably, not all are willing to do so—usually come away with a powerful impression of traumatizing life circumstances. Perhaps one of the most stark illustrations of madness and associated horrors concerns the Genain quadruplets, all of whom became schizophrenic (Rosenthal, 1963). All four of these monozygotic sisters acquired the diagnosis before age 25. Though the remarkable concordance might suggest the operation of a genetic pathogen, we choose to mention it here be-

cause the sisters were raised in a family context characterized by parental madness of outlandish proportions (e.g., clitoral circumcisions to curb childhood masturbation). Their disorders, moreover, were quite different in respect to course, severity, and relative intractableness, characteristics that in turn were strongly correlated (in the expected direction) with the degree of exposure to pathological parenting. Despite stark clinical examples such as found in the Genain sisters, the yield from studies that compare the backgrounds of schizophrenics and suitable controls has been rather unimpressive in identifying discrete circumstances that differentiate schizophrenics as a group who had particular traumatic experiences while growing up. Perhaps this is another case in which "bad luck" (see Meehl, 1989) such as the occurrence of trauma in particular patterns, sequences, or at key times in development, is more important than the actual events themselves. In any event, we call attention to how little we have to report in this area.

In an early study, Schofield and Balian (1959) compared life history data of 178 schizophrenics with those of a carefully matched normal control group. For even the few significant differences found in the variables that one might assume are critical, the most striking finding was the very considerable overlap of the two groups. Indeed, for the variables of sexual adjustment and "adequacy of sexual outlet," the backgrounds of schizophrenics were significantly superior to those of controls—certainly not the most expected of findings. Some other results, such as excessive maternal overprotection and domination among preschizophrenics, were more consistent with expectations, but again the large majority of schizophrenic persons had normally affectionate relationships with their mothers. The high frequency of supposedly pathogenic circumstances in the backgrounds of their *normal* subjects led these investigators to suggest the need to study the "immunizing" experiences that may have permitted them to overcome their noxious environments. Although we think that the latter is a good idea, the results of the study are equally consistent with the notion that growing up is normatively hard and that preschizophrenic subjects are somehow excessively vulnerable to its vicissitudes.

Schofield and Balian (1959) included assessments of parental loss through separation, divorces, or death in their schedule but failed to find

this a variable that differentiated their groups. In contrast, Roff and Knight (1981), in the retrospective but nonreactive study described before, did find that parental loss before age 7 was associated with poor outcomes among persons diagnosed as schizophrenic. Similarly, in the Mednick et al. (1978) high-risk study, there was some indication that parental loss (here occasioned by maternal hospitalization) is etiologically significant.

Shifting the focus to precipitating as opposed to predisposing environmental life events in schizophrenia, we now have a fair amount of information on the evocations of schizophrenic behavior among persons who had experienced prior schizophrenic episodes. For example, Ventura, Nuechterlein, Lukoff, and Hardesty (1989), in a 1-year prospective study of remitted schizophrenics, presented strong evidence that negative events (independent of symptoms or personal actions) are associated with relapse. By far the largest body of work in this area has been concerned with familial expressed emotion as a precipitant of new episodes of schizophrenic behavior among recovered or near-recovered persons. We turn now to a brief summary of that literature.

Research on expressed emotion (EE), usually defined as a pattern of behavior involving both high intrusiveness and high levels of criticism directed toward the former patient, began in England (Vaughn & Leff, 1976, 1981) and was in due course transported to the United States (Hooley, 1985; Vaughn, Snyder, Jones, Freeman, & Falloon, 1984; Butzlaff & Hooley, 1998; Hooley & Hiller, 1998; Linszen et al., 1997; Miklowitz, Goldstein, & Falloon, 1983). At this point, there can be no doubt that it is associated with rehospitalization of schizophrenia; it occurs in conjunction with familial communication deviance (Doane, Falloon, Goldstein, & Mintz, 1985; Miklowitz, Strachan, Goldstein, Doane, & Snyder, 1986), and its reduction is associated with relapse prevention (Falloon, Boyd, McGill, Williamson, & Razani, 1985; Hogarty, Anderson, Reiss, Kornblith, & Greenwald, 1986). There remains, however, some question of the direction of the effect (i.e., the more disturbed the former patient, the more likely is rehospitalization, *and* the more provocation of EE in family members). Basically, this argument was made by Parker, Johnston, and Hayward (1988), who presented evidence that EE was significantly associated with a poor posthospital course only in one-parent households, where the

impact of disturbed behavior would be maximally likely to lead to high EE.

However, this construction is inconsistent with data from the UCLA high-risk study indicating that high family EE (in association with other variables already mentioned) *predicts* schizophrenia spectrum disorders that have their onset much later (Goldstein, 1985), suggesting a causal role in the relapse process (Nuechterlein, Snyder, & Mintz, 1992). Given that attempts to reduce EE and associated behaviors in family members have been very impressive in relapse prevention (e.g., Falloon et al., 1985; Hogarty, Anderson, Reiss, Kornblith, & Greenwald, 1986; Leff, Kuipers, Berkowitz, & Sturgeon, 1982; McFarlane et al., 1995), the time has come to gain a fuller understanding of these processes, as Hooley & Hiller (1998) suggest.

Aberrations in Pathophysiology

Pathophysiology represents the favored model for an attempted integrative view of the interaction of biochemical, biological, and genetic findings relating to the supposed disease processes of schizophrenia. The history here is characterized by a multitude of hypotheses. The earlier ones involved the idea of autointoxication by substances, sometimes unknown and exotic ones (e.g., "taraxein"; Heath, Martens, Leach, Cohen, & Angel, 1957). The idea of a single, pathognomic agent is now for the most part duly recognized as extremely unlikely, given the complexities of such processes, and so we would assume that the days of searching for a single causative agent are over. The current tack usually entails an "integrative approach" that emphasizes the interplay of different neural systems, which is pretty much the only way to account for the massive and sometimes seemingly contradictory array of findings. Despite these presumably well-accepted cautions, however, a tendency to focus on a specific area as causative of the disorder remains. Along these lines, the dopamine (DA) hypothesis has occupied the attention of researchers for the longest period of time. There has also been some emphasis on neurons that are rich in gamma-aminobutyric acid (GABA) that, it is thought, mediate dopaminergic functioning. With the advent of the "atypical" antipsychotics, there has also been renewed interest in research on the serotonergic mechanisms. It also appears that the latter interacts with at least

some aspects of the dopaminergic system. The often disregarded caveat here is that a therapeutic role does not imply etiology (Harrison & Burnet, 1997).

Receptor-Site Theories. Hypotheses related to various receptor sites in the brain have been proposed primarily on the basis that therein lies the site of action for drugs used to treat schizophrenia. Among them is the dopamine hypothesis (e.g., Meltzer & Stahl, 1976) that has sustained the longest period of empirical attention. For interested readers, the lengthy history of this hypothesis is revealed in some detail in an earlier edition of this chapter (Carson, 1984). The basic etiologic hypothesis is that schizophrenia is the product of excess activity in dopaminergic brain pathways, caused by either increased levels of dopamine or by increased sensitivity of the receptor sites. The evidence supporting this hypothesis rests mainly on the observation that the original antipsychotic drugs used to alleviate symptoms of schizophrenia are dopamine antagonists (Creese, Burt, & Snyder, 1976; Seeman, Lee, Chau-Wong, & Wong, 1976). Of the several DA neuronal tracts known to exist in the brain, probably the most attention has been focused on one that originates in the mesencephalon and terminates in the limbic system (hence called the *mesolimbic* tract). In fact, however, the site of action of therapeutic DA blockade—if that is the principal mechanism involved in symptom moderation with neuroleptics—has not yet been precisely determined. It is likely that DA in some way plays a role in schizophrenia, as is the case of other receptor-site theories, but its causal significance is far from clear (Davis, Kahn, Ko, & Davidson, 1991; Joyce & Meador-Woodruff, 1997; Seeman, 1987).

Several basic and well-identified problems with the dopamine hypothesis persist, and it is curious that adherents are reluctant to relinquish the DA hypothesis despite these problems. First, dopamine-blocking drugs are by no means specific for schizophrenia, and their use to treat other psychotic and neuropsychological disorders, affective disorders including mania, and severe personality disorders is relatively commonplace. Second, it has been known for years that the dopamine receptor blocking effect occurs within hours of administering the drug; however, clinical effects do not emerge in some cases for several weeks. Further, the therapeutic effect is obtained not by achieving "normal" levels of dopamine functioning, but at rather

abnormally low levels, as evidenced by the correlation of clinical outcome with symptoms of Parkinsonism and more seriously of tardive dyskinesia. Finally, the newer “atypical” neuroleptics exert their symptom-alleviating effects in a wholly different manner, suggesting that the dopamine system plays a complex role in multifaceted sequencing of neurochemical events associated with the expression of schizophrenic psychopathology. Overall, these problems suggest that what is known about the involvement of dopaminergic systems only partially reveals its place in the mechanism of schizophrenia.

Increasing complexities have been discovered regarding DA receptor sites. Snyder, Burt, and Creese (1976) first proposed the idea of two types of dopamine receptors in the brain, now indexed as D_1 and D_2 . D_1 receptors stimulate production of the enzyme adenylate cyclase, implicated in the enhancement of cell responsiveness, whereas D_2 receptors inhibit adenylate cyclase production. The “blocking” effects of neuroleptics, it is now thought, involve binding to the D_2 site, thereby in some manner inhibiting DA neurotransmission, possibly by preventing transmitter binding on the D_1 site or by a more direct route of inhibiting adenylate cyclase. These DA receptors can exhibit different states of high and low affinity for the reception of neurotransmitters. The dual and bidirectional high–low conversion represents another puzzling variable in the DA regulatory process. The discovery of dopamine receptor subtypes did not stop there. In 1990, a D_3 receptor site was identified (Sokoloff, Giros, Martres, Bouthenet, & Schwartz, 1990), and, at this time, no fewer than five dopamine receptor sites have been identified (D_1 to D_5).

Another source of complexity in the dopamine hypothesis concerns locations of the dopamine neurotransmitter systems. Dopamine is pervasive throughout several different areas of the brain. One study found a decrease—not an increase—in dopamine D_1 receptors in the prefrontal cortex of those diagnosed schizophrenic and suggested that this might explain some of the cognitive impairment of the disorder (Okubo et al., 1997). The anterior cingulate cortex, which plays a role in the function of attentional processes, is another area where pathological neuroprocesses associated with dopamine have been investigated. Several studies have implicated the cingulate cortex in schizophrenia psychopathology (e.g., Andreasen,

Paradiso, & O’Leary, 1998; Tamminga et al., 1992).

There is some evidence that the dopamine systems of schizophrenics are fundamentally different. Using challenge methodology, the demonstration of abnormal reactivity of dopaminergic transmission in response to amphetamine in schizophrenic patients appears robust (Abi-Dargham et al., 1998; Breier et al., 1997). However, it has also been suggested that a more accurate model of schizophrenic-like psychosis is gleaned from the more specific action of phenylcyclohexylpiperidine (PCP), a drug that effects the channel that down-modulates glutamatergic processes. It is believed that PCP, which can induce psychotic-like states in normal individuals that last up to three or four hours, can, in schizophrenics, unleash much longer periods of psychosis by virtue of lack of a means to turn the system off (Grace & Moore, 1998).

In one study, subjects were administered a non-selective dopamine agonist, apomorphine, or placebo, and then performed a verbal cognitive task. PET scans were then obtained for two groups—schizophrenic and controls. In schizophrenic patients but not controls, administration of apomorphine enhanced cognitive activation of the cingulate cortex during the verbal task. The results provided *in vivo* evidence that an impaired cognitive-task-induced activation of the anterior cingulate cortex in schizophrenic patients can be modulated by dopaminergic manipulation (Dolan et al., 1995). By studying the interaction of manipulating the dopaminergic system with a verbal task and the effects of the activity of a specific brain area, the authors were able to demonstrate a *systemic* difference in schizophrenic patients. Rather than enabling conclusions in terms of etiology, such an approach begins to recognize the complexity and importantly attempts to bridge mind (i.e., verbal task) with body (i.e., cingulate cortex activation). Still, no doubt, there are many missing pieces to this puzzle.

The “atypical” antipsychotic drugs (e.g., clozapine, olanzapine, risperidone) further complicate the dopamine puzzle. So-called “atypical” because they do not produce the side effects associated with the traditional neuroleptic medications, notably, tardive dyskinesia, these drugs, it is assumed do not impact the same dopamine receptor sites as the traditional ones. However, the demonstration by Nyberg & Farde (1997) estimated that extrapyramidal symptoms (EPS) are not evident

until approximately 80% of the D_2 receptor sites are occupied. In other words, it may be that the new antipsychotic medications exert a clinical effect before the number of D_2 receptor sites required for extrapyramidal symptoms have been affected.

Unfortunately for the dopamine theory, these newer drugs are apparently just as effective as the older neuroleptics, although the more dangerous of these (clozapine) is reserved for those who do not respond to the more traditional drugs. Perhaps due to a desire to preserve the potential for the dopamine hypothesis, it is sometimes concluded that patients who do not respond to the traditional antipsychotics represent a subgroup of schizophrenics who have a variant dopamine pathology. However, Valenstein (1998) has pointed out the inconsistency of this line of reasoning because those patients who do respond to traditional neuroleptics respond to the atypicals as well.

It is clear that the newer antipsychotic medications that exert their effects primarily in systems other than the dopamine system pose particular problems for the dopamine hypothesis. The "atypical" antipsychotics, olanzapine and risperidone, primarily affect serotonergic receptors by decreasing transmission activity, in particular, the subtype receptors that have been labeled " $5-HT_2$." Interestingly, it is believed that these receptors sites are where LSD exerts its hallucinogenic properties (Pierce & Peroutka, 1989; Wing et al., 1990).

Of the atypicals, clozapine is a bit of an anomaly because of its far-reaching and varied effects. Clozapine affects the dopamine system as well as the serotonergic system, and also a wide range of other receptor types (Nyberg & Farde, 1997). There is evidence that clozapine achieves its effects through D_4 -mediated GABA modulation (Bergson et al., 1995). GABAergic neural systems are another area that, it is thought, plays a role in schizophrenia based on evidence from postmortem and functional imaging studies that demonstrated abnormalities (Akbarian et al., 1995; Benes, Vincent, Alsterberg, Bird, & SanGiovanni, 1992; Busatto et al., 1996; Meltzer, 1994). Further complicating matters, it appears that $5-HT_2$ receptors have a role in controlling GABAergic neurons (Harrison & Burnet, 1997).

In connecting these systems to behavioral output, there is no more specificity, although some brain areas have been broadly related to either negative (e.g., amygdala) or positive (e.g., the prefrontal

cortex) symptoms, mainly on the grounds of speculative reasoning. The serotonergic systems are related to affect, cognition, motor behavior, hormonal, sleep, and body temperature regulation (Cowen, 1991; Stephenson, 1990). Clearly, dopamine and serotonergic systems play critical roles in the schizophrenic process, but where they fall in the cascade of events that undergird the classic psychotic and thought-disordered clinical picture is much less clear (Nyberg and Farde, 1997). It may be that role of neurochemicals will have to include other influences, such as the aberration of neural circuitry, before the role of biochemical abnormalities will more completely elucidate the schizophrenic process. In any event, the limitations of psychopharmacological technology are not unlike those of some forms of cancer treatment, where cellular production of all types, not just cancerous cell growth, is stopped by some chemical interventions and produces well-known iatrogenic effects, an accepted cost given the present limitations of treatment in this area. Similarly, psychotropic drugs used to treat schizophrenia have far-reaching effects such as tardive dyskinesia.

Although perhaps painting too optimistic a picture, Nestler (1997) clearly recognizes this in emphasizing that pinning schizophrenia on a simple increase or decrease of a neurotransmitter is unlikely to pan out and that some sort of integration of brain structures and the various pathways and systems connecting them will be implicated in the emergent etiology of the disorder. Impressive work done by Grace and Moore (1998) makes a comprehensive attempt along these lines. Noting that the nucleus accumbens demonstrates a functional interdependence of the various brain areas that have been implicated in schizophrenia (e.g., the prefrontal cortex, amygdala, and hippocampus), they developed a model of pathophysiology that focuses on the *regulatory* aspects of this brain area on the other areas. Although speculative, they go on to suggest that the development of the various brain systems (including the physiological mechanisms) may be impacted by aberrant processes in the nucleus accumbens. Such an approach takes into account the interrelationships of the various systems, but we suspect that there will be limitations in the knowledge that will be acquired. Specifically, the idea persists that there is a *localized* dysfunctional brain area ostensibly responsible for the dysfunction in other brain areas (i.e., the nucleus accumbens). Simply put, there is

no a priori reason to necessarily assume a single causative agent that leads to the malfunction.

Biology and Disease Commentary. The idea that “chemical imbalances” in the brain cause serious mental disorder is for some reason an appealing proposition these days. Perhaps the complexity of these physiological processes in some way eludes careful scrutiny by those most involved with the *behavioral* pathology of the disorder. Yet the disease metaphor persists largely based on evidence that has been obtained in a sort of backward fashion. The essential strategy, now commonplace for more than a decade, has been to implicate sites in the brain known to be affected by drugs that are employed to attempt treatment of the disorder. More sophisticated approaches are being attempted with the recognition that multiple brain systems interact *as part of the pathological process*. However, the idea that there is a primary pathological factor or site in the brain persists, even in the most sophisticated of models such as that described before by Grace and Moore (1998). Focusing attention on the nodal areas where the other brain areas connect to each other is a reasonable idea, but it is still driven by the idea that there is a *single, fundamental causative agent* (or area) in the brain that is responsible for the disorder. At the present level of knowledge, such a reductionistic approach is quite possibly an unwarranted step—at least as far as etiology is implied. Observations of brain pathology are merely another level of clinical description. As such, they are important and valid descriptions, but for some reason it seems that they are accorded causal status.

We would not suggest that results from such studies are not worth pursuing, especially in the context of a richly developed theory such as that by Grace and Moore (1998). Indeed, this level of information will be a vital piece of the schizophrenia puzzle. Those models which acknowledge the complexities of interaction in brain systems in the *process* of the disorder will be especially important. For all the pieces to fall into place, however, will require relating these systems to behavioral output, and doing so will require consideration in the developmental context. Importantly, the idea of identifying a primary lesion may be one the field is ready to discard. The unfolding development of these systems, and the accompanying events (molecular and otherwise) will be key to developing an understanding of the etiology of the disorder. Our main contention here is that

brain pathology should not be accorded status above clinical description for its explanatory power. Perhaps the results of the varied attempts to treat schizophrenia can serve as a reference point for integrating the molar aspects of the disorder.

Treatment Perspectives

We cannot attempt here to approach adequately a comprehensive review of research on the treatments and outcomes of schizophrenic disorders. Therefore, we will limit our review here to treatments of historical significance and to those treatments that will hopefully provide some insight into the schizophrenia phenomena. We will be brief with—roughly speaking—the two classes of therapies: the biological approaches because we leave it to the others who present the biological view to provide a comprehensive overview, and the psychosocial therapies because, quite plainly, there is not a lot to report. The essence of our focus is also intended to shed light on the fundamental nature of the psychopathology involved. Before proceeding, we call upon the reader to reflect for a moment that schizophrenia has been a disorder, more so than any other mental disorder, that has consistently *required* multiple levels of intervention.

Biological Approaches

With the widespread introduction of the phenothiazine drugs, beginning with chlorpromazine, in the mid-1950s, the more drastic forms of biological intervention underwent a rapid decline in use. Psychosurgery, hydrotherapy, and insulin coma, all of them once fairly routinely employed, are for the most part rarely considered today for any form of mental disorder. Electroconvulsive therapy (ECT), still widely used to treat severe mood disorders and once a mainstay of “therapy” for schizophrenia to the point of abuse (e.g., “regressive” ECT involving multiple administrations per day), is now regarded at best as an improbably useful last resort for schizophrenic patients whose disorders have proven persistently refractory to other therapeutic measures, although there is some evidence to suggest that the threshold for this approach may be relaxing somewhat (e.g., Fink & Sackeim, 1996; Kales, Dequardo, & Tandon, 1999). The fact that these appallingly primitive

techniques were still in widespread use only a generation ago speaks to the desperate level to which psychiatry had fallen immediately before the present era of neuroleptics. What sometimes seems to outsiders as an excessive attachment to these drugs among many psychiatric practitioners may be more understandable when viewed in this light.

Nevertheless, that attachment—insofar as it involves a sense of delivery from helplessness by the advent of the neuroleptic era—may be misplaced to some extent. Notwithstanding the seemingly unrestrained advertising claims of pharmaceutical companies about the role of their products in bringing about an alleged mental health revolution, many forces other than the availability of neuroleptics were in operation by the 1950s that were helping to modify views about the hopelessness of severe mental disorders and therefore to transform the previously wretched and iatrogenic environment of the average mental hospital. These positive attitudinal changes were doubtless aided and accelerated by the new drug therapies, but we do not know that they would not have happened anyway.

A look at resident schizophrenic population figures of state and county mental hospitals for the period under consideration is instructive in regard to the general point we are making here. These figures, assembled by Mosher (1989) from data gathered by the National Institute of Mental Health, show that the national peak for resident schizophrenic patients in public hospitals was reached in 1960–1961 at about 269,000. This was 5 years after neuroleptics became readily available and 2 to 3 years after their use had become practically universal, clearly demonstrating that the turnaround from ever-increasing resident schizophrenic hospital populations was not primarily attributable, as is commonly supposed, to the direct clinical effects of these drugs but rather to some other factor or factors. The drop in hospital populations remained modest until 1963, the year when the federal Community Mental Health Centers Act was passed. Thereafter, the rate of decline accelerated dramatically, a trend Mosher attributes primarily to continuing federal legislation (e.g., extension of Social Security benefits to the young mentally disabled) that made community living for the seriously disturbed an increasingly feasible alternative. He points out, interestingly, that in western European countries, with equal

access to neuroleptics but with the pertinent social legislation already in place, the sharp decline during the 1960s in hospital residency for schizophrenia did not occur.

There is no denying the relief that can be brought about by neuroleptics—for both the patient and the doctor. Anyone who had seen a mental ward before neuroleptics were introduced can attest to the apparent inhumanity and suffering. But any patient will clearly inform you that the humanity is not fully restored, and the suffering is not fully relieved by drug treatment. Why else would medication compliance be such a preponderant issue in the treatment of schizophrenia? To be clear, drug bashing is not our intent. However, reservations that run counter to the widespread enthusiasm for this type of intervention need to be voiced, especially when some psychologist colleagues want prescription writing privileges. Viewed objectively, the actual record of accomplishment for neuroleptic intervention in schizophrenia is quite modest, especially where unpredictable, serious, and intractable side effects like tardive dyskinesia are factored in.

We have become accustomed in recent years to looking seriously at the results of meta-analytic studies in trying to assess treatment effectiveness. Though it has been largely overlooked in relation to schizophrenia, the original Smith, Glass, and Miller (1980) meta-analysis of the benefits of various therapies for various diagnostic groups included an assessment of drug therapy for schizophrenia. The drugs-alone average effect size (essentially the mean magnitude of the treated group's deviation from the mean of the control group, in control-group standard deviation units) in this assessment was +0.51, a figure that is decidedly on the low side for the many effect sizes reported in this remarkable work. Its basic statistical meaning is that the average functionality (as variously assessed) of exclusively drug-treated schizophrenics was at approximately the 70th percentile of that of untreated controls. By comparison, the average effect size for psychosocial interventions with "psychotics" was +0.68 (75th percentile of controls), whereas the drug-plus-psychotherapy combination for schizophrenia resulted in a very respectable average effect size of +0.80 (79th percentile).

Although these figures on the effectiveness of standard drug treatments in schizophrenia are sobering when viewed against the backdrop that they

are often the only treatment offered, they do not convey to a full extent the limitations of an exclusively pharmacological approach. These limitations reside in the virtually complete ineffectiveness of these compounds in enhancing those energies, awarenesses, and skills that form the basis for effective engagement of the social environment, a vital set of personal resources that are strikingly deficient in the behavioral repertoires of the large majority of persons who acquire the schizophrenia designation. Consider in this regard the following remarks of the distinguished Harvard social psychologist Roger Brown, reported on his attendance at a local meeting of Schizophrenics Anonymous:

[The group leader] began with an optimistic testimony about how things were going with him, designed in part to buck up the others. Some of them also spoke hopefully; others were silent and stared at the floor throughout. I gradually felt hope draining out of the group as they began to talk of their inability to hold jobs, of living on welfare, of finding themselves overwhelmed by simple demands. Nothing bizarre was said or done; there was rather a pervasive sense of inadequacy, of lives in which each day was a dreadful trial. Doughnuts and coffee were served, and then each one, still alone, trailed off into the Cambridge night.

What I saw a little of at that meeting of Schizophrenics Anonymous is simply that there is something about schizophrenia that the antipsychotic drugs do not cure or even always remit on a long-term basis. (Brown & Herrnstein, 1977, p. 641)

Brown's observations remind us that perceptive and articulate "laypersons" can often tell simple truths about mental patients in a way that jaded mental health professionals often cannot. We question only his circumspection in suggesting that the antipsychotics "do not ... always remit" the devastating social deficits that normally accompany schizophrenic disorders. We hold that they probably *never* do, and that it is unreasonable to expect that they, or any other currently conceivable drug, might have such an effect. In this sense, we see the pharmacological approach limited indefinitely to a merely palliative role in therapies for schizophrenias. The empirical evidence indicates that long-term rates of *social* recovery in schizophrenia have not improved since the advent of neuroleptic drugs (e.g., Harding, Brooks, Ashikaga, Strauss, & Breier, 1987a,b). The ambitious study by Hegarty and colleagues (1994) mentioned earlier provides compelling evidence. Moreover, a smaller scale but similar study by Warner (1994) confirms the main findings reported by Hegarty and colleagues. It seems obvious to us that our

profession is going to have to look elsewhere for the "cure" to this type of problem.

On a more optimistic note, the disappointing performance of the antipsychotic drugs in the study described relate only to the older "typical" compounds such as chlorpromazine and haloperidol, and may conceivably be overcome with further advances in pharmacological therapy. Sheitman et al. (1998) identify a number of newer "atypical" antipsychotics in various stages of development and use; any of them might produce a better record in terms of social recovery. A primary advantage of the atypical antipsychotic medications is that they are less pernicious in side effects, supporting the hypothesis that the iatrogenic effects of older psychotropic medications may play a role in limiting social recovery. In any event, these newer compounds have yet to be thoroughly evaluated along these lines.

Psychotherapies of Schizophrenia

Perhaps as a backlash to the days of the "double-bind" and other family approaches that resulted in uncalled for parent bashing and undoubtedly owing some influence to the recent "decade of the brain" that included a heavy emphasis on biologically based research at the National Institutes of Mental Health, there has been a very serious dearth of psychosocial research in schizophrenia. It should not go unnoticed that earlier forms of psychotherapy did not position themselves well in being subjected to empirical evaluation, and this inadequacy likely set the stage for the so-called biological revolution. So dominant became the latter that some extremely promising alternative approaches that appeared in the decades before the 1990s were quite simply ignored by the majority of the professional mental health community. These examples include a therapeutic community-based program of "self-help" for patients moved from the hospital to a commercially failed motel with minimal professional oversight (Fairweather, 1980; Fairweather, Sanders, Maynard, & Cressler, 1969), and a rigorous token economy "social learning" program for chronic state hospital patients (Paul & Lentz, 1977). There was also the report of a well-designed study that demonstrated the superiority of specialized individualized psychotherapy conducted by highly experienced therapists to antipsychotic medication in treating schizophrenia (Karon & Vandenbos, 1981). These studies produced ex-

citing results in patient progress without, for the most part, extensive use of medication. The randomized clinical trial (RCT), ironically borrowed from the medical field concerned with pharmacological efficacy and now a mainstay of psychotherapy research, allowed a more recent examination of the efficacy of some very specific forms of psychotherapeutic intervention for schizophrenia. We now review the various psychotherapies.

“Moral” and Milieu. Such “active” (as opposed to prophylactic or maintenance) treatment as occurs in cases of schizophrenia is probably most often conducted in inpatient settings. Even where drugs are the primary mode of intervention, therefore, it is important to ask whether the psychosocial context or milieu of the hospital or ward has any therapeutic significance. A variety of evidence indicates that it does, beginning with the apparently pronounced successes of “moral” (i.e., psychosocial milieu) therapy asylums during the earliest decades of this country’s founding.

The era of moral therapy in the United States lasted only roughly through the first half of the nineteenth century, following which it succumbed to paradigmatic social, cultural, and population changes (e.g., a huge influx of non-English speaking immigrants) that, during the subsequent century, produced the disgraceful, overcrowded, “snake-pit” conditions of public mental hospitals of the 1940s and 1950s. The rates of hospital discharge of persons suffering serious mental disorders fell precipitously during that period and resulted in the accumulation of “chronic” cases, most of them doubtless schizophrenic, in the human warehouses that mental hospitals had become. According to the old hospital records unearthed by Brockoven (1972), mental health professionals ironically had done a much better job *before* 1850, lacking as they did access to the subsequent dramatic but evidently largely irrelevant advances in biomedical science that were shortly to begin. In fact, general adoption, for all mental disorders, of the organic model suggested by general paresis, whose connection with syphilis was discovered in 1857, probably contributed significantly to the demise of the moral therapy movement.

The idea that effective treatment of schizophrenic persons should include the planned creation of a benign psychosocial environment surfaced again in the late 1920s with the establishment by Harry Stack Sullivan (1962) of a special ward at the Sheppard and Enoch Pratt Hospital for treating

young schizophrenic males. In all probability, Sullivan himself had earlier had some sort of brief personal experience with this type of disorder (see Alexander, 1990, for a detailed examination of this possibility). Whatever the case, he had some insights not widely shared among his professional peers. Revolutionary for its time, this small ward was run with tight control by Sullivan (e.g., he personally selected and trained the nursing attendant staff), and in due course it achieved considerable fame for its innovative philosophy and for the therapeutic results achieved. It was one of the factors that first catapulted Sullivan into a position of prominence in American psychiatry (Chapman, 1976). Unfortunately, few hospital directors were willing to follow his lead in treating schizophrenia, and his influence in this respect seems to have been confined chiefly to the local area around Baltimore, notably including the famed Chestnut Lodge in Rockville.

The notion of milieu therapy (alternatively, therapeutic community) did not really catch on again until approximately the 1950s, undoubtedly aided, as we have seen, by the advent of neuroleptic drugs. Subsequently, the record it compiled (reviewed by Mosher & Gunderson, 1979; Neale & Oltmanns, 1980) may be termed encouraging, although the results achieved are, of course, strongly confounded with drug effects in most settings. In one remarkable study, that of Paul and Lentz (1977), they are not; in these authors’ exceptionally well-controlled experiment, chronic patients treated with milieu therapy (in comparison to those who received standard hospital care) fared much better in outcome measures such as release to the community. We shall return to this study shortly in the following section to consider the behavioral aspects employed. In a later report, Mosher and colleagues described the “Soteria Project” and reported the results of milieu treatment, in most cases without neuroleptics that were on a par with treatment as usual for acute psychotic episodes (Mosher, Vallone, & Menn, 1995).

The beneficial effects of a psychologically wholesome milieu for chronically schizophrenic patients can apparently be gained even without hospital confinement. Fairweather and colleagues (1969) with consummate boldness, moved a substantial group of such patients out of the hospital into a commercially defunct motel (“The Lodge”) where, after a brief orientation period, the latter were left for the most part on their own with only

minimal supervision or medical coverage. The guiding principle was that of self-help. Contrary to the dire predictions many made, after a somewhat rough start, this small society began to organize itself, established a division of labor, and created various other formal arrangements essential to social living. Within a surprisingly short time, it became a truly viable and for the most part sustaining community. In due course, in fact, these “psychotic” citizens established a profitable janitorial and landscaping business! The patient cost per day to the state of California dropped to a fraction of what it had been, although that is perhaps the least of the benefits realized.

The Lodge project was eventually terminated formally, although the expatient community successfully continued on. Despite the evident promise of this approach and the considerable efforts of Fairweather and his associates to promote its consideration on a national scale, the path proved difficult (Fairweather, 1980). Although a few similar projects have been undertaken at scattered locations with comparably impressive results, support in official state or local government budgeting has been rare, as have enthusiastic expressions of interest among members of the traditional mental health disciplines. Why? We can only conjecture that this innovative concept ran so thoroughly counter to institutional bureaucracy and the prevailing professional zeitgeist that it was the victim of a destructive type of cognitive inflexibility or (more sinisterly) of political assassination. Obviously, it still deserves a serious, comprehensive, and extended trial.

Behavioral. A similar fate overtook the extraordinarily promising “social learning” program that was part of the large Paul and Lentz (1977) project mentioned before. In this treatment condition, patients were subjected to a closely monitored and continuous token economy, one whose contingencies were unusually rigorous both in behavioral expectations and the range of reinforcements meted out as a consequence of good or substandard patient performance (token acquisition). The outcomes for patients in this program exceeded by a considerable margin the very respectable ones achieved with milieu therapy (which, as noted, were notably superior to standard hospital care), again without significant contribution from drugs. Of a control-matched sample of these chronic patients, 11% achieved wholly independent functioning without readmission during the course of a 4½-

year follow up, whereas 96% of them managed continuous community living for at least 90 days. As we have learned to expect, there was modest postdischarge behavioral deterioration for many of these patients, but nondrug aftercare services were generally effective in reversing this trend. We are baffled by the practically uniform absence of response to these challenging findings—for example, among state mental health authorities—over the years since their original publication.

Although we have yet to see the potential realized in bold and imaginative therapeutic programs, our own conviction is that the real promise of behavioral intervention in schizophrenia resides in the programmed establishment (reestablishment?) of those skills essential to independent adult functioning in an increasingly demanding and complex social environment. As pointed out by Bellack, Morrison, and Mueser (1989), a dearth of significant progress in this area is attributable at least in part to misdirected effort and a related failure to analyze adequately the tasks to be accomplished. The deficits that need to be addressed, for example, are in the main at a more basic level than “problems solving.”

Family. As in other areas of psychosocial intervention in schizophrenia, research in family therapy has waned substantially in recent years, although its past record is quite respectable (Mosher & Gunderson, 1979). Our reading of the etiologic evidence is that the neglect is a very serious mistake. The primary exception to the pervasive inactivity in family therapy concerns work on the reduction of EE to prevent relapse among persons who have already had one or more hospital admissions. Not surprisingly, such interventions appear quite promising (Faloon et al., 1985; Hogarty et al., 1986). There is some suggestion that intervention to reduce EE may make it feasible to reduce neuroleptic drug dosages, with attendant benefits in instrumental and social role functioning (Hogarty et al., 1988), not to mention reducing the risk of tardive dyskinesia. Family therapy would be an excellent medium for identifying instances of EE and for teaching family members how to avoid it (Tarrier & Barrowclough, 1990).

Individual. Though the work of several gifted psychotherapists of schizophrenics, such as Sullivan, Freida Fromm-Reichmann (1950), Green (1964), and John Rosen (1953) is an important part of the history of the field, it must be acknowledged that we lack good data on long-term outcomes for

the patients that they treated. The bases for their short-term success are also obscure, although in various writings each of these individuals articulated the principles that supposedly guided their interventions. Because the "principles" are not readily transmitted to others with the assurance of comparable results, our suspicion is that the critical element in each instance was some combination of personality factors that made for facile communication with psychotic persons. Conceivably, they are factors that share some commonality with those identified by Whitehorn and Betz (1954) in isolating a group of psychiatric residents who achieved excellent results in work with schizophrenic patients in the years before neuroleptic drugs washed out the effect.

In the not so distant past, Karon and Vandenbos (1981) published a book on the psychotherapy of schizophrenia which they unabashedly subtitled "The Treatment of Choice." The recommended techniques, ample and fascinatingly illustrated, bear the unmistakable impress of John Rosen. The book ends with a complete report of a research project designed to compare the outcomes of psychotherapy administered by "experienced" and less experienced therapists, neuroleptic drug treatment, and a combination of the two for thirty-three randomly treatment-assigned patients during an effective project period (including follow-up) of 44 months. The multiple-outcome-measure results (which include rehospitalization data) are thoroughly analyzed and discussed. In summary, they showed a strong superiority in the long-term outcomes for the psychotherapy-only treatment group. The drug-plus-psychotherapy group had outcomes only slightly superior to the drug-only group, an effect the authors ascribe chiefly to drug-induced interference with the psychotherapy process.

The report just described also includes a valuable discussion and critique of earlier and probably better known comparative treatment projects of this general type, to which the interested reader is referred (they are omitted here because of space considerations). Overall, the results of these projects are less favorable to the psychotherapeutic approach in schizophrenia than those reported by Karon and Vandenbos (1981), although more encouraging than some secondary reviews have portrayed them. There is a persistent tendency in this literature, by the way, not to recognize the multiple ways in which drug treatment and psycho-

therapy differ that make direct, competitive comparisons of the two more problematic than superficial analysis would suggest. An excellent discussion of some of these considerations was offered by Stiles and Shapiro (1989).

It is striking how relatively little current research on the individual psychotherapy of schizophrenic persons is currently underway, compared to other treatments (i.e., biological) or other disorders. One wonders whether the impact of negative opinions about psychotherapy issued by some has declared the issue moot (e.g., Klerman, 1984). Coursey (1989) expressed this attitude by suggesting that we need a new type of psychotherapy for schizophrenia, one that recognizes the global inefficacy of standard psychotherapy and that accepts schizophrenia as a "biological distortion," the biological revolution in psychiatry, according to Coursey, having "won." As described, this desired form of psychotherapy, which hardly seems new, would be akin to case management for a defective organism. Apart from wondering what research literature Coursey reads and how anything has been won, we are distressed by the unrestrained condescension of his position, as we suspect many intelligent schizophrenic persons would be. Katz (1989) offered a suitable admonishment for this line of thinking.

On the other hand, the tide may be turning. The American Psychiatric Association's (1997) *Practice Guideline for the Treatment of Patients with Schizophrenia* that contains expected comprehensive recommendations on managing medication of patients in various phases and at differing severities of disorder also makes a host of recommendations relating to the desirability of vigorous psychosocial interventions. In making these recommendations, the *Practice Guideline* takes notice of the development in recent years of a number of relatively new psychosocial initiatives demonstrably effective in ameliorating the problems of schizophrenic patients, particularly those problems that seem largely unresponsive to antipsychotic drugs (Kopelowicz & Liberman, 1998). Ironically, it may be that the current scientific standard for demonstrating efficacy in the field, that of the randomized clinical trial or "RCT," is making it possible to gain a foothold in demonstrating the importance of psychotherapy for schizophrenia. In contrast to effectiveness studies (i.e., how treatment interventions hold up in the field under less controlled circumstances), RCTs aimed at efficacy

seek to demonstrate how well an intervention works under controlled conditions, thus making it possible to identify a potent treatment. A number of "psychotherapy trials" conducted in this manner reaffirm the role of psychotherapy for schizophrenia.

Hogarty and colleagues (1997a,b) report on a controlled 3-year trial of "Personal Therapy," a form of psychotherapy specifically aimed at schizophrenic individuals. This treatment was very effective in enhancing the social adjustment and social role performance of discharged patients. Personal therapy is described as a staged, nonpsychodynamic approach oriented to learning coping skills for managing emotion and stressful events. In favorably commenting on this program, Fenton and McGlashan (1997) assert the need for a flexible individual psychotherapy component in virtually all treatment packages for schizophrenia.

Training in social skills (see, e.g., Bellack, Mueser, Gingerich, & Agresta, 1997; Dilk & Bond, 1996), as has been demonstrated, has a positive impact on overcoming the embarrassment, ineptitude, awkwardness, and attentional "cluelessness" displayed in social situations by many persons who have undergone episodes of schizophrenia. A broader aspect of social relations concerns integration into a community. Many schizophrenic patients, sometimes abruptly discharged into the community, have great difficulty in marshaling resources and organizing their lives. Included here is some propensity to become involved in substance abuse, often as self-medication for unpleasant antipsychotic drug side effects (Kosten & Ziedonis, 1997). Therefore, there is considerable need for persistent and vigorous community-based follow-up and aid in managing life problems (e.g., Mueser et al., 1998), including coordinating continuing antipsychotic medication (Kopelowicz et al., 1997).

One final, less optimistic point concerns the problem of system inertia. These psychosocially based efforts to compensate for the shortcomings of antipsychotic medication in treating schizophrenia are not at present generally "in place" and functioning up to speed. An intensive effort to assess the degree of conformance of actual practice to a set of previously issued treatment guidelines similar to those described before in the mental health systems of two states found that conformance was generally less than 50%, especially to the psychosocial enhancements recommended

(Lehman et al., 1998). We suspect that a national compliance assessment effort covering all fifty states would not produce a more encouraging picture at this time. Actual mental health practice, it seems, fails to keep pace with what is known to be maximally effective in restoring schizophrenic patients to active and productive citizenship. In this sense, we have continued a very long-standing pattern of limited horizons for and neglect of this portion of the population.

Conclusion

Some behavioral scientists (e.g., Whitaker, 1992) dispute the idea that schizophrenia is caused primarily by biological factors. It is unfortunate and counterproductive that biological and psychosocial research are often conceived as mutually antagonistic and that they rarely make contact with one another. Importantly, although much lip service is paid to the evidence of interaction between biological and psychosocial variables in schizophrenia, studies that actually examine the interaction are rare. Hopefully, interest (and funding) for such endeavors will increase in the near future.

As a good illustration of this type of integration, consider an innovative project that involved rating childhood "home movies" obtained from schizophrenic patients conducted by Walker and colleagues (Grimes & Walker, 1994; Walker, 1994; Walker et al., 1994). The preschizophrenic children showed less—and less positive than negative—emotionality, had poorer motor skills, and showed a higher rate of peculiar movements, such as tic-like muscle contractions, suggestive of neuro-motor abnormalities. Bear in mind that the manifest nature of these problems would all but certainly impact the child's social environment negatively. It is extremely likely that the (presumably) neurologically based behavioral deficits observed in the then preschizophrenic children would be noticed and responded to negatively by others who come into contact with them. The child who rarely manifests joy (even on celebratory occasions such as birthdays), whose emotional expressiveness is prevailing in the bland to negative range, who is motorically clumsy or awkward, and who may evidence peculiar involuntary movements, is likely to have a far less stress-free early life than the child endowed with the opposite characteristics. Mini-

mally, such a scenario suggests that the occurrence of stressful life events may affect social and personality development and is not independent of a potentially pathogenic biological "diathesis." In fact, this idea has been a central element in the important contributions of psychologist Paul Meehl (1962, 1989, 1990) in tracing the developmental course of schizophrenic outcomes. Berenbaum and Fujita (1994) offered a similar conceptualization.

Meehl's (1962, 1989) concepts relating to the genesis of schizophrenia are in broad outline—if not in their details (e.g., we find implausible the notion that a single dominant gene controls vulnerability)—refreshingly closer to what we envisage as a more ideal approach to finding the answers. It seems inescapable in our reading of the evidence that the connections of causal links from the molecular to the molar (behavioral) levels, from the endoenviornment to the ectoenviornment, are both lengthy and intricately interlaced. To unravel the mysteries will require the talents and skills of many different kinds of scientists, from the molecular biologist to the specialist in the social development of children, working in a framework in which some minimal level of collaboration will be essential. Divided research camps devoted primarily to furthering of ideologies are a decided hindrance that we can ill afford in this type of scientific context. Until we can move beyond the clash of genetic/biological *versus* environmental/psychosocial paradigms, we will be limited to a vision holding that the etiology of schizophrenia resides in some imprecisely specified combination of "bad luck."

The simple fact is that in much of the contemporary literature, the psychosocial dimensions of schizophrenia are denied at intensities that approach religious fervor. We fear that the "great and desperate cure" mentality (Valenstein, 1986), the magic-bullet fantasy now embraced by much of psychology as well as our sister discipline of psychiatry, is a step backward in time, one that retards scientific progress and deprives untold numbers of persons designated as schizophrenic of the demonstrable benefits of soundly planned and executed psychosocial intervention. Meanwhile, an egregiously imbalanced allocation of scarce research resources deprives the mental health professions of opportunities to develop vitally needed knowledge that could lead to psychosocially based techniques enhanced in cost-effec-

tiveness, possibly even ones that would enormously potentiate the now rather limited horizons of the growing catalog of antipsychotic drugs.

Personality Disorders

This page intentionally left blank.

Antisocial Personality Disorder

Patricia B. Sutker and Albert N. Allain, Jr.

Introduction

Behaviors that fly in the face of social convention and legal restraint have provoked interest and argument throughout recorded history. Early clinical accounts described individuals who failed to conform to moral and legal expectations by referring to evil spirits, moral defects, and personal inferiorities. More recent clinical and research work has focused on measuring the antisocial personality and developing a nomenclature for distinguishing antisocial from other categories of character disorder. The literature continues to reflect a deficit model that explains antisocial proclivity, and the search persists for biological and psychological corollaries of blatant nonconformity. This chapter reviews historical and present conceptualizations of antisocial personality from a broad perspective. Competing views concerning classification of the disorder are presented, and etiologic theories that attempt to account for its origins, concomitants, and progression are described. Empirical tests of assumptions derived from these theories are discussed, as are available assessment techniques and current approaches to treatment or behavior change.

Labeling of Antisocial Personality

Early nineteenth century accounts described individuals whose behaviors offended normative cultural standards and subgroup ethics yet lacked symptomatology easily classified as psychotically deranged or frankly delusional. Puzzled by persons who seemed to share disregard for conventional mores, observers of behavior disorders sought an explanation in the concept of moral deficiency. In 1801, Phillipe Pinel (1801/1962) identified “*manie sans delire*,” a disorder characterized by aberrant affect, proneness to impulsive rage, but no deficit in reasoning abilities. Also writing in the early nineteenth century, the American psychiatrist Benjamin Rush (1835) described individuals who were constitutionally deficient in moral faculties. These notions were elaborated by the English psychiatrist J. C. Prichard (1835) who popularized the label “moral insanity” and beliefs that antisocial behaviors resulted from organic or constitutional factors with poor prognosis for change. Early German contributions to the classification of behaviorally deviant individuals included references to “psychopathic inferiorities” (Koch, 1891) and typologies of “psychopathic personality” (Kraepelin, 1907/1923; Schneider, 1923).

Contemporary synonyms for the theoretical constructs “psychopathic inferiority” and “psychopathic personality” include “sociopathic personality,” “psychopathy,” and “antisocial personality disorder.” Each label has been a target of criticism and argument, although all refer to a disposition to antisocial behavior and social deviance resulting from personal deficiencies or psychological abnormalities. In the tradition of Ger-

man nosologists, Cleckley (1982) and Hare (1980) defined psychopaths as individuals who combined deviant personality traits and antisocial behaviors which were often criminal in their severity. Taking a different perspective, Partridge (1930) coined the term "sociopathic personality" to emphasize failure to conform to societal demands and pointed to the role of environmental or cultural factors in the etiology of behavioral deviance. During the 1960s and 1970s, psychosocial theorists and psychiatric clinicians preferred the term sociopathy (Robins, 1966; Vaillant, 1975), and "sociopathic personality" was included in the *Diagnostic and Statistical Manual* of the American Psychiatric Association (APA) in 1952 (DSM-I).

Most widely accepted in recent years has been the label *antisocial personality disorder* (ASPD), which appears in the last three editions of the DSM (APA, 1980, 1987, 1994). DSM-III and DSM-III-R criteria for ASPD differed significantly from those enumerated in DSM-II (APA, 1968). Whereas the 1968 diagnosis was composed largely of attributions regarding personality traits and inferences about underlying processes derived primarily from the Cleckley (1941) conceptualization of psychopathy, the newer criteria constituted a lengthy checklist of antisocial behaviors developed in large measure from criteria proposed by Robins (1966) that must be present in certain frequencies before and after age 15, conveying both the severity and chronicity of the disorder. References to irresponsibility, irritability, aggressiveness, impulsivity, and lack of remorse represented the few psychological characteristics on this list. Critics of the revised nomenclature and diagnostic criteria complained that though reliability was enhanced by criteria operationalization, the clinical meaning of the category had been compromised with definitive criteria both overly inclusive (Wulach, 1983) and exclusive (Hare, 1983; Millon, 1983).

Additionally, critics of the revised diagnostic criteria pointed to a neglect of the trait concepts of psychopathy and the complexity and length of diagnostic criteria (Alterman & Cacciola, 1991; Hare, Hart, & Harpur, 1991; Widiger & Corbitt, 1993; Widiger, Frances, Pincus, Davis, & First, 1991). It was suggested that clinicians often found traits of psychopathy (e.g., disregard for consequences of behavior, disregard for feelings of others) more relevant to ASPD than such DSM-III and DSM-III-R criteria as unemployment for six months and traveling from place to place without a

prearranged job or plans (Tennent, Tennent, Prins, & Bedford, 1990) and that DSM-III and DSM-III-R criteria resulted in overdiagnosis of ASPD in criminal and forensic settings (Hart & Hare, 1989). For example, Hart and Hare (1989) reported that 50% of the men remanded by courts to forensic units met the criteria for ASPD, whereas only 13% met the criteria for psychopathy, as defined by the Psychopathy Checklist (Hare, 1980). In contrast, Robins, Tipp, and Pryzbeck (1991) reviewed Epidemiological Catchment Area (ECA) data and found that only 47% of individuals who met the DSM-III ASPD criteria had significant arrest records and reported that adult symptoms of job troubles (94%), violence (85%), multiple moving traffic offenses (72%), and severe marital difficulties (67%) were more typical of ASPD than criminality. Further, Robins et al. (1991) observed an ASPD prevalence of 50% among prisoners within the ECA database but concluded that a 50% base rate for ASPD in a prison setting is consistent with theoretical and clinical explanations, thus refuting claims that DSM criteria equate ASPD with criminality.

Given this background, two important directions were considered during the development of DSM-IV and in designing and executing the DSM-IV field trial for ASPD: (1) greater emphasis on personality traits of psychopathy and (2) simplification of the criteria set without substantially changing the diagnosis (Widiger et al., 1996). With regard to the first proposal, the DSM-IV ASPD Field Trial considered two alternative criteria sets in addition to that of DSM-III-R: a modified version of the criteria for the Psychopathy Checklist-Revised (PCL-R: Hare, 1991) and research criteria for dissocial personality disorder as derived for the 10th edition of the International Classification of Diseases (ICD-10, World Health Organization, 1990). Thus, the reliability and concurrent validity of the DSM-III-R criteria, a ten-item version of the PCL-R criteria (Hare, Hart, & Harpur, 1991), and ICD-10 criteria were examined as sets and as individual items. The field trial also examined whether the DSM-III-R criteria set could be abbreviated without affecting the diagnosis (Frances, Pincus, Widiger, Davis, & First, 1990).

As a result of this and other field trials, as well as a review of the literature, data reanalyses, and the desire for compatibility with ICD-10 Diagnostic Criteria for Research (APA, 1994), the DSM-IV criteria for ASPD were modified from those of

DSM-III-R in the following manner. Two DSM-III-R items related to behaviors present since age 15 were deleted from ASPD criteria for DSM-IV: parental irresponsibility that included six subitems and failure to sustain a monogamous relationship for more than one year. Items related to failure to meet financial obligations and inconsistent work history were collapsed into a single item reflecting "consistent irresponsibility, as indicated by repeated failures to sustain consistent work behavior or honor financial obligations" (APA, 1994, p. 650). As a result of these deletions and consolidations, the threshold for diagnosis among the items that must be present since age 15 was changed from four of ten items (DSM-III-R) to three of seven items (DSM-IV).

The field trial did not provide conclusive support for the proposal to include traditional traits of psychopathy. Items from the psychopathy criteria set that correlated highest with clinician and interviewer ratings were those that most closely approximated DSM-III-R criteria, that is, early behavior problems and adult antisocial behavior, although in a prison site, items obtaining the highest correlations were those related to traditional conceptualizations of psychopathy, for example, lacks empathy, inflated and arrogant self-appraisal, glib, superficial charm. As a result, in the section on Associated Features and Disorders, DSM-IV specified that traditional conceptions of psychopathy (i.e., lack of empathy, inflated self-appraisal, superficial charm) "may be particularly distinguishing of Antisocial Personality Disorder in prison or forensic settings where criminal, delinquent, or aggressive acts are likely to be non-specific." (APA, 1994, p. 647).

DSM-IV specified that an individual must exhibit evidence of Conduct Disorder with onset before age 15 years to warrant ASPD diagnosis, whereas DSM-III-R requirements for ASPD included a listing of twelve antisocial behaviors, three of which must have been present before age 15. These behaviors were similar to the thirteen behaviors listed in the DSM-III-R Conduct Disorder standards, but an item describing breaking into someone else's house, building, or car was not included. DSM-IV Conduct Disorder criteria were expanded to include items relating to staying out at night and intimidating others, and the resulting fifteen items were grouped in four categories (aggression against people and animals, destruction of property, deceitfulness or theft, and serious

violations of rules). Consequently, DSM-IV Conduct Disorder diagnosis required the presence of at least three of the fifteen targeted behaviors in the past 12 months and at least one described in the past 6 months. DSM-IV also differentiated Conduct Disorder into Childhood-Onset Type (onset of at least one criterion prior to age 10) and Adolescent-Onset Type (absence of all criteria prior to age 10). Early onset was said to predict a less favorable prognosis and an increased risk in adult life for Antisocial Personality Disorder, as well as Substance-Related Disorders.

Despite the scientific rigor applied to developing DSM-IV ASPD criteria, the current conceptualization is not endorsed universally. Commenting that the traditional conceptualization of psychopathy is not adequately embodied in DSM-IV, Newman and Brinkley (1998) nevertheless concluded that "Cleckley's view of psychopathy as a psychological dysfunction that interferes with self-regulation and precludes the systematic pursuit of long-range personal goals represents an important clinical syndrome" (p. 5) and that continued research into psychopathy in its own right was necessary. This position has been emphasized by Hare (1996b) who referred to psychopathy as a clinical construct whose time has come. However, there is no end to the debate over the nature and meaning of the antisocial personality construct. For example, Blackburn (1988) argued that the DSM-III-R system combined the two universes of personal and social deviance (i.e., those of personality traits and specific acts). Explaining that the contributions of personality characteristics to antisocial behaviors can be unraveled only when the two are identified independently, Blackburn concluded that the diagnostic concept of antisocial personality is "little more than a moral judgment masquerading as a clinical diagnosis." Such arguments recapitulate earlier concerns that the antisocial diagnosis represents a "wastebasket" category limiting assessment of other psychopathology and attenuating treatment efforts (Lewis & Balla, 1975; Rotenberg, 1975), thus creating a "myth" (Karpman, 1948). Nevertheless, the disorder is certainly one of the most researched of the personality disorders (Widiger & Frances, 1985) and accounted for 37% of the personality disorder literature in 1975 and 25% in 1985 (Blashfield & McElroy, 1987). As Robins (1978) pointed out, if the notion of the antisocial personality is a myth, it is one told over and over among different groups of people in

different places at varying times—yet with surprising similarity.

Historical Clinical Perspective

One of the most comprehensive descriptions of the psychopath was offered by Hervey Cleckley in six editions of *The Mask of Sanity* (1941) and related articles (e.g., Cleckley, 1971). Lacking experimental support for his claims, Cleckley nevertheless laid a strong foundation for efforts to define the traits and behavior patterns of antisocial individuals. He outlined sixteen distinguishing characteristics:

Superficial charm and good intelligence; absence of delusions and other signs of irrational thinking; absence of “nervousness” or other psychoneurotic manifestations; unreliability; untruthfulness and insincerity; lack of remorse or shame; inadequately motivated antisocial behavior; poor judgment and failure to learn by experience; pathologic egocentricity and incapacity for love; general poverty in major affective reactions; specific loss of insight; unresponsiveness in general interpersonal relations; fantastic and uninviting behavior, with drink and without; suicide rarely carried out; sex life impersonal, trivial, and poorly integrated; failure to follow any life plan. (Cleckley, 1982, p. 204)

Cleckley (1971) pointed to clear-cut differences between psychopaths and “ordinary lawbreakers” and suggested that psychopaths lack such qualities as purposeful intent, consistency in avoiding consequences, and loyalty to the members of a group. He emphasized that deficits in the experience of emotionality and attachment underlie their callous interpersonal behaviors, coined the term “semantic dementia” to capture their inability to react appropriately to verbal content that typically elicits emotional responses, and characterized their seemingly normal outward appearance as the “mask of sanity.” These and other descriptions (McCord & McCord, 1964) were prototypical of the DSM-II (1968) outline of underlying personality traits considered definitive of the antisocial personality.

Vaillant (1975) proposed a more optimistic view of psychopathy and argued that the Cleckley characterization represented a mythical beast. Using the histories of four narcotic addicts, he illustrated the underlying dynamics associated with what he called sociopathy and thus the “humanness” and treatability of individuals so classified. Whereas sociopaths were described as having an apparent absence of anxiety and depression and an inability to learn, Vaillant reasoned that they are more ado-

lescent than ineducable, concealing negative affect by such immature defenses as conversion symptoms, acting out, passive-aggressiveness, and projection. In emphasizing unhealthy defense mechanisms, this view was reminiscent of Thorne’s (1959) conceptualization of sociopathy as a lifestyle disorder in which initially normal persons are conditioned to depend upon maladaptive mechanisms for need gratification. Despite this focus on learning or conditioning and affirmation of behavior reversibility, Thorne’s view of sociopathy was decidedly negative and included references to an ever-downward spiral of self-hate, alcohol and drug abuse, physical and mental deterioration, and ultimate despair.

During the past four decades, clinical impressions of the psychopathy construct have been subjected to experimental scrutiny. Foremost among these researchers are Robert Hare and his colleagues (Hare, 1978, 1996b; Harpur & Hare, 1994; Hare & Hart, 1993; Harpur, Hare, & Hakstian, 1989; Hart & Hare, 1997; Hemphill, Hare, & Wong, 1998)—who, persuaded by the veracity of Cleckley’s clinical description of the entity, attempted to identify the psychological deficits associated with the disorder. Using global ratings of personality traits and behaviors presumed to be characteristic of psychopathy, Hare and his colleagues accumulated a database that describes the Cleckley psychopath primarily among white, male criminal inmates. An array of studies has concentrated in the areas of psychophysiology and autonomic arousal (Hare, 1982; Hare, Frazelle, & Cox, 1978; Williamson, Harpur, & Hare, 1991), information processing and language (Forth & Hare, 1989; Hare & Jutai, 1988; Intrator et al., 1997; Jutai, Hare, & Connolly, 1987; Louth, Williamson, Alpert, Pouget, & Hare, 1998), learning and self-regulatory performances (Hare, 1965, 1984; Hart, Forth, & Hare, 1990), and analysis of criminal behaviors and recidivism (Hart & Hare, 1997; Hart, Kropp, & Hare, 1988; Hemphill et al., 1998). Summarizing much of this work in a series of manuscripts that describe a two-factor conceptualization of psychopathy, Hare and colleagues discussed psychopathy as a unitary clinical syndrome consisting of telltale personality traits, selfish interpersonal style, and shallow affect, as well as a clustering of unstable and antisocial behaviors reflecting social deviance (Harpur et al., 1989; Hart & Hare, 1997).

Although much of the recent research has explored fundamental deficits among psychopaths as

defined by personality and behavioral traits, the criteria included in the DSM system since 1980 (DSM-III, 1980; DSM-III-R, 1987; DSM-IV, 1994) draw attention to demonstrably nonconforming, antisocial, and interpersonally disregarding behaviors that are consistent over time. Based in part on the research criteria developed by Spitzer, Endicott, and Robins (1975), diagnostic labeling requires a history of continuous and chronic antisocial behavior in which the rights of others are violated. This conceptualization reflects the well-established association between childhood and adult antisocial behaviors (Bardone, Moffitt, Caspi, & Dickson, 1996; Farrington & West, 1990; Loeber & Dishion, 1983; Robins, 1966; Wells & Forehand, 1985). And as observed earlier, diagnosis of antisocial personality disorder in DSM-III through DSM-IV has required evidence of conduct-disordered behaviors before age 15.

Unlike characterizations of psychopathy that emphasized deficient capacity for genuine human emotion, the DSM system has allowed for significant affective involvement in individuals diagnosed as antisocial by including possibly associated features of dysphoria, such as complaints of tension, inability to tolerate boredom, and depressed mood. Although the disorder has been described as chronic, it has been noted in the DSM-IV that symptom expression may remit with increasing age, particularly by the fourth decade of life, and although such remission tends to be observed primarily with respect to involvement in criminal behaviors, decreases may occur across the full range of antisocial behaviors. Thus, these criteria may be regarded as less pessimistic and significantly more objective than both earlier personality descriptions and the DSM-II (APA, 1968). At the same time, critics have argued that the quest for reliability has resulted in abandoning the personality construct of psychopathy or antisocial personality well known to clinicians and a discrepancy between the disorder and the people it is used to label (Hare, 1996b; Newman & Brinkley, 1998; Widiger & Frances, 1985).

ASPD Prevalence and Associated Disorders

ASPD diagnosis, defined by a pattern of continuous and chronic antisocial behaviors that are initiated before age 15, persist into adulthood, and disrupt interpersonal and work performances, is

often synonymous with criminality. Wulach (1983) estimated that the changes in diagnostic criteria in the 1980s increased ASPD prevalence among criminals by 250%, and Hare (1976) and Hart and Hare (1989) found DSM-III ASPD prevalences of 76% in a male prison sample and 50% in a sample of men remanded to a forensic unit. Similarly, Robins et al. (1991) reported a DSM-III-R prevalence of ASPD among prisoners of 50%, although these investigators considered a base rate of 50% in a prison setting to be consistent with theoretical and clinical explanations. Antisocial psychopathology has traditionally been elevated among samples of opiate addicts (Alterman et al., 1998; Sutker, 1971) and alcoholics (Morgenstern, Langenbucher, Labouvie, & Miller, 1997; Schuckit, 1973), and researchers have reported strong associations between diagnoses of ASPD and substance abuse categories (Gerstley, Alterman, McLellan, & Woody, 1990; Koenigsberg, Kaplan, Gilmore, & Cooper, 1985). For example, Kosten, Rounsaville, and Kleber (1982) found that roughly 55% of opiate addicts met criteria for present and lifetime ASPD, and Hesselbrock, Meyer, and Keener (1985) cited a rate of 49% among hospitalized alcoholics.

More recent estimates of ASPD prevalence among samples of substance abusers have been lower but nevertheless disturbingly high. Kidorf, Brooner, King, and Chutuape (1996) found that 39% of opioid-dependent outpatients met criteria for ASPD, and Alterman et al. (1998) reported a prevalence of ASPD of 33% among a sample of men undergoing methadone maintenance treatment. Ball, Tennen, Poling, Kranzler, and Rounsaville (1997) found an ASPD rate of 32% among a mixed gender sample receiving treatment for various types of substance abuse (e.g., cocaine, opiates, alcohol), and Morgenstern et al. (1997) sampled a group comprised predominantly of women (56%) undergoing treatment primarily for alcohol abuse/dependence, although high rates of concurrent drug use (approximately 50%) were observed, and reported an ASPD prevalence of 23%, including 26% among men and 9% among women. Mueser et al. (1997) assessed ASPD in a community-based sample of dual-diagnosis patients (i.e., those who met DSM-III-R criteria for alcohol or substance use disorder in combination with a DSM-III-R schizophrenia or schizoaffective disorder diagnosis) and found that 22% met criteria for ASPD. Smith and Newman (1990) evaluated the prevalence of DSM-III substance use disorders

among a sample of incarcerated psychopaths and reported that 93% met criteria for alcohol dependence or abuse, 74% for dependence or abuse of a drug other than alcohol, and 26% for opioid dependence or abuse.

When prevalence data are collected for ASPD among hospitalized psychiatric patients and in community samples, rates are considerably lower than among those predominantly nonconforming samples in correctional facilities and alcohol and drug rehabilitation programs. Dahl (1986) reported that 14% of 18- to 40-year-old consecutive psychiatric admissions in Oslo, Norway were assigned diagnoses of ASPD, accounting for roughly 18% of personality disorder labels. Studying hospital outpatients, Kass, Skodol, Charles, Spitzer, and Williams (1985) reported that 2% met full and 4% fulfilled partial DSM-III ASPD criteria. Approximately 4% of adult first admissions to public inpatient and outpatient mental health facilities were assigned diagnoses of antisocial personality disorder (Weiss, Davis, Hedlund, & Cho, 1983). Looking at data generated from the community at large, Robins et al. (1984) found that lifetime ASPD prevalences rates varied from 3 to 5% in a community sample using the National Institute of Mental Health (NIMH) Diagnostic Interview Schedule (DIS; Robins, Helzer, Croughan, & Ratcliff, 1981); ASPD was documented in one of forty persons, thereby suggesting a disorder more common than schizophrenia. Similarly, Zimmerman and Coryell (1989) showed that ASPD was the most common disorder among first-degree relatives of normal controls and psychiatric patients (with a rate of 3.3%), and Helzer and Pryzbeck (1988) reported a lifetime prevalence rate of 2.5% in the general population using the five-site ECA data. Newman, Moffitt, Caspi, and Silva (1998) followed a New Zealand birth cohort and reported a DIS-derived DSM-III-R prevalence of ASPD at age 21 of 3.2%, although 74.2% of those assigned an ASPD diagnosis met criteria for a concurrent Axis I disorder. Berman, Fallon, and Coccaro (1998) assessed a community-recruited sample of research volunteers and found a DSM-III-R ASPD prevalence of 5.1%, and Barry, Fleming, Manwell, & Copeland (1997) surveyed 1944 outpatients in the offices of sixty-four primary care physicians and reported that 8% of men and 3% of women met DSM-III-R criteria for ASPD.

Diagnoses of ASPD are more common among men than women across all samples investigated (Blazer et al., 1985; Dahl, 1986; Kass, Spitzer, &

Williams, 1983; Robins et al., 1984). Other demographic correlates of ASPD include younger age (Blazer et al., 1985; Robins et al., 1984; Zimmerman & Coryell, 1989), less education (Blazer et al., 1985; Morey & Ochoa, 1989), and lower socioeconomic status (Robins et al., 1984). Few questions have been raised about such characteristics as age and socioeconomic class, but controversy has arisen over explanations for gender differences. The possibilities of stereotyping and sex biases in clinical diagnosis and labeling, sex differences resulting from acculturation experiences, and/or actual sex differences attributed to other factors have been discussed. Kaplan (1983) argued that masculine assumptions about what behaviors are healthy and appropriate influence the behaviors of women and men as well as clinical impressions regarding these behaviors. Kass et al. (1983) described the distribution of DSM-III personality disorder diagnoses in two groups of adult patients and found sex differences in the diagnosis of histrionic and dependent personality disorders (more common among women) and ASPD (more common among men). Nevertheless, they maintained that there were no greater tendencies to label women personality disordered than men and concluded that there was no support for Kaplan's hypothesis of sex bias in DSM-III criteria. Their study, however, neglected Kaplan's charge that sex role stereotyping and societal judgments influence both the behaviors and their perception in the eyes of clinicians.

In a careful and comprehensive test of the hypothesis of sex bias in the diagnosis of personality disorders, Ford and Widiger (1989) assessed bias and base rate explanations, as well as the influence of case presentation ambiguity, clinician gender, and the specificity of individual criteria on diagnostic assignments, using ASPD and Histrionic Personality Disorder (HPD) descriptions. Results indicated that psychologist judges more often failed to diagnose HPD among men than women and ASPD among female compared to male patients and that antisocial female patients were more likely to be diagnosed as HPD than ASPD. Ford and Widiger (1989) minimized the significance of their finding that female psychologists' antisocial ratings for the antisocial case history were not affected by the patient's sex compared to those generated by the male psychologists. They concluded that though the individual criteria may not be intrinsically sex-biased, final diagnoses were influenced by stereotypic expectations elic-

ited by conceptualizations of the disorders themselves.

Clinical meaningfulness or validity, diagnostic reliability, multiple diagnoses, and diagnostic overlap are among the problems highlighted in the literature on personality disorders generally and ASPD specifically (Widiger & Frances, 1985; Jordan, Swartz, George, Woodbury, & Blazer, 1989). The symptoms of one personality disorder, such as disturbed interpersonal relationships, antisocial behaviors, and impulsivity, may represent defining or associated features of other Axis I and II disorders, and strong associations have been observed between certain personality disorders and such Axis I disorders as alcohol and drug abuse and dependence (Grande, Wolf, Schubert, Patterson, & Brocco, 1984). Multiple diagnoses are the likely inevitable consequence of polythetic criteria sets in classification systems where category membership is heterogeneous and boundaries overlap. Therefore, considerable complexity exists in attempts to identify prevalence rates, understand disorder etiologies, and forecast outcomes and treatment responses (Widiger & Frances, 1985). It is important, then, to consider some of the ways in which the diagnosis of ASPD interfaces with the labeling of other psychopathology.

Overlap within Personality Disorders. A growing literature reflects considerable overlap among the personality disorders (Morey, 1988; Pope, Jonas, Hudson, Cohen, & Gunderson, 1983; Widiger & Corbitt, 1997; Widiger, Frances, Warner, & Bluhm, 1986) as well as covariation among these diagnoses. Widiger, Frances, Pincus, Davis, and First (1991) reported that diagnostic interviewing yielded an average of four personality disorders per patient, and Widiger and Corbitt (1997) reported that in clinical settings, most individuals who meet criteria for ASPD also meet criteria for at least one other personality disorder. Morgenstern et al. (1997) found that most individuals in a mixed-gender group of substance abusers who met criteria for one personality disorder also satisfied criteria for at least two personality disorders. Berman et al. (1998) reported that 29% of a community-recruited sample of research volunteers met criteria for a personality disorder and that these individuals were assigned an average of 1.55 personality disorder diagnoses. Among a sample of cocaine-dependent outpatients, 48% met criteria for at least one personality disorder diagnosis, and 18% met criteria for two or more. Of those assigned a personality diagnosis, 65%

were diagnosed with a Cluster B personality disorder, and antisocial and borderline personality disorders were the most common (Barber et al., 1996).

The overlap among personality disorders is not surprising in view of the DSM aggregation of personality disorders into clusters, with antisocial, borderline, histrionic, and narcissistic personality disorders forming a constellation that shares such common features as impulsive acting out, unpredictable behaviors, and dramatic presentation. ASPD diagnosis is most often associated with those of borderline, histrionic, narcissistic, and, before DSM-IV, passive-aggressive personality disorders. Pope et al. (1983) found that it was difficult to separate antisocial and borderline personality disorders in men and borderline and histrionic personality disorders in women and suggested that the clustering of borderline, histrionic, and antisocial disorders may reflect a true lack of differentiation. Interviewing psychiatric inpatients for whom personality disorders were the principal treatment issue, Widiger et al. (1986) discovered a particularly strong association between ASPD and borderline, passive-aggressive, histrionic, and schizotypal personality disorders. Widiger and Corbitt (1997) reviewed six studies that assessed Axis II psychopathology in general clinical populations using semistructured interviews and reported high median rates of comorbidity of ASPD and borderline personality disorder (75%), histrionic personality disorder (56%), passive-aggressive personality disorder (36%), paranoid personality disorder (31%), and narcissistic personality disorder (28%).

After reviewing thirteen studies that assessed comorbidity of ASPD and borderline personality disorder, Zanarini and Gunderson (1997) concluded that in samples of individuals with criterion-defined borderline personality disorder, rates of co-occurring ASPD range from 0–60%, with most falling between 10 and 25%, whereas, in samples of nonpsychotic individuals and with study focus solely on rates of Axis II comorbidity, a substantially smaller percentage of patients who met criteria for borderline personality disorder also met criteria for ASPD (i.e., mean = 22.5%, range = 0–68%) than patients who met criteria for ASPD and also met criteria for borderline personality disorder (i.e., mean = 50.25%, range = 0–80%). At the same time, prototypical categorization allows for covariation, and Morey (1988) showed that features of the narcissistic personality disorder

combined with nonaggressive antisocial features formed a distinct cluster reminiscent of the Cleckley concept of psychopathy. Similarly, Blashfield, Sprock, Pinkston, and Hodgkin (1985), using multidimensional scaling to study relationships among the eleven DSM-III PD diagnoses, suggested a circumplex ordering, with antisocial personality relatively independent from other diagnoses.

The association between antisocial and histrionic personality disorders has sparked recurring speculation that hysteria and antisocial personalities constitute sex-typed versions of the same condition. Cloninger, Reich, and Guze (1975) proposed a multifactorial model in which male sociopathy, female hysteria, and female sociopathy constitute an increasingly severe expression of a shared liability. Reviving the question of whether antisocial personality disorder, somatization disorder or hysteria, and histrionic personality disorder fundamentally constitute the same clinical entity, Lilienfeld, Van Valkenburg, Lartz, and Akiskal (1986) conducted diagnostic interviews among 250 patients sampled from psychiatric care settings. They confirmed reports of a positive relationship between antisocial personality and somatization disorders within individuals of both sexes as well as a strong association of antisocial and histrionic personality, with the latter appearing to moderate the relationship between antisocial personality and somatization disorder. Similarly, Spalt (1980) found close associations between antisocial personality and hysteria in women, but this was not the case for men. It has also been observed that female hysterics and male sociopaths tend to marry each other (Woerner & Guze, 1968) and beget hyperactive children (Morrison & Stewart, 1971) who grow up to be sociopathic (Satterfield, 1978) or hysteric (Cloninger & Guze, 1975).

Whether psychopathy or ASPD and hysteria or histrionic disorder constitute sex-typed expression of the same underlying substrate involves analyzing several complicated hypotheses within the changing climate of psychiatric and psychological assessment. As described before, there are sex-related biases in the conceptualization of antisocial and histrionic personality disorders that may operate differently, depending on the diagnostician's sex (Ford & Widiger, 1989). Moreover, the sociocultural standards for socially appropriate and conforming behaviors may be stronger for women; thus women may depart from societal

constraints less frequently because of cultural pressures. This reasoning is supported by two lines of research. Heilbrun and Gottfried (1988) tested the notion that feminine constraints on physical aggression may decrease with the erosion of traditional sex-role commitments associated with the rise of the feminist movement. They found that although antisociality proved to be a significant predictor of more dangerous criminal behavior from 1965 to 1971 among incarcerated women, this predictiveness was lost for the period 1980–1985, reflecting perhaps lessening of prior role restraints. Second, the literature suggests that for women to display criminality, the congenital predisposition to criminal behavior has to be more severe than for men (Sigvardsson, Cloninger, Bohman, & von Knorring, 1982).

If antisocial behaviors result from stereotyped perceptions and/or less demonstrative display, they may be minimized, overlooked, or mislabeled among women, whereas characteristics defined traditionally as histrionic may be emphasized. Conversely, antisocial behaviors may be more readily recognized among men because such deviance is seen as more male role congruent. Extending this logic, it might be conjectured that women express social nonconformity through different behavioral means, perhaps greater emphasis on sexual promiscuity, neglect of parenting duties, crimes which go undetected, and alcohol and drug abuse. Some years ago, Hammen and Padesky (1977) showed that men and women differed in the behavioral expression of depression. It is conceivable that sociocultural influences lead to sex-typed expression of social deviance as well as difficulties in identifying ASPD among women. Few studies have explored possible differences between male and female patients in measures of personality traits considered antisocial or on behavioral indices of deviance. It has been shown, however, that antisocial women selected more negative adjective self-descriptors than their male antisocial counterparts (Sutker, DeSanto, & Allain, 1985), perhaps reflecting greater internalization of societal prejudice toward deviant or nonconforming behaviors.

Association with Axis I Disorders

Interrelationships among the major psychiatric illnesses defined on Axis I and those that reflect

“inflexible and maladaptive traits” listed on Axis II have constituted a focus for clinical speculation and research activity since the multiaxial classification system was introduced in 1980. Conducting a comprehensive study of the association of personality disorders and Axis I diagnoses among 2462 patients referred for psychiatric evaluation, Koenigsberg et al. (1985) found high overlap between diagnoses of substance abuse and Axis II disorders. Comorbidity was particularly strong for the substance use disorders, categories traditionally identified with neuroses such as the anxiety-based and somatoform disorders, phobic and panic disorders, and dysthymia and atypical depression. Among patients assigned substance use diagnoses, borderline and antisocial were the most common personality disorders, although borderline disorder was distributed across Axis I diagnoses and antisocial disorder clustered strongly with substance abuse. Consistent with these findings, Malow, West, Williams, and Sutker (1989) reported that antisocial and borderline personality disorders were the most prevalent Axis II diagnoses in a drug-abusing sample, and these results were replicated among mixed substance abusers (Ball et al., 1997) and cocaine-dependent outpatients (Barber et al., 1996), as well as in a sample undergoing treatment for alcohol abuse (Morgentstern et al., 1997).

The association between antisocial personality and the substance use disorders has sparked theoretical debate and ongoing research interest. Finding that diagnoses of alcoholism, antisocial personality, and drug dependence form one of two primary psychopathological clusters in a study of DIS-generated diagnoses among psychiatric inpatients, Wolf et al. (1988) concluded that these three disorders constitute a relatively homogeneous triad that is independent of other diagnoses. Strong diagnostic interactions between alcoholism and antisocial personality disorders have been reported in patients referred for psychiatric consultation (Lewis, Rice, & Helzer, 1983), a community sample of black men (Lewis, Robins, & Rice, 1985), and adult male and female adoptees (Cadoret, O’Gorman, Troughton, & Heywood, 1985; Cadoret, Troughton, Bagford, & Woodworth, 1990). Drake and Vaillant (1985, 1988) also pointed to a high degree of association between diagnoses of personality disorders and alcoholism in community samples and called attention to complications of dysphoria among men with personality

disorders; Vaillant and Hiller-Sturmhoefer (1996) summarized longitudinal studies of 268 male college students and 456 inner city 11- to 16-year-old male adolescents selected from 1934 to 1944 and identified co-occurring sociopathy, along with ethnicity and family history of alcoholism, as risk factors for alcoholism.

Koenigsberg et al. (1985) found that borderline, dependent, schizotypal, passive-aggressive, and mixed personality disorders were common among anxiety- and depression-based disorders identified traditionally as neuroses, but antisocial personality disorder was not. However, data derived from studies of comorbidity of ASPD and posttraumatic stress disorder (PTSD), considered an anxiety-based disorder, ranged from 3% in older Vietnam, Korean, and World War II (WWII) veterans (Davidson, Swartz, Storck, Krishnan, & Hammett, 1985), to 10% in an outpatient sample of Vietnam veterans (Uddo-Crane, Thompson, & Sutker, 1991), to 14% among Vietnam veteran outreach clients (Green, Lindy, & Grace, 1985), and to 64% in an outpatient sample of primarily Vietnam veterans (Sierles, Chen, Messing, Besyner, & Taylor, 1986). Although a nonconforming, antisocial flair has often been considered complementary if not integral to diagnosis of PTSD, especially among younger men, rates of ASPD are remarkably low among some samples of patients who suffer anxiety-based PTSD, especially in view of the consistently high rates of substance abuse disorders that often overlap with ASPD. For example, Keane and Wolfe (1990) found that 70% of treatment-seeking PTSD patients met criteria for alcohol abuse or dependence, 42% for drug abuse or dependence, and only 26% for ASPD or mixed personality disorder with antisocial features.

Typologies and the Psychopathy Construct

Recognition of the heterogeneity among antisocial individuals is not of recent origin or unique to disagreements centered around defining criteria. Kraepelin employed the term psychopathic personality in his textbook *Lehrbuch der Psychiatrie* (1907/1923) and outlined four types of psychopathic personalities that were characterized in varying degrees by antisocial behaviors and traits. Presenting a typology of ten overlapping psychopathic or deviant personalities, Schneider (1923,

1958) described several clinical varieties that might lead to antisocial behavior. In his review of the concept of psychopathic personality, Lykken (1994) characterized the psychopathic personality as a "family of disorders" comprising four subtypes that may then be subdivided. He described dissociated psychopaths whose personality deviations are implied by adherence to the values or code of their predatory, criminal, or other social group, neurotic or impulsive characters in whom antisocial behavior constitutes neurotic acting out or an unconscious need for punishment, antisocial individuals whose behaviors are influenced by organic dysfunction or abnormality in inhibitory control, and primary or idiopathic psychopaths. Lykken (1994) further distinguished two subtypes of primary psychopaths: those whose empathy for others is lessened because of exposure to human suffering and the Cleckley psychopath.

Simple classifications of psychopathic or antisocial personality are based on the presumption of bimodal-like clusterings of individuals using discriminating dimensional constructs such as anxiety (Hare, 1970; Lykken, 1957; Newman & Schmidt, 1998), social withdrawal (Blackburn & Lee-Evans, 1985), and intellectual sophistication (Arieti, 1967). Lykken (1957) distinguished primary and secondary psychopaths on the basis of anxiety, and Weiss et al. (1983) identified a subgroup of "dysphoric psychopaths" who constituted perhaps as many as one-fourth of patients assigned diagnoses of antisocial personality disorder and were characterized by depression, anxiety, difficulties in intellectual functioning, and irritability, in addition to defining antisocial features. Arieti (1967) described simple and complex types differentiated by intelligence level, and the notion that cognitive variables, particularly intelligence, moderate antisocial behaviors, and violence specifically has been a topic for investigation. Heilbrun (1982) reported that psychopathic criminals with low intelligence were impaired in impulse control and empathy compared to psychopathic criminals with greater intelligence and that both empathy and impulse control could contribute to violence. Expanding their model to include Blackburn's social withdrawal variable (Blackburn & Lee-Evans, 1985), Heilbrun and Heilbrun (1985) found that low intelligence predicted dangerousness among psychopathic criminals regardless of situation, whereas social withdrawal enhanced the

prediction of dangerousness within prison, but not in community or parole situations.

A related line of research has attempted to isolate factors that differentiate children at high and low risk for delinquency. Testing the hypothesis that high intelligence may protect individuals at high risk for antisocial outcome, Kandel et al. (1988) showed that high intelligence diminished the risk of criminal behavior in men. Addressing methodological weaknesses in the Kandel et al. (1988) retrospective effort, White, Moffitt, and Silva (1989) replicated findings showing the protective effects of intelligence among male, and to a lesser extent, female youth at risk for delinquency. These investigators reported that average or above average intelligence was associated with less serious and chronic delinquent behaviors among groups of boys and girls at low and high risk. However, high-risk boys may require more sophisticated intellectual functioning than low-risk boys to remain free of delinquent involvement completely. Lynam, Moffitt, and Stouthamer (1993) showed that the protective function of IQ is independent of social status and education, and not due merely to lower intelligence increasing the probability of getting caught (Moffitt & Silva, 1988). Caspi and Moffitt (1995) concluded that perhaps the best focus of study to explain the continuity or stability of antisocial behavior is compromised cognitive ability.

Psychopaths can also be differentiated using such outcome variables as degree of adaptiveness or capacity to avoid negative consequences. In this context, the more positive personal features attributed to psychopaths are relevant. For example, psychopaths have been portrayed as adroit social manipulators (Cleckley, 1982), persistent goal-seekers (Buss, 1966), intellectually capable and observant individuals (Sutker, Moan, & Allain, 1974), survivors in American society (Smith, 1978), and the most adept of human "cheaters" in reproductive strategy (MacMillan & Kofoed, 1984). Clearly, some psychopaths function more adequately in society than others, suggesting a continuum of adaptiveness or gross subdivisions into successful and unsuccessful subtypes. Several research studies have explored the characteristics of these more adaptive psychopaths.

Widom (1977) used newspaper advertisements to identify male psychopaths who were relatively successful in avoiding the negative consequences

of antisocial behaviors, and Sutker and Allain (1983) employed MMPI-defined criteria to isolate an even more successful antisocial subgroup among male medical students. In this study, students labeled adaptive sociopaths and normals were compared on measures of cognitive control, planning and organization, interpersonal functioning, and sensation seeking. Adaptive sociopaths produced more qualitative errors on the Porteus Mazes, scored higher on Zuckerman's measure of Experience Seeking (1972) and lower on the California Psychological Inventory (CPI) Scales Socialization (*So*) and Self-Control (*Sc*), reported more arrests, and admitted tendencies to act on impulse. For sociopaths to contemplate an action, deviant or not, suggested greater probability for behavioral execution. This combination of lower self-control, less inhibitory regulation, and greater interest in experience seeking was predictive of greater behavioral deviance among this intellectually sophisticated sample of young adults.

Dichotomous subtypings have been important in conceptualizations of psychopathy, but more complex formulations are required to refine descriptions of prototypical and associated varieties among clinical samples and to characterize disorder expression and severity. Questions of typology have been approached with factor analytic strategies used to define personality traits and behaviors thought to represent psychopathy (Hare et al., 1990; Harpur et al., 1989; Harpur, Hakstian, & Hare, 1988) and to describe the full spectrum of antisocial psychopathology. This latter approach is illustrated by the work of Jordan et al. (1989) who applied grade of membership analysis to identify symptom clusters of antisocial personality and related psychiatric disorders. Results showed seven pure clusters, including two that resembled the DSM-III portrait of ASPD and were strongly associated with DIS-generated diagnoses of ASPD. Two pure types emerged that consisted of alcohol abuse/dependence and recreational illicit drug use symptoms, and two types were identified predominantly among women. Of these, one was characterized by marital instability, other domestic problems, and employment and interpersonal difficulties, and the second was defined by multiple symptoms of depression and selected features of other Axis I disorders. Serving as a comparison group for the other types, the seventh cluster reflected no symptomatology.

These more complex factor and cluster analytic approaches suggest ways to conceptualize predictive and outcome variables relevant to psychopathy, taking into account both person and environment factors. Because a dimensional, prototype model of classification tolerates heterogeneity, there will be variations on the prototypic example, and individuals can be rated on diverse dimensions that transcend simple categorization or bimodal clustering. Psychopathy may best be conceptualized as a cluster of clusters in which the fundamental feature is that of nonconforming or antisocial behaviors persisting over time and usually leading to unfortunate circumstances. Although researchers and clinicians are accustomed to working with the extreme subsets of antisocial individuals or those ranking high or low on various dimensional variables, there appear to be persons whose behaviors approximate the antisocial model but fall short of full expression. There are also factors that operate to protect individuals at genetic or environmental risk for ASPD. An important research task is to guide conceptualizations of cognitive, affective, and behavioral features that are seen as aggregating to create the psychopathy construct and to differentiate subtypes predictive of specific types of antisocial outcomes.

Etiologic Factors and Antisocial Personality

There has been compelling recognition of the multidetermined nature of antisocial behaviors, including the contributions of biological, psychological, and social variables. Questions of nature versus nurture are less pivotal than those spurring studies that describe the interplay between genetic and environmental variables in predicting antisocial behaviors and gender/sex-related differences in antisocial expression. Cloninger, Reich, and Guze (1978) emphasized that any plausible model of the transmission of antisocial behavior disorders must allow for genetic and environmental factors without making unwarranted assumptions about their relative importance, and the model outlined by Reich, Cloninger, and Guze (1975) assumed that pathogenetic factors relevant to specific disorders are multiple and additive. In search of biological and psychological factors that contribute to antisocial behaviors, investigators

have launched twin, family, and adoption studies, the latter being best suited to separating genetic and biological effects from those attributed to social learning and the sociocultural context.

Genetic and Genetic–Environment Factors

With few exceptions, evidence from twin (Christiansen, 1977; DiLalla, Carey, Gottesman, & Bouchard, 1996; Slutske et al., 1997; van den Oord, Verhulst, & Boomsma, 1996), family (Cloninger et al., 1978), adoption (Mednick, Gabrielli, & Hutchings, 1984), and combined, for example, twin-sibling, (O'Connor, McGuire, Reiss, Hetherington, & Plomin, 1998) research has supported the contributions of genetic and congenital factors in transmitting antisocial behaviors and related personality correlates. Reviewing results of concordant studies, Eysenck and Eysenck (1978) concluded that 55% of monozygous (MZ) twins were concordant for criminal conduct, as opposed to 13% of dizygous (DZ) twins. Cloninger et al. (1978) pointed to concordance rates as high as .70 for MZ twins and .28 for DZ twins. Centerwall and Robinette (1989) searched for a genetic component to antisocial behavior by studying concordance rates for dishonorable discharge among 15,294 pairs of White male twins, both of whom served in the U.S. military. Results indicated greater pairwise concordance for dishonorable discharge in monozygous versus dizygous pairs; the risk of such discharge was fifty-six times more likely among monozygous co-twin dishonorably discharged veterans than among dizygous twins in general. Although these researchers recognized distinctions between dishonorable discharge and antisocial personality, they concluded that results added weight to the presumed importance of genetic contributions to antisocial behavior. More recently, Slutske et al. (1997) examined retrospective reports of conduct disorder in a community-based Australian sample of 2682 twin pairs and reported concordances of .53 for MZ male twins, .37 for DZ male twins, .30 for female MZ twins, and .18 for DZ female twins. Their best-fitting model yielded variance estimates for additive genetic influences of 71%.

Examining prevalences within family units, Cloninger et al. (1978) reported data obtained for 227 first-degree relatives of three types of probands (sociopathic men, sociopathic women, and

hysterical women) and 800 subjects in the general population (see Cloninger et al., 1975). Hysteria and sociopathy were more frequently found among the relatives of all three proband types than in the general population, and data were consistent with the notion that hysteria in women is a more prevalent, less deviant manifestation of the same process that causes sociopathy. Cloninger et al. (1978) also concluded that alcoholism and sociopathy may be genetically independent and cited findings that adult sons of Danish alcoholics who were adopted away in infancy showed increased frequency of alcoholism but not antisocial personality, whereas an increased proportion of psychopaths and criminals, but not of alcoholics and drug dependents, was documented among the adopted-away offspring of psychopathic parents.

Carey and Goldman (1997) pointed out that many potential family environment factors, for example, single-parent household, poverty, and housing density, may impact the expression of similar antisocial behaviors among siblings or other relatives and that antisocial behaviors such as aggression can be induced experimentally in the laboratory using social learning techniques (Bandura & Walters, 1959). Hence, they suggested that family studies may not be as appropriate in determining the role of genetics in antisocial behavior as investigating twins, separated relatives, and adoptive relatives. U. S., Danish, and Swedish studies of adopted children of criminals, alcoholics, and otherwise antisocial parents separated at birth suggest significantly increased antisocial behaviors among adoptees with antisocial or criminal backgrounds, but not necessarily parental alcoholism. These investigations revealed increased criminality and personality disorders among the biological, but not adoptive, relatives of psychopathic or criminal probands compared to relatives of controls (Schulsinger, 1972) and pointed to the interaction between genetic factors and the influence of gender and infancy conditions on adult outcomes (Crowe, 1972, 1974). Specificity of inheritance, that is, different heritabilities, of antisocial behaviors such as criminality and alcohol abuse has been reported by Cadoret et al. (1985); Bohman, Cloninger, Sigvardsson, and von Knorring (1982); Crowe (1972, 1974), and Cloninger, Sigvardsson, Bohman, and von Knorring (1982) showed that both genetic and postnatal factors could be sufficient to predispose to criminality, but that specific combinations of gene–environment

antecedents may modify the risk factors such as low social status and unstable preadoptive placements may modify the risk factors.

Using data derived from 913 women and 862 men in the Stockholm Adoption Study, Sigvardsson et al. (1982) explored sex differences in criminality and alcoholism, such postnatal antecedents to criminality as prolonged institutional care and urban adoptive placement, and severity of antisocial predisposition. Although the genetic antecedents of petty criminality were qualitatively similar between the sexes, criminal women had more biological parents with petty criminality, and hence a stronger genetic predisposition, than their male counterparts. These researchers concluded that the deviant predisposition must be greater in women than in men to manifest adolescent social maladjustment and adult antisocial personality or petty criminality. Additionally, postnatal antecedents differed according to sex. Results were interpreted as emphasizing the complex pathogenesis of criminality with genetic heterogeneity, sex specificity, heterogeneity in postnatal antecedents, and non-additive gene-environment interaction.

Cadore and Cain (1980, 1981) used multiple regression analyses to predict the number of antisocial behaviors in 246 adoptees, a sample that included children and adolescents adopted from psychiatrically disordered parents and matched controls with no evidence of family disorder. Findings pointed to a genetic predisposition to antisocial behavior in offspring who had alcoholic and antisocial biological family members and no apparent sex differences in the biological predictors of antisocial behavior. However, male and female subjects differed in susceptibility to adverse environmental factors such as psychiatric illness in an adoptive parent, adoptive parental divorce, and discontinuous mothering; environmental variables were more predictive of antisocial behavior in male than female participants. Results suggested that men may have a lower threshold for developing antisocial personality in the presence of predisposing environmental factors.

Reporting data derived from a register of 14,427 nonfamilial male adoptions in Denmark, Mednick et al. (1984) described a strong relationship between biological parental criminality and adopted-son criminality, an association that was enhanced if both sets of parents were criminal. These investigators observed, however, that genetic influence was not sufficient to produce criminal convictions

and underscored the finding that 75% of adoptees whose biological parents received three or more convictions were never convicted themselves. Using the same data set, Moffitt (1987) reported that multiple recidivistic nonviolent criminal activity was significantly increased in adopted sons when mental disorder and serious criminal involvement were found in the biological families. Further analyses indicated that the types of mental illness that contributed most strongly to the risk of criminal conviction were personality, drug, and alcohol disorders. Neither parental mental illness nor multiple convictions alone greatly increased the risk of offspring violence, but when both were present in the biological parents, the percentage of adoptees convicted for violence more than doubled.

Results of twin studies of antisocial behavior have been consistent with those of adoption studies in demonstrating a genetic effect for antisocial behavior but not to the exclusion of environmental influences. Grove et al. (1990) studied thirty-two MZ twin pairs raised apart from a very early age and observed the following probandwise concordance rates (i.e., the probability of having an affected co-twin, given that one is an affected twin) for psychiatric diagnoses generated by the Diagnostic Interview Schedule (DIS: Robins, Helzer, Croughan, & Ratcliff, 1981): 29% for antisocial personality disorder, 33% for alcohol abuse and/or dependence, and 36% for drug abuse and/or dependence. These researchers examined frequency counts of DIS symptoms and found greater numbers of symptoms of alcohol problems and childhood and adult antisocial behaviors among men than women and greater numbers of drug problems among younger subjects. Slutske et al. (1997) studied retrospectively genetic and environmental influences in the etiology of conduct disorder among a community-based Australian sample of 2682 MZ and DZ adult twin pairs. The best fitting model demonstrated a substantial genetic influence that accounted for 71% of the variance in DSM-III-R conduct disorder diagnoses. A modest but not significant effect for shared environment was also observed. The magnitude of the genetic and environmental effects for conduct disorder liability did not differ for girls and boys, and the specific genetic and environmental mechanisms important for development of conduct disorder appeared to be similar for both sexes. In the same sample, Slutske et al. (1998) also examined common genetic risk factors for conduct disorder

and alcohol dependence and found that genetic factors accounted for most of the association between conduct disorder and alcohol dependence liability in both women and men. These researchers concluded that there are common genetic risk factors for conduct disorder and alcohol dependence, or that conduct disorder itself is an important genetically influenced risk factor for alcohol dependence.

O'Connor, McGuire, Reiss, Hetherington, and Plomin (1998) examined possible genetic and environmental contributions to the co-occurrence of antisocial behavior and depression in adolescents. The sample comprised 720 same-sex adolescent siblings ranging in age from 10 to 18 years and included monozygotic and dizygotic twins, non-twin full siblings, half siblings, and unrelated siblings. The study used a dimensional model of psychopathology based on symptom checklists completed by adolescents and their parents. A composite score for depressive features was derived from self-, mother, and father reports on the Child Depression Inventory (CDI), the depression factors from both the Behavior Problems Inventory (BPI) and Behavior Events Inventory (BEI), and observer reports of depressed mood; an antisocial composite score was derived from self-, mother, and father reports of the antisocial factor of the BPI and BEI and observer reports of antisocial behavior. Approximately 45% of the observed covariation between depressive and antisocial features could be explained by a common genetic liability, although shared (30%) and non-shared (25%) environmental influences were also significant. Results were interpreted to suggest that genetic influences underlie the tendency for developing a specific disorder or dimension (in this case, depressive symptoms and antisocial behavior) and also the co-occurrence of maladjustment and that environmentally mediated risks play an important role in the development of depressive symptoms and antisocial behavior and of the co-occurrence of these dimensions in adolescence. Working with younger children, van den Oord et al. (1996) examined genetic and environmental influences on problem behaviors as determined by mother and father ratings obtained with the Child Behavior Checklist. The sample consisted of 1358 three-year-old twin pairs recruited from the Netherlands Twin Register. On average, genetic, shared environmental, and nonshared environmental influences accounted for 64, 9, and

27% of the variance, respectively, and the strong genetic effect suggests that children with behavior problems are likely to show an innate vulnerability.

The heritability of personality indicators of psychopathology as measured by the Minnesota Multiphasic Personality Inventory (MMPI: Hathaway & McKinley, 1942) was studied in a sample of sixty-five pairs of monozygous twins reared apart (MZA) and fifty-four pairs of dizygous twins reared apart (DZA) (DiLalla, Carey, Gottesman, & Bouchard, 1996). Using the original version of the MMPI, these investigators examined scores on the basic validity and clinical scales and the Wiggins Content Scales (Wiggins, 1966). Consistent with findings of other twin research, MZ twins showed substantial similarity, but there was no significant effect of zygosity, even though the degree of DZA similarity was more variable than the MZA variability. Approximately 44% of the variance in MMPI clinical and content scales was accounted for by genetic variability. Among the clinical scales, there was evidence of strong heritability on the two MMPI scales most typically associated with antisocial personality disorder, the Psychopathic Deviate (Pd) Scale and the Hypomania (Ma) Scale, with heritability estimates of .61 and .55, respectively. Similarly, Miles and Carey (1997) found a substantial heritability estimate of 0.42 for the Socialization Scale (Gough, 1960) of the California Psychological Inventory (Gough 1975).

Carey and Goldman (1997) reviewed and summarized the literature regarding genetic influences on antisocial behavior as follows: (1) identical twins are more similar than fraternal twins, and adoptees correlate more with their biological relatives than with their adoptive relatives—findings that hold for multiple definitions of antisocial behavior, for example, whether defined narrowly such as a felony conviction or more broadly such as symptom counts for antisocial personality disorder or conduct disorder criteria, as self-reported delinquency, or as scores on relevant personality scales; (2) violations of the assumptions of the twin and adoption methods and possible effects of twin imitation cannot account for observed genetic effects; (3) the influences of environmental factors are implicated in all studies; (4) the influences of shared environment are stronger among adolescents than among adults, suggesting that some social factors may contribute to initiating but

not maintaining antisocial behavior; (5) genetic effects are implicated in the comorbidity of antisocial behaviors and alcohol abuse/dependence and other substance abuse/dependence; (6) evidence for the heritability of violent behavior is less consistent than evidence for general deviant or antisocial behavior; (7) caution is required in interpreting existing data with regard to a common family environment; and (8) caution is required in extrapolating findings to populations other than those on which they are based.

Review of these studies suggests that we have barely scratched the surface in identifying specific factors, as well as their complex interplay, that constitute risk for criminality and antisocial behavior. In addition to genetic predisposition, environmental variables cited as influencing expression of antisocial personality are unfavorable infancy conditions and delayed home placements (Crowe, 1974); low social status (Cloninger et al., 1982); prolonged institutionalization and urban adoptive placements (Sigvardsson et al., 1982); psychiatric illness in adoptive parents and discontinuous mothering (Cadoret & Cain, 1980, 1981); and single-parent households, poverty, and housing density (Carey & Goldman, 1997). Other studies pointed to the significant impact of assortative mating (Mednick et al., 1984) and adoptive parent criminality (Hutchings & Mednick, 1975).

The study of the heritability of antisocial personality has also included attempts to identify genetic markers (i.e., stable characteristics more readily observable/measurable than the potential pathologic gene) that signal risk for antisocial psychopathology. In the case of schizophrenia, researchers have searched for biochemical abnormalities as well as psychophysiological characteristics (Holzman, 1987; Iacono, 1983); however, this line of investigation is less well developed for antisocial personality disorder. As an example, exploration of the "XYY syndrome" for etiologic significance to antisocial behavior failed to yield useful findings (Witkin et al., 1976). Of greater relevance have been proposed associations between neurological abnormalities and antisocial personality (Fishbein & Thatcher, 1986; Hare, 1970; Henry & Moffitt, 1997), neurotransmitter dysfunction and psychopathy (Berman, Kavoussi, & Caccaro, 1997; Fishbein & Thatcher, 1986; Mawson & Mawson, 1977), EEG and criminality (Raine, 1993), psychopathy and frontal lobe deficiency (Devonshire, Howard, & Sellars, 1988;

Gorenstein, 1982, 1987), anomalous hemisphere lateralization and psychopathy (Day & Wong, 1996), cerebral glucose metabolism and criminality (Goyer et al., 1994; Goyer & Semple, 1996; Raine et al., 1994), and pathological levels of cortical and autonomic arousal and psychopathy (Ellis, 1987; Fowles, 1980; Gorenstein & Newman, 1980; Hare, 1970, 1978; Quay, 1965; Raine, 1997). For example, Raine, Venables, and Williamson reported that electrodermal, cardiovascular, and cortical underarousal (1990a,b) and enhanced attentional processing (1990c) among 15-year-old youths were significantly related to subsequent adult criminality and suggested that underarousal of the autonomic and central nervous systems may represent manifestation of a genetic predisposition to criminality and a possible early predictor of criminal behavior.

Learning and Behavioral Factors

Speculations regarding family characteristics that influence acquisition of antisocial behaviors originated in psychoanalytic case formulations (Bowlby, 1951). Consensus on specific factors was limited, but most early theorists hypothesized that psychopathy was the result of faulty early childhood processes. For example, insecure attachments during infancy in high-risk families have been associated with increased risk of later disruptive behaviors during toddler, preschool, and school-age periods (Erickson, Sroufe, & Egeland, 1985; Renken, Egeland, Marvinney, Mangelsdorf, & Sroufe, 1989; Shaw & Vondra, 1995). However, economic and social support and quality of alternative care facilities may serve as a buffer to prevent the insecurely attached infant from becoming dysfunctional (Shaw & Vondra, 1995). Research supports the significance of dysfunctional family characteristics and poor parenting techniques in contributing to aggressive, delinquent, and otherwise antisocial behaviors. Olweus (1978) suggested that hostile, rejecting, or power-assertive parental attitudes, combined with minimal demands for responsible, relatively non-aggressive behaviors, were important factors in facilitating aggressive, antisocial childhood involvements. Raine et al. (1994) also pointed to early maternal rejection in combination with birth complications as predictive of violent offending.

Patterson (1982) found that coercive interaction patterns are often found in families with school-

age children who exhibit conduct disorder. Similarly, Dumas (1989) and Dumas and Wahler (1985) showed that the parents of antisocial children respond to misbehavior in an aversive, erratic manner, allocate higher levels of positive and negative attention to inappropriate rather than prosocial behaviors, and thereby increase the likelihood of deviant behaviors. Indeed, Shaw and Winslow (1997) suggested that a child who has received less contingent caregiving might act more disruptively to obtain parental attention (Greenberg & Speltz, 1988) and have less to lose by disobeying parental requests (i.e., loss of love, Shaw & Bell, 1993). In a meta-analysis of forty-seven studies, Rothbaum and Weisz (1994) found stronger relationships with child behaviors when multiple parenting characteristics were measured rather than examined individually and that global parenting styles were better predictors than individual dimensions.

Pollock et al. (1990) found that antisocial behavior defined as aggression, criminal acts, and clinician ratings of potential for acting out aggression was associated with a history of physical abuse in a group of young adult Danish men aged 18–21, whereas parental alcoholism and its interaction with childhood physical abuse did not increase the risk of antisocial behaviors. Dodge, Bates, and Pettit (1990) also pointed to the important effect of physical abuse and suggested that physical abuse leads to aggressive behaviors by impacting the development of hostile social information processing patterns, that is, physically abused youths become predisposed to attribute hostile interpretations in social interactions. In a systematic study of the association between childhood physical abuse and neglect and adult antisocial personality disorder, Lutz and Widom (1994) used a prospective cohort design to follow 699 subjects from ages 18 to 35. They found a higher prevalence of DIS-defined ASPD (13.1%) among subjects who had been physically abused or neglected compared to those who had not been abused or neglected (ASPD prevalence = 7.1%). These investigators also reported that a history of childhood abuse and neglect was predictive of the number of ASPD symptoms exhibited in adulthood.

Current thinking about the contributions of learning and behavioral factors to antisocial outcome is heavily influenced by accumulating evidence that antisocial and aggressive behaviors are stable over time (Shaw & Winslow, 1997; Wells & Forehand, 1985). For example, Lahey et al. (1995)

found that 88% of clinic-referred conduct-disordered youths still met criteria for the diagnosis in the next three years. Examining childhood predictors of adult antisocial behavior, Robins (1978) found that all childhood antisocial behaviors are strongly predictive of adult antisocial activities, as well as highly intercorrelated. Consistent with her earlier report (1970) that 40% of conduct-disordered children were diagnosed with antisocial personalities in adulthood, she showed that the number of antisocial behaviors or the severity of childhood antisocial involvement was a better predictor of severe adult antisocial behavior than specific childhood behaviors or family variables. The importance of such behavior-behavior relationships has been discussed thoroughly by Hundleby (1978), as has the clustering of various types of antisocial behaviors in adolescents (Sutker, 1982).

Antisocial behaviors tend to cluster and perpetuate, but studies have highlighted particular psychosocial circumstances that increase the probability of antisocial involvement. Recent examples include the work of Farrington (Farrington, 1995, 1997; Farrington & West, 1990) who reported findings from a prospective longitudinal survey of crime and delinquency among 411 male youths drawn from a working-class area of London. Participants were interviewed and tested at ages 8, 10, and 14 and interviewed again at ages 16, 18, and 21 and at ages 25 and 32. Intelligence, academic achievement, school behaviors, personality, psychomotor skills, living circumstances, employment histories, interpersonal relationships, and delinquent acts were assessed, and interviews from teachers and parents yielded additional data. Childhood factors at age 10 that were predictive of future delinquency included teacher ratings as troublesome and dishonest, larger sized families, criminal parents and delinquent older siblings, harsh or erratic parenting techniques, passive or neglectful parental attitudes, and parental conflict. Investigators highlighted the behavioral continuity of this sample and reported that the best independent predictor of offending at any age was troublesome or deviant behaviors at an earlier time. Additional predictors of antisocial offending were economic deprivation, family criminality, poor parenting techniques, and school failure. They also pointed out that the most deviant individuals at one age were the most deviant individuals at later ages, although absolute levels of behavioral deviance could change over time.

These results are consistent with findings that emerged from Loeber and Dishion's (1983) innovative analysis of delinquency data. Attempting to identify variables to improve prediction of the criterion over chance, these researchers reported that parental childrearing techniques, followed by childhood problem behaviors, were most predictive of delinquency. Similarly, Loeber and Stouthamer-Loeber (1987) pointed to such parental factors as supervision, attitude, and involvement as powerful predictors of childhood conduct problems. Reviewing the major epidemiological studies of antisocial behavior in children, Robins (1981) cited a conglomerate of factors that children at risk for antisocial behaviors, including male sex; status as black, urban, and poor; antisocial parents; large sibship size; erratic or excessively lenient parental discipline; and illegitimate or adoptive child status. Robins (1981) underscored the compatibility of these results with explanations that feature social disadvantage, genetic predisposition, family modeling, and psychosocial stress.

Empirical Tests of Clinical Theory

During the past four decades, researchers have subjected the clinically derived, traditional concept of psychopathy to experimental scrutiny. In addition to efforts to define its inclusionary and exclusionary features, investigators have tested the behavioral excess-deficit hallmarks of psychopathy and attempted to pinpoint shared deficiencies that account for persistently antisocial adjustment. The resulting literature may be summarized by categorizing studies into five subsets, including those that target learning and performance, behavioral extremes and impulsiveness, peculiarities in interpersonal interaction patterns, cognitive or neuropsychological characteristics, and autonomic and cortical arousal phenomena. Although studies have varied in quality, many were executed with sound methodology, and more recent work shows careful regard for multimethod assessment of study participants. Yet, most research has been restricted to prison or drug and alcohol treatment situations, and conclusions based on typically all-male samples are biased by gender effects, as well as by the extreme psychological and physical conditions in which participants are found. Research also suffers from the universal problems of generalizing from the labo-

ratory to the natural environment and inferring individual characteristics from group-derived similarities.

Learning and Performance Deficits

Theories of psychopathy derived from clinical accounts incorporate the notion that antisocial individuals are inherently deficient in acquiring learned responses. Eysenck (1964) characterized psychopaths as poor learners who extinguish quickly, and Cleckley (1982) described them as incapable of profiting from experience, particularly when the consequences involve punishment. Assumptions of defective learning among psychopaths have captured the interest of researchers since the mid-1950s, and investigators have compared samples of antisocial and control subjects on various tests of learning abilities. The findings generated have not been uniform, but psychopaths have been shown to be inferior in verbal conditioning and verbal learning (Henry & Moffitt, 1997; Johns & Quay, 1962; Quay & Hunt, 1965), semantic processing (Day & Wong, 1996; Hare & Jutai, 1988; Williamson, Harpur, & Hare, 1991), classical conditioning and generalization of autonomic responses (Hare, 1965; Hare & Quinn, 1971), and passive-avoidance learning (Gorenstein & Newman, 1980; Lykken, 1957; Newman, Patterson, & Kosson, 1987; Newman & Schmitt, 1998; Waid & Orne, 1982). At the same time, psychopaths have not necessarily performed more poorly on tasks involving social learning (Kadlub, 1956), learning sets (McCollough & Adams, 1970), verbal conditioning using social reinforcement (Bryan & Kapche, 1967), probability learning where punishment is a near certainty (Siegel, 1978), and paired-associate verbal learning (Gullick, Sutker, & Adams, 1976; Sutker, Gil, & Sutker, 1971). Additionally, psychopaths have not always exhibited deficient avoidance learning (Kosson, Smith, & Newman, 1990; Newman & Kosson, 1986; Newman, Patterson, Howland, & Nichols, 1990; Newman & Schmitt, 1998; Schmauk, 1970; Siegel, 1978).

Given these apparent contradictions, investigators have looked more closely at the parameters of learning, such as the nature of reinforcement, to account for discrepancies. In early studies, Painting (1961) found that primary psychopaths performed as well as controls when incorrect responses resulted in the loss of cigarettes, and

Schmauk (1970) reported that psychopaths behaved comparably to controls when mistakes resulted in monetary losses rather than electric shock or negative social comments. Siegel (1978) found that diminished responsiveness to punishment among psychopathic offenders was greatest when the probability of punishment was most uncertain, whereas Fairweather (1954) showed that psychopaths exhibited maximum performance under conditions of uncertain as opposed to certain or no reward. These studies suggest that both the probability and type of reinforcement can influence learning and performance among psychopaths.

Other aspects of the learning situation may alter performance among psychopaths, such as the timing of reward and response feedback, as well as the sex of the experimenter. In the Painting (1961) study, success rates of primary psychopaths were higher than controls under conditions of reward in which stimuli and responses were delivered in close temporal proximity, but performance decreased as the contiguity between events diminished. Gullick et al. (1976) reported that the acquisition of a paired-associate learning list was slowed by increasing information delay among sociopathic prisoners. Newman, Schmitt, and Voss (1997) demonstrated that low-anxious psychopaths, compared to low-anxious controls, do not exhibit the typical interference due to motivationally neutral contextual cues when the inter-stimulus interval is short but perform similarly to controls under the long interval-stimulus condition. Newman et al. (1987) compared prison psychopaths and controls on a card-playing task involving monetary rewards and punishments, demands for response set alteration as contingencies changed, and such manipulations as cumulative delay of response feedback and forced postfeedback delays. Psychopaths failed to alter dominant response sets for reward, losing more money than controls, although the combination of postfeedback delays and cumulative feedback reduced their perseverative deficits. Other variables shown to influence learning in psychopaths include the content of the material to be learned (Sutker et al., 1971) and experimenter gender (Bernard & Eisenman, 1967; Stewart & Resnick, 1970).

Several research studies were designed to isolate the factors that contribute to presumed deficiencies in passive-avoidance learning among psychopaths. Linking passive-avoidance deficits

with behavioral disinhibition and pursuit of reward, Newman, Widom, and Nathan (1985) hypothesized that psychopaths falter on passive-avoidance tasks when salient cues for approach responding interfere with processing additional cues that signal the need for response inhibition or behavioral alterations. Testing this notion, Newman et al. (1985) compared psychopathic delinquents and controls using a passive-avoidance paradigm that provided monetary rewards for responding to both positive and negative stimuli. In a second task, rewards were contingent on responding to positive stimuli and withholding responses to negative stimuli. As predicted, psychopathic delinquents committed more passive-avoidance errors than controls on the task that involved both reward and punishment, but not on the reward-only task, that is, delinquent adolescents were deficient in avoiding loss of money when provided competing goals of avoiding punishment while earning rewards.

Newman and Kosson (1986) replicated and extended these findings among White adult prison samples by demonstrating that psychopaths committed more passive-avoidance errors than nonpsychopaths on a computerized task that involved competing reward and punishment contingencies, but performed as well as nonpsychopaths on the same tasks with punishment only. Inconsistent with the authors' reasoning, however, was the absence of performance differences between the two tasks within the psychopathic group. Psychopaths committed no fewer avoidance errors in the punishment-only condition than they did when faced with both reward and punishment. By way of explanation, the researchers suggested that the latter condition may have been more difficult than the former. In a subsequent study involving Black criminal psychopaths and nonpsychopaths, Kosson et al. (1990) found no differences in passive-avoidance performance under competing reward and punishment contingencies, although between-group differences emerged when data from Black subjects were combined with those of White subjects in the earlier study. Newman et al. (1990) also demonstrated a mediating effect of anxiety on passive-avoidance performance among psychopaths such that poor passive-avoidance learning was specific to low-anxiety psychopaths, and Newman and Schmitt (1998) replicated the findings of poor passive-avoidance learning among incarcerated White psychopaths relative to incar-

cerated White nonpsychopaths. However, consistent with Kosson et al. (1990), Newman and Schmitt (1998) failed to observe the same pattern of results among incarcerated Black psychopaths and nonpsychopaths, and deficits in passive-avoidance learning have not been demonstrated in samples of female psychopaths.

In recent years, Newman and colleagues (Newman, Schmitt, & Voss, 1997; Patterson & Newman, 1993) examined passive-avoidance learning in psychopaths using a response-modulation model, rather than one targeting low fear or insensitivity to punishment cues. Testing this model, Newman, Schmitt, and Voss (1997) studied the effects of peripherally presented motivationally neutral cues on cued recognition in psychopathic and nonpsychopathic (control) prison inmates. Consistent with predictions, low-negative affectivity psychopaths showed significantly less interference when motivationally neutral cues were presented peripherally than low-negative affectivity controls under a short interstimulus interval but not under a long interstimulus interval. These results were not observed in high-negative affectivity psychopaths and controls and were not applicable to Black subjects. Overall, findings were interpreted as supportive of an information-processing response modulation model. On the other hand, Howard, Payamal, and Neo (1997) used a modified version of a cued-reaction task (Howland, Kosson, Patterson, & Newman, 1993) and found no evidence to support response modulation deficits in psychopaths. In fact, subjects showed insensitivity to cues of reward/nonpunishment consistent with an active avoidance deficit, and these investigators interpreted overall performances as congruent with global affective-motivational deficits. Hence, findings remain inconsistent, but the possibility that the passive-avoidance learning deficit among psychopaths may be specific to situations characterized by competing reward and punishment contingencies and to particular subject groups remains an important target for future investigation.

Several studies have shown that psychopaths may not be deficient in acquiring learned responses, learning to avoid punishment, or performing tasks for reward, depending upon the type of comparisons conducted (e.g., Newman & Schmidt, 1998). However, they do behave differently from so-called normal control groups, and the quality of their efforts is more variable and more influenced by salient (and perhaps subtle)

differences in learning context. Type of reward, reinforcement delay, relative probabilities of punishment or reward, timing of discriminative or signaling stimuli, forced response delays, perception of tasks and context, and characteristics of the experimenter have been shown to modify performance. As Lykken (1978) urged, laboratory research must exceed measurement of the obvious situational variables to assess the extent to which the task strikes the fancy of psychopathic subjects. In any case, problem-solving strategies, learning strengths and weaknesses, and characteristic cognitive sets in learning situations remain a fascinating area for research among antisocial individuals.

Behavior Extremes and Impulsiveness

Clinical observations of behavioral extremes and impulsivity in the face of almost certain untoward consequences led to proposals that psychopaths are characterized by exaggerated needs for sensation-seeking, vulnerability to boredom, and deficits in delay of gratification. Early motivational theories suggest that organisms are driven by needs both to increase and to reduce stimulation. Primate studies show that animals work to glimpse a change of scene (Butler, 1953), manipulate novel stimuli (Harlow, Harlow, & Meyer, 1950), and experience unpatterned light if reared under sensory deprivation (Wendt, Lindsley, Adey, & Fox, 1963), and prolonged sensory deprivation in humans has been associated with severe cognitive and emotional reactions (Zubek, Pushkar, Sansom, & Gowing, 1961). Integrating this knowledge with findings from research with psychopaths (Fairweather, 1954; Fox & Lippert, 1963), Quay (1965) hypothesized that psychopaths require higher, more variable stimulation to maintain positive affect because of their lowered basal reactivity and more rapid adaptation to stimulation. That is, low arousal is seen as representing an aversive physiological state that prompts antisocial individuals to seek out stimulation to increase arousal to optimal or normal levels (Eysenck, 1964; Quay, 1965; Raine, 1993, 1996, 1997). Thus, psychopaths were viewed as fluctuating from baseline stimulus deprivation and affective unpleasantness to states of brief relief associated with sensation-seeking.

Speculations that psychopaths are prompted to exaggerated sensation-seeking and thus to antisocial behaviors were investigated during the

1970s using Zuckerman's Sensation Seeking Scale (SSS; Zuckerman, 1972, 1977). Sensation-seeking reflected by SSS scores has been associated with such antisocial behaviors as gambling among college students (Zuckerman, 1974), prison escapes and disobedience of authority figures among female delinquents (Farley & Farley, 1972), drug use in male veterans and college students (Kilpatrick, Sutker, Roitzsch, & Miller, 1976), arrest chronicity among skid-row alcoholics (Malatesta, Sutker, & Treiber, 1981), college student alcohol and drug use (Zuckerman, Bone, Neary, Mangelsdorff, & Brustman, 1972), and psychopathy in a prison sample (Blackburn, 1978). Additionally, Sutker, Archer, and Allain (1978) found that high sensation seekers among chronic drug using men and women in treatment exhibit Minnesota Multiphasic Personality Inventory (MMPI) responses reflective of greater antisocial inclination, behavioral impulsiveness, and social introversion than their low sensation seeking counterparts. Self-reported behaviors were consistent with SSS and MMPI data, as high sensation seekers reported earlier and more varied drug use as well as pleasure motives for initial alcohol use compared with low sensation seekers who cited peer pressure and conformity as primary motives.

Relationships between sensation-seeking and antisocial behavior have also been implicated in performance studies among children and adults. In two related investigations, DeMyer-Gapin and Scott (1977) and Whitehill, DeMyer-Gapin, and Scott (1976) showed that antisocial children exhibited less time viewing boring material, higher initial levels of attention to novel stimuli, and more extraneous behaviors during experimental tasks than children classified as neurotic. Using a monotonous task called the Prisoner's Dilemma Game, Widom (1976b) found that adult primary psychopaths were as able as nonpsychopaths to tolerate sameness, but that secondary or neurotic psychopaths exhibited greater inability to manage monotony. Widom's (1976b) task required ongoing reciprocal interactions, and results suggested that the conditions under which psychopaths become bored may vary, depending on situational demand characteristics. Her work also highlighted the role of neurotic features in influencing vigilance and other performance behaviors.

Questions concerning capacities for sustained effort and tolerance for sameness among psychopaths have been addressed by evoked potential

investigations of attention and information processing. Results from several studies show that psychopaths are capable of proficient selective attention to a video task (Jutai & Hare, 1983) and directing high levels of attention to stimuli of interest (Forth & Hare, 1989; Jutai et al., 1987). Raine and Venables (1987) reported that antisocial 15-year-old boys were more reactive (showed larger P300s) to warning stimuli than their "pro-social" counterparts, and data derived from a subsequent investigation (Raine & Venables, 1988) supported the hypothesis that adult psychopaths are characterized by heightened ability to attend to task-relevant events. Attempting to reconcile these findings with the Cleckley deficit model, Raine and Venables (1988) cautioned that some performance tasks may be too brief to elicit the type of attention deficits described by Cleckley and argued that overly focused short-term attention to events of interest reflects undue emphasis on short-term gratification.

It has been theorized that inability to delay gratification coupled with sensation-seeking contributes to behavioral impulsivity and antisocial outcome (Maher, 1966). Looking at the inability to delay gratification as integrally related to impulsivity, investigators have examined Porteus Maze Test qualitative performance among psychopathic and control groups to assess difficulties in inhibiting impulsive errors. Contrary to expectations, several investigators failed to show performance deficits on this measure. Sutker, Moan, and Swanson (1972) found that prisoner psychopaths showed better qualitative Porteus Maze Test performance than prisoner normals or prisoners labeled antisocial psychotics, differences that could not be attributed to intelligence. Widom (1977) also found relatively fewer Porteus qualitative errors among institutionalized psychopaths than those reported in earlier studies (Fooks & Thomas, 1957; Schalling & Rosen, 1968). Sutker and Allain (1983) reported that male adaptive sociopaths identified among medical students produced significantly more errors on the Porteus qualitative index than their school counterparts who had no detectable psychopathology, whereas overall performance did not differ. In this study, neither group was characterized by significant depression or anxiety, and both showed high levels of intellectual ability. Thus, to some extent, the outcome of psychopath/nonpsychopath comparisons is a function of the subject groups sampled.

Using a different approach, Gullick et al. (1976) investigated the effects of information feedback delay on acquisition rates in paired-associate learning among nonaddict sociopaths, addict sociopaths, and normal controls recruited from male prisoners. Drug use histories were collected by self-report and review of prisoner files, and only primary sociopaths and controls without remarkable psychopathology, defined by a set of MMPI criteria, were recruited. Results showed that reinforcement delay did not interfere with performance among normal subjects, but acquisition rates were significantly slowed under the maximum delay condition in both addicted and non-addicted sociopathic prisoners. Short delays in information feedback did not impair learning rates, but the maximum delay condition was associated with apparent frustration, annoyance, and self-imposed distractions among primary sociopaths who became restless and bored while waiting for the correct answer. The investigators reasoned that as the structure of the learning task was altered to include frustrating delays, primary sociopaths became impatient for reinforcement and performed less well on task demands than normals who tolerated reinforcement delays without performance changes.

Other factors modified responses to delay conditions when study participants were allowed reward choices. Widom (1977) found that psychopaths recruited from the community chose larger, delayed monetary rewards over smaller, immediate amounts of money and that these decisions were influenced by employment status and MMPI elevations on the Psychopathic Deviate Scale (*Pd*, or Scale 4). Brown and Gutsch (1985) investigated preferences among primary psychopathic, secondary psychopathic, and nonpsychopathic prisoners for smaller immediate versus larger delayed rewards. Results revealed no significant group differences in reward selection, but neurotic psychopaths were distinguished from primary psychopaths and normal prisoners by what the investigators described as a neurotic cognitive set, including a sense of urgency, indecision, impulsivity, and lack of trust and forethought. By contrast, the other prisoner groups appeared more decisive, agreeable, trusting, and able to delay gratification without accompanying distress. These investigators hypothesized that a relationship exists between deficient ability to delay gratification and neurotic mediating conditions among secondary psycho-

paths. In addition to highlighting the potentially confounding contributions of negative affect, such as depression and anxiety, this study fills an important gap in the psychopathy literature by targeting some of the cognitive underpinnings that prompt behavior in antisocial individuals.

To date, research fails to support the hypothesis that psychopaths cannot postpone gratification or inhibit impulsive errors across situations. Rather, the relationship between impulsivity, at least as related to the delay of gratification, and psychopathy appears to be influenced by such factors as intellectual sophistication, employment status, other types of psychopathology such as anxiety and depression, groups used for comparison, individual learning histories, and other person and situational variables. On the other hand, there is evidence that impulsiveness, eagerness for reward, and antisocial behaviors cluster in association and that the combination may predispose certain individuals to greater impulsivity than might be expected among normal controls. In any case, review of the studies reported here makes it clear that simple generalizing statements about psychopaths are likely to be misleading.

Peculiarities in Interpersonal Interaction Patterns

Traditional concepts of psychopathy emphasize the blatantly egocentric and unconsciously selfish aspects of associated behaviors. Gough (1948) attributed this deficiency to an inability to view personal actions from another's perspective or to assume another's interpersonal role, and Cleckley (1982) concluded that psychopaths are apathetic to the suffering of others, despite superficial displays of concern. Ullman and Krasner (1975) noted the apparent skillfulness of sociopaths in interpersonal manipulation, and McCord and McCord (1964) pointed to their incapacity to love or form close social attachments. Gorenstein and Newman (1980) wrote that psychopaths disregard totally the sufferings or hardships which may accrue to themselves or others as a result of their behaviors and argued that they adhere to no moral code. These extreme characterizations persist without regard for a growing body of experimental evidence that challenges the assumption of uniform interpersonal deficit and callousness.

Subjecting Cleckley's notion of social insensitivity to experimental scrutiny in a vicarious

conditioning paradigm, Sutker (1970) showed that noninstitutionalized sociopathic men were more autonomically responsive than their nonsociopathic counterparts to a stimulus paired with apparently immediate shock to another individual. Sociopaths overresponded to what seemed to be an exciting social stimulus, and it was suggested that sociopaths are sensitive to social cues and emotionally provocative stimuli. In another study, Sutker et al. (1971) reasoned that if this were true, social stimuli might serve as positive reinforcers to modify their behavior more effectively than neutral or nonsocial stimuli. These researchers tested the effects of varied social content ratings of consonant–vowel–consonant (CVC) combinations on speed of acquisition in a serial learning task among imprisoned sociopaths and nonsociopaths. As predicted, sociopaths performed significantly better than nonsociopaths on the list comprised of highly relevant CVCs and acquired this material faster than low social content CVCs, although lists were equated for learning difficulty. Nonsociopaths showed no significant differences in speed of acquisition for the two lists. Complementing these results were those reported by Sutker, Moan, and Allain (1974) who found that noninstitutionalized sociopaths scored significantly better than normals on measures that required observation for detail in the social as well as the tangible environments.

Widom (1976b) investigated interpersonal cooperation during game playing among pairs of primary psychopaths, secondary psychopaths, and controls. Psychopaths did not behave more selfishly or egocentrically, show greater concern with personal gain, or act less responsibly than normal subjects. Widom found that if rewards were sufficient and feedback immediate, psychopaths cooperated with one another, at least for short periods of time. Interestingly, however, psychopaths and normals differed in their perceptions of game partner roles. Nonpsychopathic partners viewed their relationship as a cooperative endeavor, whereas primary and secondary psychopaths regarded their partners as competitors. The strongest support for assumed interpersonal competence deficits among psychopaths was associated with performance among the secondary psychopaths who showed more difficulties in anticipating unpleasant future consequences of their behavior and less accuracy in predicting the behavior of others. Widom reasoned that the discrepancy between primary and

secondary psychopaths represented evidence of the utility of these labels for subtyping antisocial individuals.

Rime, Bouvy, Leborgne, and Rouillon (1978) used videotaped interviews to examine verbal and nonverbal interpersonal behaviors in young male psychopaths aged 12 to 20. Global ratings of their emotional states (e.g., happy, sad, or mad) were also obtained. Compared with controls, psychopathic youths used more hand gestures, leaned toward the interviewer more often, maintained greater eye contact, and tended to smile less frequently. These researchers interpreted their findings as consistent with previous notions about the interpersonal behavior of psychopaths, indicating that the increased levels of nonverbal activity displayed by psychopathic subjects represented intrusive and troublesome behaviors that were likely to be the result of social skill and awareness deficits. Questions can be raised regarding this interpretation, and study findings may be challenged on two counts. Psychopathic subjects in this study received less verbal attention and no tangible reward for participation, and interviews were conducted by an experimenter of the same sex. Both variables have been shown to affect performance among psychopathic participants.

Lee and Prentice (1988) examined empathy, role-taking, cognition, and moral reasoning among incarcerated delinquent boys grouped into psychopathic, neurotic, and subcultural categories and nondelinquent community control subjects. These investigators predicted that psychopathic and neurotic delinquents, compared to subcultural delinquents and nondelinquent controls, would demonstrate relatively deficient performance on such socialization tasks as identifying emotionally with other people, assuming another's perspective, and coping with moral dilemmas. Although delinquents as a group exhibited significantly more immature modes of role-taking, logical cognition, and moral reasoning than nondelinquents, psychopathic and neurotic delinquents did not differ from subcultural delinquents on these measures. Contrary to predictions, no differences in empathy were found among any of the groups. The authors acknowledged that their findings conflict sharply with clinical descriptions of delinquents, particularly psychopaths, as starkly egocentric and deficient in emotional empathy.

Using the repertory grid technique, Widom (1976a) compared the interpersonal and personal

construct systems of psychopaths and normals. She found that the construct systems of primary psychopaths were lopsided and idiosyncratic but highly consistent and suggested that they fail to distinguish between their conceptualizations and those of people in general. Secondary psychopaths and controls manifested less lopsidedness, consistency, and social discrepancy. Psychopathic groups showed a significant degree of misperception concerning people in general, but particularly along the dull–exciting construct dimension. Widom concluded that psychopaths failed to entertain adequately the idea that other people construe events differently from them and seem to make little effort to modify their rigid construct systems. These findings underscore the need for continued examination of cognitive inflexibility and idiosyncracies among psychopaths, as well as the extent to which results may be consistent across situations and circumstances.

At least three studies documented bias toward attributions of hostility among aggressive male youths (Dodge & Newman, 1981; Dodge, Pettit, Bates, & Volante, 1995; Nasby, Hayden, & DePaulo, 1980), raising the question whether psychopaths view social situations with overriding negative perceptual sets. Exploring this issue, Blackburn and Lee-Evans (1985) classified sixty offender patients at a psychiatric security hospital into four subgroups using median splits on psychopathy and social withdrawal dimensions. Comparisons of their ratings of reactions to hypothetical situations that represented aspects of frustration, threat, attack, and pain showed more intense responses among psychopaths to anger-provoking situations. Findings were interpreted as evidence of cognitive bias in perceiving interpersonal threat among psychopaths who appeared to be more hypervigilant to violation of their personal domain and more vulnerable to interpersonal than frustrating provocation. Consistent with these data, Sterling and Edelman (1988) reported that both anxiety and anger situations were perceived as more anger-inducing among psychopaths, compared to nonpsychopathic participants.

Continued study of interpersonal perceptions and behavior among psychopathic or antisocial groups is needed. Research indicates that psychopaths are keen observers of social behavior, are as empathic as nonpsychopaths, find themselves stimulated by socially relevant stimuli, and participate cooperatively in various types of game situa-

tions. That psychopaths have been shown to lean toward their interviewers, make longer eye contact, and gesture in conversation is probably as suggestive of facile interpersonal poise as any data yet considered. At the same time, there is evidence that psychopaths share rigid cognitive sets and perceptual biases, particularly with regard to assessing interpersonal threat and the resulting perception of anger. Additionally, psychopaths find difficulty in understanding what others are thinking and feeling because of their own peculiar constructs and assumptions that others perceive circumstances in the same way as themselves. Further investigation of these areas of perceptual and cognitive biases, as well as their implications for communication and interpersonal behavior, may yield results relevant to clinical assessment and management of antisocial individuals.

Cognitive and Neuropsychological Deficits

Attempts to explain delinquency and antisocial behaviors have included suggestions that there may be relationships between various types of cortical dysfunction and disorders characterized by marked deviations in emotional, motor, and cognitive behaviors. Research speculation in this area has concentrated on frontal lobe dysfunction (e.g., Henry & Moffitt, 1997; Kandel & Freed, 1989), dominant hemisphere dysfunction (Hare, 1979), and weak or unusual lateralization of language function (Day & Wong, 1996; Hare & Jutai, 1988; Raine, O'Brien, Smiley, Scerbo, & Chan, 1990). Probably the most consistently presented of these notions involves positing a relationship between frontal lobe dysfunction and delinquency in youth and antisocial behaviors in adults. As Stuss and Benson (1986) pointed out, however, researchers also attempted to link such major psychiatric disorders as schizophrenia (Benson & Stuss, 1990; Buschbaum, 1990; Robbins, 1990) and depression (Buschbaum, 1986) to frontal lobe pathology.

The special appeal of the frontal lobe hypothesis derives from clinician observations of similarities between problems with cognitive control and uninhibited hedonistic actions thought to characterize psychopaths and the behaviorally restless and apparently gratification-seeking posture often associated with prefrontal pathology. Described as “pseudopsychopathic,” the constel-

lation of features often documented following orbital frontal brain damage includes motor disability with the pursuit of immediate gratification, minimal regard for social propriety, and such impulsive, antisocial acts as sexual excesses, crude humor, and unreliability (Stuss & Benson, 1986). Obvious analogies between delinquent and antisocial impulsivity and the disinhibited behaviors of patients with assumed frontal lobe impairment have led to exploration of possible deficits in neuropsychological performance among antisocial subsets which could explain persistent delinquent and antisocial involvements.

Schalling (1978) proposed that some aspects of psychopathy may be attributed to deficiency in frontal lobe processes associated with regulation of attention, emotional responsiveness, and behavioral persistence. Integrating evidence that frontal-lobe immaturity may contribute significantly to delinquent behavior, Pontius and her colleagues suggested that delinquency may be tied to frontal lobe system dysfunction (Pontius, 1974; Pontius & Ruttiger, 1976; Pontius & Yudowitz, 1980). A similar line of inquiry offered evidence that anterior neuropsychological dysfunction was associated with criminality, delinquency, and depressive and violent symptoms (Yeudall & Fromm-Auch, 1979; Yeudall, Fromm-Auch, & Davies, 1982). The most clear statement linking frontal lobe dysfunction to neuropsychological deficits among psychopathic subjects, however, was offered by Gorenstein (1982) who classified forty-three male psychiatric patients and eighteen male university students into psychopathic and nonpsychopathic groups. Subjects were administered a battery of cognitive tests, including the Necker Cube, the Wisconsin Card Sorting Test (WCST), a sequential matching memory task (SMMT), the Stroop Color-Word Test, and an anagram task. Group performance did not differ on the latter two measures, but psychopaths exhibited more spontaneous reversals of the Necker Cube, greater numbers of SMMT errors, and more perseverative errors on the WCST. Based upon these data, Gorenstein concluded that psychopaths were deficient in cognitive processes associated with frontal lobe functioning and suffered impaired ability to modulate dominant response sets.

Limitations in the Gorenstein (1982) study conceptualization and methodology, as well as in this researcher's conclusions, have been described in

subsequent reports. Hare (1984) criticized Gorenstein (1982) for procedures used to subdivide participants into psychopathic/nonpsychopathic categories and suggested that group differences might be attributed to the influences of age, education, ability, substance abuse, and college student status. Attempting to replicate Gorenstein's (1982) findings, Hare (1984) compared three groups of White prison inmates divided by thirds into high, medium, and low psychopathy categories based on his twenty-two-item psychopathy checklist. Because groups did not differ in intelligence, age, education, or CPI *So* score or in performance on the three cognitive tasks used by Gorenstein (1982), Hare (1984) concluded that the efforts of psychopaths were not at all like those of frontal lobe patients. Subsequently, Hart, Forth, and Hare (1990) found no differences in neuropsychological test performance of two samples of high, moderate, and low psychopathy subjects. Results were consistent with earlier data reported by Sutker, Moan, and Allain (1983) who demonstrated that psychopathic and normal control prisoners showed no differences in tendencies to persist in incorrect responding, to disregard cues suggesting the need to modify behavior, or to proceed impulsively in problem solving as reflected by performances on the WCST and circle drawing and maze tracing tasks.

Sutker and Allain (1987) administered the WCST, Visual Verbal Test, and Porteus Maze Test to nineteen psychopathic and fifteen normal patients undergoing substance abuse treatment, subjects drawn from a population demographically similar to that of Gorenstein's (1982). These investigators assessed the effects of intellectual sophistication by using analyses of covariance and tested the hypothesis that psychopaths are characterized by no greater difficulties in controlling impulsiveness, planning ahead, and exercising cognitive flexibility (such as accommodating shifts and avoiding perseverations) than nonpsychopathic controls. Psychopathic subjects did not differ from controls across the cognitive measures thought to reflect frontal lobe functioning, specifically, planning, flexibility, attention, control, and abstraction. Sutker and Allain (1987) suggested that it may be misleading to conceptualize behavioral or neurophysiological analogies between frontal lobe and psychopathic patients. Hoffman, Hall, and Bartsch (1987) also failed to find evidence that

psychopathic individuals performed more poorly than nonpsychopaths on tasks sensitive to frontal lobe functioning.

Devonshire et al. (1988) criticized both Gorenstein (1982) and Hare (1984) for ignoring the distinction drawn by Blackburn (1979b) between primary and secondary psychopaths. Examining performance on a modified version of the Wisconsin Card Sorting Test, these investigators found no differences between subjects classified legally as psychopathically disordered or as mentally ill, and no differences between those classified as high or low in psychopathy using an abbreviated form of Hare's Psychopathy Checklist. A subgroup of primary psychopaths achieved significantly more categories and made fewer errors than a subgroup of secondary psychopaths, leading to the hypothesis that anxious, socially withdrawn individuals, regardless of psychopathy, may be unable to maintain a cognitive set resulting from overappraisal of threat. They proposed that the discrepancy between Gorenstein's (1982) and Hare's (1984) data can be attributed to inconsistent selection criteria and suggested that studies using Hare's Psychopathy Checklist for classification fail to find differences in frontal lobe functioning because of failure to differentiate primary and secondary psychopaths. Supporting this logic in part, Smith, Arnett, and Newman (1992) reported poorer performance among low-anxious psychopaths than high-anxious psychopaths on Trail Making Part B and WAIS-R Block Design tests. However, differences were predicted on six tests of the battery but were found on only two, and the observed significant differences were not apparent when groups were collapsed across anxiety levels.

In a review of the frontal lobe hypothesis and psychopathy, Kandel and Freed (1989) highlighted the complexities in attempting to evaluate frontal lobe dysfunction among antisocial samples. Allowing that such deficits were possible, particularly as regards associations between criminality and dysfunction localized in the anterior regions of the brain, they concluded that existing evidence does not point conclusively to frontal lobe dysfunction in psychopaths. Among the limitations of research studies in the area, they called attention to problems with selecting psychopaths and appropriate control samples, and Henry and Moffitt (1997) concurred and suggested that varied and sometimes unreliable diagnostic procedures

used to define psychopathy may well account for inconsistency of findings. Kandel and Freed (1989) also pointed to contributions of confounding variables such as alcohol and drug abuse, institutionalization, use of questionable frontal lobe measures, lack of dependent measures reflective of other cognitive functions, and absence of corroborative evidence from neuroanatomical indexes. Taking a broader perspective, Stuss and Benson (1986) cautioned that disorders that alter frontal lobe functions exert widespread effects because of frontal anatomical connections with other cortical and subcortical structures; argued against easy localization of mood, behavioral, or cognitive functions to this area; and presented evidence that most measures considered sensitive to frontal lobe impairment can also be affected by impairment in other areas. Clearly then, a hasty diagnosis of frontal lobe malfunction based on the results of several psychological tests may be misleading.

In addition to the complex integrative functions of the frontal lobes and limitations in our expertise to measure such functions with specificity are the problems associated with comparing grossly defined psychopathic and nonpsychopathic groups. Devonshire et al. (1988) criticized Hare (1984) for ignoring differences between primary and neurotic or secondary psychopaths, but more critically limiting factors are failures to employ both exclusionary and inclusionary criteria to define psychopathic and nonpsychopathic groups and to take into account the total range of possible psychopathology that might characterize psychopaths or nonpsychopaths and thereby influence findings. It is insufficient to define psychopaths by reference to psychopathy criteria alone or without regard for the assessment of complicating psychopathology such as depression, anxiety, schizophrenia, and other Axis II disorders. By the same token, selection of control subjects using criteria that solely determine that they are not psychopathic ignores the possibility and perhaps likelihood that other significant psychopathology may exist.

Arousal Levels and Responsivity

There is a rich tradition of attempts to account for functional disorders and dysregulated emotions and behaviors by reference to what has been called arousal theory. Operational definitions of arousal vary widely, depending upon researcher orientation

and measurement expertise. Descriptions of arousal may highlight nonspecific baseline or resting levels and changes to such, attentional phenomena and mental control, autonomic responsivity and energization associated with threat, and activation of behaviors in the service of specific appetitive or aversive needs or in response to incentives. Assessment of arousal can incorporate tests of mental alertness and diligence, measures of resting level and reactive electrodermal and heart rate activity, electrophysiological monitoring of event-related potentials and other central nervous system (CNS) phenomena, and, more recently, brain imaging technology such as single photon emission computerized tomography (SPECT). Whether studies target attention and orientation, learning and performance, or autonomic reactivity and conditioning, there is a fundamental interrelatedness to this work, because of commonalities in the neuro-anatomical basis for arousal described by Stuss and Benson (1986) as the tripartite neural axis, including the reticular activating system, thalamus, and frontal lobes and their connections.

One of the first investigators to call attention to the relationship between psychopathy and arousal idiosyncracies was Lykken (1957) who showed that psychopaths were slow to condition fear to warning signals, inclined to ignore painful electric shocks that normals learned to avoid, and less influenced by fear reactions. Building on this classic investigation and the arousal literature, Quay (1965) and Eysenck (1964) developed arousal models to account for psychopathy and posited mechanisms of hypoarousal and rapid habituation to stimuli as prompting behaviors which were apparently unfettered by fears of consequences and such psychological deterrents as anxiety and anticipation of shame. There has been no decline in interest in arousal theory related to psychopathy, as evidenced by more than forty years of research by Hare (1970, 1978, 1982; Jutai et al., 1987), work by Raine and colleagues (1987; Raine, Venables, & Williams, 1990a,b,c, 1995, 1996; Brennan et al., 1997), and conceptual papers by Fowles (1980, 1993), Ellis (1987), Gray (1994), Mawson and Mawson (1977), and Quay (1993).

A considerable body of experimental findings has been generated in attempts to elucidate the arousal characteristics of psychopaths. Evidence is reasonably clear-cut that psychopaths do not necessarily differ from nonpsychopaths in cardiovascular activity in resting situations (Blackburn,

1978, 1979a; Hare, 1982; Hare et al., 1978; Steinberg & Schwartz, 1976). Raine (1993, 1997) reviewed this extensive literature and concluded with respect to heart rate that studies of institutionalized criminals and psychopaths have not evidenced lowered resting heart rate levels, whereas research with noninstitutionalized conduct-disordered, delinquent, and antisocial children and adults has consistently shown lowered resting heart rate levels in antisocial youth. Raine (1997) concluded that lowered heart rate is a common predisposition to antisocial behavior in general but not to institutionalized, psychopathic criminal behavior in particular (p. 290).

Studies of electrodermal activity among antisocial individuals have yielded mixed results. Some research has documented significantly lower resting levels of skin conductance among psychopaths (Blankstein, 1969; Dengerink & Bertilson, 1975), whereas other studies showed no differences (Borkovec, 1970; Hare, 1982; Hare & Craigen, 1974; Hare et al. 1978; Schmauk, 1970; Sutker, 1970). In a group of 16-year-old delinquents, Raine et al. (1990b) found lower resting skin conductance levels among those who later became criminals by age 24, compared to those who did not. There are also reports of decreased frequency of nonspecific electrodermal responses in resting situations in psychopaths (Fox & Lippert, 1963; Hare & Quinn, 1971), no differences (Hare et al., 1978; Steinberg & Schwartz, 1976), and higher nonspecific frequency (Blankstein, 1969).

The hyporeactivity hypothesis has led to studies of skin conductance orienting amplitude to un signaled neutral tone stimuli. Borkovec (1970) found that psychopathic delinquents gave smaller orienting responses to the first in a series of neutral tones than a group of subcultural and neurotic delinquents, results similar to those reported by Siddle, Nicol, and Foggitt (1973). Other investigations of electrodermal responses to un signaled stimuli have yielded conflicting findings when adult psychopathic and nonpsychopathic groups were compared. In most cases, researchers reported no differences between psychopaths and nonpsychopaths on such measures (Blackburn, 1979a; Hare et al., 1978), whereas other work showed that psychopaths were less responsive (Blankstein, 1969; Hare, 1978). To some extent, the discrepancies in findings may be attributed to inconsistencies in the selection procedures of clinical samples as well as differences in measurement methodology, but re-

sults do not necessarily support the hypoarousal hypothesis.

Two additional studies failed to obtain lower than normal skin conductance orienting responses among children with delinquent potential (Mednick, 1977) or antisocial behaviors (Venables, 1987). However, as described earlier in this chapter, Raine et al. (1990b) found lower resting skin conductance levels among 16-year-old youths who later became criminals by age 24, compared to those who did not. With respect to skin conductance levels, reviews were conducted and summarized by Fowles (1993) and Raine (1993, 1997). Fowles (1993) reported that differences in the direction of lowered resting levels of sweat gland activity among psychopaths may occasionally be observed, but the effect sizes are small, and evidence for nonspecific fluctuations is even weaker. Raine (1993, 1997) concluded that there is minimal evidence for lower skin conductance arousal levels in psychopaths. However, when groups are defined on the basis of antisocial behavior in general, there is clear evidence of lower skin conductance levels and fewer nonspecific skin conductance responses during rest.

Contradictory findings weaken the case for the notion that psychopaths share baseline levels of underarousal, although this possibility has not been fully dismissed. Hare (1978) argued that basal skin conductance in psychopaths was lower in absolute magnitude in several studies where significant differences were not necessarily observed. He reported that when data from eight studies were pooled, psychopaths showed significantly lower skin conductance but not differences in nonspecific frequencies. Mawson and Mawson (1977) disagreed with this line of reasoning and proposed a neurochemical model to account for patterns of psychophysiological and behavioral activity manifested by psychopaths. These investigators suggested that rather than higher or lower arousal levels *per se*, psychopaths might best be described as more variable and unpredictable in their arousal tendencies than others. This hypothesis is consistent with accumulating data describing their learning performance, attention characteristics, and interpersonal behaviors. Clearly, psychopaths are more variable in the level to which they apply themselves in structured situations as well as more vulnerable to the influence of factors which do not impact so-called normals.

Some research showed that the amplitude of

electrodermal responsivity among normal participants may be proportional to the extent to which the eliciting stimuli evoke emotion or attention (Raskin, 1973). Most data on the psychophysiology of antisocial subjects have been generated in paradigms with low sensory stimulation and relatively uninteresting stimuli, such as tones. However, the extent to which stimuli may be viewed as exciting, either positively or negatively, has relevance to tests of hypoarousal theories of psychopathy, but these parameters have been explored minimally among psychopaths. Studying electrodermal activity as a measure of vicariously instigated autonomic conditioning in a time-delay paradigm and using electric shock to a model as the unconditioned stimulus (UCS), Sutker (1970) found that observing another in discomfort elicited changes in electrodermal activity in sociopathic compared to nonsociopathic men to the stimulus paired with shock. Sociopaths showed less electrodermal anticipation of shock and responded less to the shock stimulus in later conditioning trials. That sociopaths displayed greater initial responsiveness to an exciting stimulus and produced responses out of proportion to the situation suggests a pattern of hyperreactivity and rapid return to the baseline consistent with Quay's (1965) hypoarousal model.

Contrary to diminished anticipatory electrodermal activity in conditioning situations, psychopaths are not deficient in heart-rate (HR) conditioning or anticipatory HR responses preceding noxious stimulation (Hare, 1978). In fact, studies indicate that psychopaths exhibit greater HR increases to signals of impending noxious stimuli than control subjects. For example, Hare and Craigen (1974) requested psychopathic and nonpsychopathic prisoners to administer electric shocks preceded by a 10-second tone to themselves and others. In anticipation of shock to themselves or others, psychopaths showed initial HR acceleration in contrast to nonpsychopaths, whose HR decelerated. In another study, Hare et al. (1978) divided groups of psychopathic prisoners into high and low scorers on the CPI *So* Scale and exposed them to a series of 120-db tones, preceded by 12-second countdown. Subjects defined as high in psychopathy differed from the other groups in showing marked HR acceleration and small increases in electrodermal activity before tone presentation.

Hare (1978) hypothesized that anticipatory HR

acceleration observed among psychopaths in conjunction with small increases in electrodermal arousal may be part of an active process for coping with perceived threat and reducing the salience and arousing functions of premonitory cues. Using a distraction paradigm to determine whether psychopaths exhibit a pattern of HR acceleration and little electrodermal arousal when able to remove themselves physically from the warning signals, Hare (1982) found that small electrodermal responses in psychopaths were associated with decreased HR during trials that included avoidable punishment in conjunction with an opportunity for distraction from premonitory cues, rather than the increase found in previous studies. He speculated that psychopaths may use active coping mechanisms associated with the observed HR increase only when the nature of the situation forces them to attend to premonitory cues (as in countdown and classical conditioning procedures), whereas under other conditions, they may be able to focus on stimuli of immediate interest and effectively ignore warning cues.

In an interesting series of studies of arousal, Raine and colleagues collected psychophysiological data in an unselected school sample of male youths at age 15, followed the youths to determine who exhibited adult criminal behavior, and retrospectively analyzed the data to identify characteristics predictive of subsequent criminality. Raine et al. (1990a,b,c) found that youths who went on to become criminals showed electrodermal, cardiovascular, and cortical underarousal (i.e., fewer nonspecific skin conductance responses, lower resting heart rate levels, excessive theta wave electroencephalograms, and lower amplitudes of skin conductance orienting responses to a tone) and enhanced attentional processing as measured by P300 event-related potentials (ERPs). In later studies (Raine, Venables, & Williams, 1995, 1996), the sample was further subdivided into seventeen antisocial adolescents who desisted from adult crime, seventeen antisocial adolescents who became criminals by age 29, and seventeen nonantisocial, noncriminal controls. The groups were matched in demographic and, where appropriate, adolescent antisocial behavior variables. Compared to those who became criminals, subjects who desisted from adult crime exhibited significantly higher heart rate levels at age 15, more nonspecific skin conductance responses, higher amplitudes of skin conductance orienting re-

sponses, better skin conductance conditioning, and faster half-recovery time of the skin conductance response. Findings were specific to autonomic arousal because the groups did not differ in resting EEG levels, and were interpreted as suggesting that higher levels of autonomic activity during adolescence may act as a protective factor against the development of adult antisocial behavior defined by criminal conviction.

Raine and colleagues further investigated the possible protective effects of elevated autonomic arousal in different samples. Brennan et al. (1997) collected skin conductance and heart rate data in an orienting paradigm in four groups of Danish men: criminal sons with criminal fathers, noncriminal sons with criminal fathers, criminal sons with noncriminal fathers, and noncriminal sons with noncriminal fathers. Skin conductance, heart rate orienting activity, and the percentage of subjects who evidenced a skin conductance orienting response were greater among the noncriminal sons with criminal fathers than in the other groups. These results were consistent with earlier work by Raine et al. (1995, 1996) who identified elevated autonomic nervous system reactivity as an apparent protective factor for male subjects at high risk of criminal behavior, i.e., elevated skin conductance and heart rate orienting reactivity was associated with a lower likelihood of a criminal outcome. Additionally, Scarpa, Raine, Venables, and Mednick (1997) measured heart rate and skin conductance arousal in a large sample of 3-year-old Mauritian children classified on the basis of social behavior as inhibited, uninhibited, or neither inhibited nor uninhibited. They found that at this young age, inhibited children could be differentiated from uninhibited children by faster heart rate and higher skin conductance in response to a tone stimulus and, given that reduced behavioral inhibition may underlie psychopathic behavior, suggested that early detection of inhibited and uninhibited individuals may have implications for prevention of antisocial behaviors.

Two attempts to create order from the complex array of data extracted from the studies that targeted arousal characteristics among psychopaths are papers by Fowles (1980, 1984, 2001) and Ellis (1987). Both are important for their integrative perspective and suggestions of promising research directions. Drawing from a broadly-based literature on learning and motivation, Fowles (1980, 1984, 2001) called attention to Gray's (1975, 1976,

1985) hypothesized antagonistic appetitive and aversive motivational systems. The proposed aversive system is labeled the behavioral inhibition system (BIS) and is conceptualized as responsible for inhibiting behavior in punishment and extinction situations and, hence, as the substrate for anxiety. In this model, the BIS has input into the nonspecific arousal system associated with the reticular activating system. Arousal effects are thereby inferred when there is increased behavioral vigor without an increase in incentive. The BIS acts in opposition to the approach system, the Behavioral Approach System (BAS), that activates behavior in response to conditioned stimuli for rewards. Thus, two mutually antagonistic systems determine whether behavior will be activated or inhibited, and both are assumed to have positive input into the arousal system that increases behavioral vigor or intensity.

Given this background, Fowles (1980, 2001) hypothesized that the clinical aspects of psychopathy are interpretable as direct manifestations of a weak or deficient BIS in combination with a normal or strong BAS that predicts reduced sensitivity to threatening stimuli and attenuated anxiety in normally stressful situations. This assumption also predicts that reward-seeking behavior will be disinhibited by virtue of the inability of punishing conditioned stimuli and rewarding conditioned stimuli to inhibit approach responses. Fowles noted that this notion has appeal because it complements the psychophysiological evidence reviewed by Hare (1978) as well as data collected in animal experiments, where septal lesions produced similar behavioral deviance. He observed that psychopaths are not deficient in their behavioral activation system and that, therefore, reward-seeking and active-avoidance behaviors are not implicated or deficient. In a variant on this theme, Gorenstein and Newman (1980) and Newman and Wallace (1993) presented psychopaths as characterized by the most extreme form of human disinhibition and posited a functional analogy between animals with septal lesions or septohippocampal system dysfunction and psychopathy. Deriving from this "septal model" is the hypothesis that the psychopath's apparent insensitivity to punishment reflects a deficiency in response modulation, that is, difficulty in suspending a dominant set to accommodate feedback from the environment.

Taking a somewhat different approach, Ellis (1987) proposed that if psychopathy and crimi-

nality were integrally associated with suboptimal arousal, they should correlate positively with other hypothesized behavioral systems of arousal deficiency. After reviewing of the literature on arousal theory applied to criminality and psychopathy, he suggested that eight behavior patterns besides criminality and psychopathy should be enhanced by suboptimal arousal: resistance to punishment, impulsivity, childhood hyperactivity, sensation-seeking and risk-taking, neurologically active recreational drug use including heavy alcohol use, extraversion, sexual promiscuity, and poor academic performance. He concluded that the data reviewed supported the proposed relationship between criminality and psychopathy and the hypothesized behavioral manifestations of suboptimal arousal. Attempting to account for variations in these arousal tendencies, Ellis (1987) cast arousal theory in an evolutionary context and argued that hormonal and genetic factors combined to contribute to variations in criminal behavior and psychopathy.

An exciting and promising advance in the study of arousal and antisocial behavior involves recent applications of brain imaging technology. Intrator et al. (1997) used single photon emission computerized tomography (SPECT) to investigate relative cerebral blood flow (rCBF) during a semantic and affective processing task in two patient groups, PCL-R-defined psychopaths ($n = 8$) and nonpsychopaths ($n = 9$), and a normal control group ($n = 9$). Patient groups were recruited from an inpatient substance abuse program at a Veterans Affairs Medical Center. Subjects were administered a lexical decision task that required rapid identification of strings of letters as real words or nonwords. Words and nonwords were presented in separate blocks counterbalanced across subjects. One block consisted of neutral words, whereas the other block comprised emotional words. Psychopaths showed greater activation (i.e., perfusion) in the emotional condition relative to the neutral condition in four areas—the left and right frontal temporal regions and the left and right subcortical regions contiguous to them. In contrast, nonpsychopaths and controls exhibited the opposite pattern—greater activation in the neutral condition relative to the emotional condition in these areas. Groups did not differ in decision times or accuracy levels on the lexical decision task. Thus, it was unlikely that SPECT findings reflected group differences in levels of alertness or motivation.

Other studies applying brain imaging technology to the study of social deviance focused on specific antisocial behaviors such as violence. For example, Raine and colleagues used positron emission tomography (PET) to study glucose metabolism in murderers (or attempted murderers) who pleaded not guilty by reason of insanity (Raine, Buschbaum, & LaCasse, 1997). Compared to age- and sex-matched normal controls, murderers showed lowered glucose metabolism in the prefrontal cortex, superior parietal gyrus, left angular gyrus, and the corpus callosum, as well as abnormal asymmetries of activity (i.e., left hemisphere lower than right hemisphere) in the amygdala, thalamus, and medial temporal lobe (Raine et al., 1997). Subsequently, Raine et al. (1998) reanalyzed these data after subdividing the murderer group into affective murderers who acted impulsively and predatory murderers who planned their crimes. Of the forty-one murderers, fifteen were categorized as strongly predatory and constituted the predatory group, and nine murderers classified as strongly affective comprised the affective group. Murderers who were rated as neither strongly predatory nor strongly affective ($n = 17$) were eliminated from data analyses. Relative to control subjects, affective murderers showed lower left and right prefrontal functioning, higher right-hemisphere subcortical functioning, and lower right-hemisphere prefrontal/subcortical ratios. Predatory murderers exhibited prefrontal functioning similar to that of controls but significantly higher right subcortical activity. Raine et al. (1998) suggested that although excessive subcortical activity may predispose to aggressive behaviors, murderers who act emotionally, impulsively, and without planning are less able to control aggressive impulses generated from subcortical structures because of deficits in prefrontal regulatory functioning. In contrast, predatory murderers who act purposefully to achieve a goal have sufficient prefrontal functioning to regulate aggressive impulses deriving from excessive subcortical activity.

Regardless of the differences in subject selection procedures and measurement methodology, the conglomerate of attention, learning, conditioning, and arousal studies suggests certain commonalities in responding by psychopaths that set them apart from so-called normal individuals and in some instances from other clinical groups. Comparisons with psychotic and other clinical groups

have been conspicuous for their absence, although attention has been focused on clinical samples that share antisocial and schizoid or schizophrenic-like symptomatology (Crider, 1993; Goodwin & Guze, 1989; Raine, 1987; Sutker et al., 1972). The most uniform and salient findings to be extracted from the literature on arousal and psychopathy are those suggesting that psychopaths are slow to condition fear to warning signals, are less influenced by threats of punishment, are capable of anticipating negative consequences at least on some level, and are inclined to overrespond to unusual or exciting stimuli. Implications for arousal theory in accounting for sensation-seeking behaviors, problems with delay of gratification, peculiarities in attention to cues that are relevant and irrelevant, and performance in a variety of learning situations have yet to be explored fully. That such neurotic features as anxiety and depression may influence responses on many dependent variables employed in research with psychopaths suggests the need for more careful definition of subject groups, and comparisons of psychopaths with other clinical groups might shed light on both their relative areas of deficiency and their strengths.

Assessment of Antisocial Personality

Beginning with publication of the DSM-III (1980) and continuing through the publication of DSM-III-R (1987) and DSM-IV (1994), clinicians and researchers have refined their conceptualizations of psychological assessment and methodologies for identifying and describing psychopathology. Renewed interest in the area of clinical diagnosis has increased recognition of the need for multimethod, multivariate measurement and widespread attention to the problems of assuring diagnostic validity and reliability. Disorders or symptom clusters are less likely to be viewed in isolation, and requirements for uncovering comorbidities and areas of symptom overlap and differentiation are better understood. Hence, the appropriateness of simple distinctions between pathological and nonpathological groups has been called into question. Topics in clinical assessment are now scrutinized in the light of the literature on behavioral consistency over time and situations, the relationships of traits and symptoms to biological substrates, and the perspectives on continuity in behavioral nor-

mality and disorder. Assessment researchers have also become more interested in the results of studies describing relationships between specific disorders and models of personality superstructures (Cloninger, 1987; Eysenck & Eysenck, 1985; Tellegen, 1985), including the DSM-III-R and DSM-IV defined personality disorder clusters (Axelrod, Widiger, Trull, & Corbitt, 1997; O'Connor & Dyce, 1998).

Issues in classifying and labeling psychopathology are presented by Adams, Luscher, and Bernat in Chapter 1 of this volume. This discussion calls attention to the changing nature of clinical and research assessment and the proliferation of instruments developed to measure personality disorders and antisocial personality in particular. A series of reviews describes these changes in standardized measurement (Lilienfeld, Purcell, & Jones-Alexander, 1997; Reich, 1987, 1989; Widiger & Frances, 1987), and a discussion of the instruments developed for this purpose and their relative strengths and weaknesses is presented by Widiger and Trull (1993). It is worth noting, however, that unstructured approaches to clinical diagnosis have declined in popularity and usefulness, and behavior rating and symptom checklists are being superseded by more sophisticated techniques that accomplish many of the same purposes and considerably more. Complementing similar approaches to Axis I disorders, a variety of structured interview and self-report inventory methodologies is available for personality disorder diagnosis, facilitating multimethod, multivariate assessment and offer options to enhance reliability and validity.

Structured and Semistructured Interviews

Widiger and Frances (1987) described nine structured interviews for personality disorder diagnosis, and Reich (1989) added three to the list. With ongoing data collection and instrument revisions, it becomes difficult to select measures appropriate to clinical or research tasks and likely to yield data comparable to those collected by others, especially in the future. Among the more widely used instruments is the Structured Clinical Interview for DSM-IV Personality Disorders (SCID-II: First, Spitzer, Williams, Gibbon, & Benjamin, 1994), companion to the SCID-I for Axis I disorders and said to be relatively efficient in time

demands. The eighty-one-item Personality Interview Questions (PIQ-II) developed by Widiger (1987) yields nine-point ratings based on reported behaviors and patient self-evaluations, and interviewers solicit behavioral examples or supporting incidents for each symptom. Other useful interviews are the Structured Interview for DSM-III-R Personality Disorders (SIDP: Pfohl, Coryell, Zimmerman, & Stangl, 1986) and the Personality Disorder Examination (PDE) developed by Loranger and colleagues (Loranger, 1988; Loranger, Susman, Oldham, and Russakoff, 1987).

Self-Report Inventories

Multiscale inventories have been published for personality disorder diagnosis, including the Personality Diagnostic Questionnaire (PDQ: Hyler et al., 1989), Personality Adjective Checklist (Strack, 1987), and Wisconsin Personality Inventory (WISPI: Klein, Benjamin, Greist, Rosenfeld, & Treece, 1989). The most popular and widely applied instruments are the Millon Clinical Multiaxial Inventory (MCMI: Millon, 1983) and its successors, the MCMI-II (Millon, 1987) and MCMI-III (Millon, 1994), which are probably more reflective of Millon's (1981) comprehensive explication of personality disorder psychopathology than that offered by the DSM-III, -III-R, and -IV. Cloninger's (1987) Tridimensional Personality Questionnaire (TPQ) reflects an ambitious theoretical integration of relationships among neurochemical substrates and the behavioral traits of novelty seeking (dopamine system), harm avoidance (serotonergic system), and reward dependence (norepinephrine system). Presented in a 100-item forced-choice format, the TPQ may stimulate brain-behavior investigations innovatively.

Morey, Waugh, and Blashfield (1985) introduced a set of eleven scales for diagnosing personality disorder using a combined rational/empirical strategy for selecting 164 items from the MMPI pool. Although correlations among the scales in a sample of 475 patients were consistent with theoretical expectations regarding personality disorder relationships, questions have been raised about the diagnostic efficiency and validity of the MMPI personality disorder scales (Widiger & Frances, 1987). Dubro, Wetzler, and Kahn (1988) found that the scales are sensitive and specific for diagnosing any DSM-III personality disorder and for diagnosing Cluster 2 and 3 disorders; however, the instru-

ment tended to underdiagnose borderline, histrionic, and dependent psychopathology. The personality disorder scales appear to discriminate patients with specific personality disorders from normal and other personality-disordered patients (Morey, Blashfield, Webb, & Jewell, 1988), and robust correlations between MMPI PD and MCMI scale scores have been reported (Dubro & Wetzler, 1989). Preliminary studies suggest that although the PD scales warrant further testing and validation, they hold promise for clinical and research applications (Wiggins & Pincus, 1989).

Several unidimensional self-report scales have been widely accepted for identifying antisocial features. These include the MMPI and MMPI-2 Psychopathic Deviate (*Pd*) Scale, often used in combination with the MMPI Hypomania (*Ma*) Scale, and the Socialization Scale (*So*) derived from the CPI. The *Pd* Scale (Scale 4), particularly when combined with *Ma* (Scale 9), has become synonymous with the hallmark features of psychopathy or antisocial personality. Developed to identify nonconforming and antisocial individuals, or psychopathic personalities (McKinley & Hathaway, 1944), the *Pd* Scales derived from the MMPI and now the MMPI-2 have been associated with textbook definitions of the characteristics traditionally assigned to psychopaths (Gilberstadt & Duker, 1965; Graham, 1993; Marks, Seeman, & Haller, 1974). Clinical descriptions of the 4-9/9-4 and spike 4 code types emphasize irresponsible, egocentric, demanding, impulsive, poor socialization, and acting-out features. Additionally, research showed associations between *Pd* elevations and criminality (Sutker & Moan, 1973), antisocial personality in offender populations (Walters, 1985), illicit drug dependence in men and women (Sutker, 1971; Sutker, Patsiokas, & Allain, 1981), alcoholism (Kammeier, Hoffman, & Loper, 1973; Overall, 1973), and more general antisocial features (Graham, 1987, 1993). Scores on *Pd* have been used effectively in combination with *So* and indexes of psychopathology such as anxiety and depression to derive antisocial or psychopathic groups (Brown & Gutsch, 1985; Gullick et al., 1976; Heilbrun, 1979, 1982; Newman et al., 1985; Sutker & Allain, 1987), although Hare and his colleagues (Harpur et al., 1989) cautioned against using them for these purposes.

Predicated on Gough's (1948, 1960) view of sociopathy as a defect in role-taking and socialization, Gough and Peterson (1952) developed a De-

linquency (*De*) Scale which was cross-validated and revised to form the *So*. Lower scores on the fifty-four-item *So* have been related to rule breaking and norm violations (Megargee, 1972) and to performance and physiological correlates of psychopathy (Rosen & Schalling, 1971; Waid & Orne, 1982). Widom (1976a) found that lower *So* scores were associated with lopsided and idiosyncratic personal construct systems among psychopaths, and Rosen (1977) concluded that subjects can be ordered along a latent dimension of differences in role-taking ability that relate to varying degrees of general socialized behavior. Gough (1975) contended that scale scores were not significantly influenced by socioeconomic status or intelligence and could be expected to predict, as a broad dispositional variable, a range of interpersonal behaviors and social activities that in themselves might not be highly correlated. Among other scales developed to measure the psychopathy construct is Hare's (1985) Self-Report Psychopathy Scale (SRP) and the revised Self-Report Psychopathy Scale-II (SRP-II: 1996a), designed to complement his behavioral checklist. Although Hart and Hare (1997) pointed out that the SRP-II constituted part of the DSM-IV field trial for antisocial personality disorder (Widiger et al., 1996), they cautioned that scores on self-report scales should not be confused with clinical or behavioral assessments based on reliable and valid criteria for the disorder (p. 26).

Attempting to isolate the emotional and interpersonal features fundamental to a working concept of psychopathy, Blackburn (1974, 1979b) constructed the Special Hospitals Assessment of Personality and Socialization (SHAPS), a 213-item, ten-scale self-report inventory composed of MMPI items, including some from the MMPI *Pd* Scale and items from the Buss-Durkee Hostility Inventory (Bendig, 1962) and Psychopathic Delinquency Scale of Peterson, Quay, and Cameron (1959). Cluster analysis of the SHAPS indicated four broad offender classes (primary psychopathic, secondary psychopathic, controlled, and inhibited) and two factors (one defined by psychopathy and antisocial aggression; the other by shyness, introversion, anxiety, and depression). Emerging from this research, Blackburn (1987) developed forty-item Belligerence (*B*) and twenty-seven-item Withdrawal (*W*) Scales which were highly correlated with factor scores among psychiatric offender samples. Blackburn (1987) argued that the *B* Scale offered advantages over *Pd*

as a unitary measure of psychopathy, because it tapped an interpersonal dimension reflecting mistrust and lack of regard that is expressed in punitive and coercive behaviors and correlates highly with *Pd*, observer ratings of antisocial aggression, and Cleckley's criteria of psychopathy.

Behavior and Symptom Checklists

Several behavior checklists have been designed for assessing psychopathy and antisocial personality. One of their primary advantages has been to collect objective, performance-based ratings of specific symptoms and their severity applicable to individuals at certain times. Judgments are rendered by clinicians or by significant others (e.g., by parents or teachers in the case of children and adolescents), and descriptions may be generated from behavioral observations and/or reviews of medical and institutional records. Robins' (1966, 1978) research contributions have been significant in pinpointing the behavioral symptoms associated with the natural course of ASPD, as has the work of Quay and his colleagues (Peterson, Quay, & Cameron, 1959; Peterson, Quay, & Tiffany, 1961; Quay, 1964; Quay & Parsons, 1970). This latter group of investigators developed two scales, the Behavior Problem Checklist and the Checklist for the Analysis of Life History Data, to distinguish among delinquent groups, particularly for comparisons of neurotic and psychopathic delinquents (Ellis, 1982; Johns & Quay, 1962; Lee & Prentice, 1988; Orris, 1969).

The Psychopathy Checklist (PCL) and its successor, the Psychopathy Checklist-Revised (PCL-R) were developed by Hare (1980, 1991) to assess psychopathy in adult, male criminal populations. Based on Cleckley's view of the necessary and sufficient features for defining psychopathy, the PCL consisted originally of twenty-two items (twenty items in the revised 1991 version) rated on three-point scales from both interview and file information. It included items that assess personality traits such as lack of remorse or guilt and lack of empathy as well as overt behaviors such as pathological lying, irresponsible parenting, and juvenile delinquency. Interrater reliabilities have been reported in the range of .84 to .90 (Hare, 1985; Harpur et al., 1988; Hart, Forth, & Hare, 1990; Schroeder, Schroeder, & Hare, 1983), and convergent and construct validity data have been similarly supportive (Hare, 1985; Hart et al., 1988).

The PCL obtained high correlations with subjective, global ratings of psychopathy (.80) and antisocial diagnoses based on DSM-III criteria (.67), and research has suggested that the correlation of PCL-R scores with DSM-IV ASPD diagnoses may be enhanced compared to that observed with ASPD diagnoses based on DSM-III-R criteria (Stalenheim & von Knorring, 1996, 1998). As discussed earlier, much of the research with the PCL and PCL-R has focused on factors underlying the items, in addition to total scores (Harpur et al., 1988, 1989). Kosson et al. (1990) administered the PCL to a multiracial sample and noted similarities in interrater reliabilities and indexes of internal consistency for PCL ratings of Blacks and Whites; however, they reported racial differences in the distributions of PCL scores and the underlying factor structure. Other investigators found sex differences in the PCL-R factor structure (Salekin, Rogers, & Sewell, 1997).

In addition to possible racial and sex differences, concerns may be raised regarding the intended use and appropriate target populations for the PCL and PCL-R, given the nature of samples on which much of the research has been based. The instruments have been used primarily with White institutionalized men, although there are examples of application in other populations (e.g., Alterman et al., 1998). Lack of clarity concerning instrument purpose and target populations is evidenced in marketing materials for the PCL-R from the publisher, Multi-Health Systems. Catalog descriptions specify that the PCL-R is intended for use with forensic populations; however, the Hare Psychopathy Checklist: Screening Version (PCL: SV; Hart, Cox, & Hare, 1995) is listed for use with individuals in the general population as well as forensic or psychiatric populations (Multi-Health Systems, 1999). In any event, there have been increasing efforts to apply the PCL and PCL-R to diverse samples (see Hart & Hare, 1997), and recently, researchers have attempted to extend the concept of psychopathy to adolescents by using assessment instruments modeled on the PCL-R. These include the Childhood Psychopathy Scale (Lynam, 1997, 1998) and the Psychopathy Screening Device (Frick, O'Brien, Wootton, & McBurnett, 1994).

In summary, investigators and clinicians can now select from structured interview, self-report inventory, and behavioral rating technologies and can employ the more traditional types of clinical

assessment to identify personality disorders, anti-social personality in particular, and the potentially complicating psychiatric disorders listed on Axis I. Decisions are required regarding the comprehensiveness of assessment goals versus specificity of symptom definition as well as the appropriateness of measurement content. Questions of whether to sample from both normal and disordered behaviors are pivotal, and resolution of this dilemma may not be accomplished without carefully considering the samples to be selected for measurement and criterion validation, for example, community, psychiatric, and forensic samples. Hare (1985) documented the fact that convergence among self-report and interview measures for assessment of psychopathy is disappointing, but more fundamental to assessment is the absence of a universally agreed upon conceptualization of the nature of psychopathy. Thus, there is the problem of establishing validity for both assessment instruments and the construct they are purported to measure.

Summary and Conclusions

Despite arguments regarding their validity or usefulness, constructs describing persistent antisocial behaviors without demonstrable loss of reality contact have found their place in the literature on general psychopathology. The fascination of psychosocial and biological scientists with habitual rule breaking and chronic disregard for socio-legal restraints in the face of predictably negative consequences is documented by an ever-increasing bibliography of books and articles. Confusion in this literature derives from using several different labels to describe similar behavioral phenomena, from arguments centered on the significance of these definitions and their unique meanings, and from lack of clarity in defining terms. The term sociopathy and the more prevalent label psychopathy have been popularized in the psychological literature, whereas the construct of antisocial personality disorder has assumed importance for psychiatric diagnosis. This divergence between psychological research with its emphasis on psychopathy and psychiatric nomenclature positing an antisocial personality disorder has widened in the past two decades. The confusion resulting from either equating or differentiating these terms has yet to be resolved.

Dating to conceptualizations of the psychopath

as morally deranged and pathologically inferior, the notion of a psychopathic personality is founded on a behavioral deficit-excess model that is defined, on the one hand, by deficiencies in interpersonal warmth, capacity to empathize, autonomic conditioning and fear arousal, learning and other cognitive performances, and control of impulsiveness and, on the other hand, by behavioral excesses in the service of aggressive, sexual, and sensation-seeking needs. Gough (1948) proposed that psychopaths are pathologically deficient in role-playing ability, but Cleckley's (1971, 1982) clinical observations and the research of Hare and his colleagues (Hare, 1978, 1980; Harpur et al., 1989; Hart & Hare, 1997) have pointed to the psychopathic personality as prototypical of individuals who are deficient across multiple domains. Evidence is disregarded that, at least in some aspects of behavior, individuals labeled psychopathic may be similar to those considered to be functioning normally. More complex psychopathy constructs were proposed by Blackburn (1988) and Heilbrun (1982; Heilbrun & Heilbrun, 1985) who posited that fundamental deficits in socialization define the core of the psychopathy construct but tied predictions regarding severity and specificity to individual variations in such moderator variables as social withdrawal, impulsivity, and intelligence.

If psychopaths are seen as incapable of profiting from experience, are rarely distressed by their behaviors or interpersonal suffering, are unable to form emotional attachments, and are concerned primarily with the circumstances of immediate gratification, it is not surprising that predictions for response to treatment, regardless of type of intervention, have been pessimistic (Suedfeld & Landon, 1978). As greater attention has been focused on personality disorders, several papers have been published which offer hope for behavior change among antisocial individuals (Davidson & Tyrer, 1996; Kellner, 1986; Sutker & King, 1985). Treatment successes have been documented among antisocial patients enrolled in a therapeutic community (Copas, O'Brien, Roberts, & Whiteley, 1984) and methadone maintenance patients diagnosed with antisocial personality (Altermann, 2001; Brooner, Kidorf, King, & Stoller, 1998; Gerstley et al., 1989). Studies with antisocial children have shown even more promising results (Kazdin, Bass, Siegel, & Thomas, 1989; Kazdin, Siegel, & Bass, 1992; Kazdin & Weisz, 1998;

Wells & Forehand, 1985). These findings, combined with results derived from empirical tests of the psychopathy construct, suggest that antisocial behaviors, ranging from idiosyncratic to maladaptive, are subject to prescribed principles of acquisition and modification, as are any sets of behaviors that might be described in categorical terms. The contingencies for altering antisocial expression may be less apparent than for normals but need not be assumed to be nonexistent.

The research and clinical data reviewed in this chapter call into question the viability of a unitary conceptualization of psychopathy defined by pervasive personal deficits. At the same time, the construct of psychopathy has been important from the standpoint of stimulating research that describes the evolution of behavioral deviance from childhood; the contributions of genetic, familial, environmental, and learning factors to the etiology of antisocial behaviors; and the complexities involved in attempting to account for persistent behavioral deviance and specific types of nonconformity. The construct has been also useful when it has been understood that it represents a set of personality traits, cognitive styles, and emotional dispositions that may be combined in certain clusters and with varying degrees of intensity to predict severity and type of antisocial behaviors. If we assume that these characteristics are dimensional and can be identified among all population subgroups, it is possible to extend the knowledge of behavioral maladjustment and the circumstances under which it becomes exacerbated by studying personality deviation in pathological and normal samples of both sexes.

After more than five decades of clinical observations and research, it is timely to turn greater empirical scrutiny to understanding the full range of personal and situational characteristics associated with antisocial behaviors. Rather than focusing exclusively on the behavioral deficit-excess model, especially among the more disadvantaged and antisocial of our population, greater attention can be directed toward studying the strengths and weaknesses of individuals who are considered fundamentally psychopathic, particularly within the community context. This line of work might well yield findings that will enhance efforts to encourage prosocial behaviors generally and foster more effective behavioral change strategies for severely antisocial persons. It may also lead to better understanding of the mechanisms by which

psychopaths cope with fears and insecurities under trying circumstances and thus find application to stress management approaches among persons who are rendered ineffective by anxieties and fearfulness.

Borderline Personality Disorder: An Overview

**Henry E. Adams, Jeffrey A. Bernat,
and Kristen A. Luscher**

Introduction

The diagnosis of Borderline Personality Disorder (BPD) is new. It first appeared as a diagnostic entity in the *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III; American Psychiatric Association, 1980), but the concept has a long history first delineated by Stern (1938) to describe a group of patients who did not profit from psychoanalysis and did not seem to fit into the categories of neurotic or psychotic. Patients with affective lability, unstable interpersonal relationships, transient psychotic disturbances, impulsivity, and chronic suicide attempts seemed to defy categorization, and the term “borderline” denoted this diagnostic ambiguity. These confusing cases were often labeled perversive personality, psychotic personality, inadequate personality (Green, 1977), schizophrenia, latent type, pseudoneurotic schizophrenia (Hoch & Polatin, 1949), and patients with borderline states (Knight, 1953). These early conceptualizations emphasized the belief that borderline patients were suffering

from a milder form or an atypical presentation of schizophrenia.

For the next 35 years, the concept of borderline was largely confined to the psychoanalytic literature and did not appear in either the DSM-I or DSM-II (Paris, 1999). Kernberg (1975, 1984) was largely responsible for the resurgence in interest in borderline personality, particularly among psychoanalysts. Although Kernberg popularized the concept of “borderline,” he used the term to describe a level of personality organization that reflected the most serious forms of character pathology rather than a discrete personality disorder. In fact, borderline personality organization (BPO) is not specific to those patients who meet the current DSM-IV (American Psychiatric Association, 1994) diagnosis of BPD.

A turning point came in the 1970s when Gunderson and Singer (1975) developed the first operational definition of BPD, based on integrating findings in the existing empirical literature. Gunderson and colleagues were the first to demonstrate that BPD could be reliably observed, scored, and differentiated from other psychiatric disorders (Gunderson & Kolb, 1978). This empirical work, coupled with the research of others (Perry & Klerman, 1978, 1980), led to a formalized and accepted diagnosis of BPD. BPD became an “official” disorder with the publication of the DSM-III. In DSM-III, the diagnosis of BPD was reserved for the more interpersonally unstable and affectively labile patients. Schizotypal personality disorder,

on the other hand, was used to describe patients who were more closely connected to schizophrenia and more closely related to earlier descriptors of borderline patients (e.g., “pseudoneurotic schizophrenia” and “schizophrenia latent-type”) (Spitzer et al., 1979). Although BPD has undergone considerable revision since 1980, many of the essential features remain the same in DSM-IV (for a comprehensive review of criterion changes, see Gunderson, Zanarini, & Kigel, 1995).

DSM-IV Diagnostic Criteria

BPD is characterized by a pattern of instability and dysregulation across emotional, interpersonal, behavioral, and cognitive domains. In the DSM-IV, a new criterion was added to capture cognitive aspects of the disorder (i.e., transient stress-related paranoid ideation or severe dissociative symptoms). Table 1 provides the DSM-IV criteria for BPD, in which five of nine specified criteria are required. Both Linehan (1993), who reorganized and summarized the DSM-IV criteria, and Paris (1999) described the essential features of BPD. First, individuals with BPD experience *emotional dysregulation* or *affective instability*. The moods of borderline individuals are highly reactive, labile, and depend on environmental stimuli. Radical shifts in mood may occur during the course of a day. For example, Freeman and colleagues (1990) described the case of a woman who was performing competently in an advanced work setting. However, at the end of the day, she would experience extreme depression and struggled with impulses to cut herself with broken glass. These mood shifts were so transient that her supervisor was unaware of the extent or seriousness of her problems. Because of episodic mood changes, individuals with BPD are often misdiagnosed as bipolar disorder. However, the key difference is that the time frame for mood changes in BPD is hours rather than weeks or months, as in bipolar disorder (Paris, 1999). Moreover, episodes of anxiety, depression, irritability, and dysphoria usually occur in response to environmental stressors that the borderline individual feels helpless to influence (Gunderson & Phillips, 1991; Linehan, 1993; Paris, 1999). Emotion dysregulation is also exemplified by difficulty controlling and expressing anger.

Second, individuals with BPD experience *inter-*

Table 1. DSM-IV Criteria for Borderline Personality Disorder^a

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment (do not include suicidal or self-mutilating behavior covered in criterion 5)
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating) (do not include suicidal or self-mutilating behavior covered in criterion 5)
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior
6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
7. Chronic feelings of emptiness
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
9. Transient, stress-related paranoid ideation or severe dissociative symptoms

^aAPA (1994, pp. 650–654).

personal difficulties. Although they become easily involved with people, their relationships tend to be chaotic, intense, and marked with difficulty (Linehan, 1993). They may alternate from feeling completely consumed by other people to feeling totally abandoned (Megles & Swartz, 1989; Paris, 1999). Individuals with BPD are exquisitely sensitive to perceived threats of abandonment or rejection. These fears make it very difficult for them to maintain stable, close relationships. Consequently, long-standing difficulties with relationships are common. Many engage in frantic efforts to prevent significant others from leaving them. For example, it is not uncommon for individuals with BPD to take pills or self-mutilate (e.g., cut themselves) following an argument. Paris (1999) de-

scribed this *impulsive behavior* (i.e., *behavioral dysregulation*) as the sine qua non of BPD. Self-destructive, impulsive behavior, which may take the form of substance abuse, sexual promiscuity, overdosing, binge eating, and reckless behavior, is viewed as a maladaptive strategy for coping with dysphoric affect (Linehan, 1993). Indeed, the impulsive behavior pattern that is most important in identifying BPD patients is a pattern of self-injurious behaviors and suicide attempts (Gunderson, 1984; Linehan, 1993; Morey, 1988).

Another central feature of BPD is *cognitive dysregulation*. In response to stressful situations, many borderline patients experience transient, quasi-psychotic forms of thought disturbance, including auditory and visual hallucinations, dissociation, depersonalization, and paranoid ideation. Because many borderline individuals hear voices, they may be misdiagnosed as schizophrenic (Paris, 1999). However, unlike schizophrenics, individuals with BPD recognize that voices are produced from their own minds; moreover, they do not respond to them with delusional thinking (Paris, 1999). Paranoid thinking can also occur in response to stress. However, symptoms are rarely of delusional intensity and usually abate by removing or ameliorating the stressor (Linehan, 1993; Paris, 1999). Finally, borderline individuals experience *self-dysregulation*. They are often confused about their own identities and may look to the environment for clues on how to behave, what to think, and how to feel (Linehan, 1993). They may experience a profound and intolerable sense of emptiness and loneliness (Gunderson & Phillips, 1991; Linehan, 1993; Paris, 1999), and some patients report no sense of self at all.

Assessment

There are several methods for assessing personality disorders, including BPD. The most common method of assessment in clinical practice is the unstructured clinical interview (Western, 1997), but the preferred method is the semistructured or structured interview. The main advantage of the structured interview is that it provides a comprehensive, reliable, and objective assessment of personality disorder diagnosis (Segal, 1997). Zimmerman and Mattin (1999), for example, demonstrated that clinicians who used a semistructured clinical interview (i.e., the Structured Interview for DSM-

IV Personality Disorders) were significantly more likely to diagnose patients with BPD than clinicians who relied on routine unstructured clinical interviews. Moreover, without the benefit of detailed information from the semistructured clinical interview, clinicians rarely diagnosed BPD during a routine intake evaluation.

There are a number of semistructured and structured clinical interviews for categorically diagnosing DSM-IV personality disorders, including the Structured Interview for DSM-IV Personality Disorders (SIDP-IV; Pfohl, Blum, & Zimmerman, 1995), Structured Clinical Interview for DSM Personality Disorders (SCID-II; First, Spitzer, Gibbon, Spitzer, Williams, & Benjamin, 1997), International Personality Disorder Examination (IPDE; Loranger et al., 1994), Personality Disorder Interview-IV (Widiger, Mangine, Corbitt, Ellis, & Thomas, 1995), and Diagnostic Interview for Personality Disorders (DIPD; Zanarini, Frankenburg, Sickel, & Yong, 1996). For a review of the reliability and validity of these instruments, the interested reader is referred to Segal (1997). Unfortunately some of these instruments may diagnose different individuals as borderline (Perry, 1992). Thus, some researchers and clinicians prefer the Diagnostic Interview for Borderlines-Revised (DIB-R; Zanarini, Gunderson, Frankenburg, & Chauncey, 1989), which is a semistructured clinical interview designed specifically to measure BPD criteria. The DIB-R has 136 questions, which correspond to four scales: affect, cognition, impulsivity, and interpersonal relationships. In scoring the DIB-R, the latter two criteria (impulsivity and interpersonal relationships) are assigned heavier weighting; BPD is assigned if the individual scores at least eight on a ten-point total score (Paris, 1999; Reich, 1992).

Because administration of structured interviews can be extremely time-consuming, especially in clinical settings, one strategy is first to administer a screening instrument to determine whether a patient may meet criteria for BPD and then to assess further using a structured interview format (Lezenweger, Loranger, Korfine, & Neff, 1997; Widiger & Bornstein, this book). There are several screening and self-report instruments to assess personality disorder criteria, including the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) personality disorders scales developed by Morey, Waugh, and Blashfield (1985), Millon Clinical Multiaxial Inventory-III (Millon, Davis, & Millon,

1997), Personality Diagnostic Questionnaire-IV (PDQ-IV; Hyler, 1994), Wisconsin Personality Inventory (WISPI; Klein et al., 1993), Personality Assessment Inventory (PAI; Morey, 1991), and Schedule for Normal and Abnormal Personality (SNAP; Clark, 1993). The MMPI-2 and MCMI-III enjoy the most empirical support. The PAI has a Borderline Features Scale that taps four empirically derived dimensions that underlie borderline phenomenology: affective instability, identity problems, negative relationships, and self-harm. Studies have demonstrated that this scale has good internal consistency, high test–retest stability, and good convergent and discriminant validity (Morey, 1991; Trull, 1995).

Prevalence

Interest in BPD increased greatly in the last 20 years, primarily due to the growing number of individuals presenting to mental health centers and practitioner's offices. Although the prevalence of BPD was not determined in the Epidemiological Catchment Area (ECA) study or in the recent National Comorbidity Survey, several studies (e.g., Ross, 1991; Swartz, Blazer, George, & Winfield, 1990) indicate that approximately 2% of the general population meet criteria for BPD (Paris, 1999). As would be expected, this figure is elevated in clinical samples. For example, approximately 11% of individuals seen in outpatient mental health settings meet criteria for BPD (Widiger & Frances, 1989). The prevalence of BPD again increases in psychiatric inpatient settings, where approximately 19% of individuals receive a diagnosis of BPD (Widiger & Frances, 1989). Additionally, among patients diagnosed exclusively with personality disorders, the prevalence rate of BPD ranges from 30 to 60% (Widiger & Trull, 1993), which is consistent with data showing that BPD is the most common personality disorder in clinical settings around the world (Loranger et al., 1994).

Social factors, it has been hypothesized, play a role in the development of BPD (Millon, 1993), although there are no existing cross-cultural studies examining the prevalence of BPD (Paris, 1999). In the United States, approximately 75% of individuals diagnosed with BPD are women (Swartz et al., 1990; Widiger & Trull, 1993), although many have argued that this gender difference is an arti-

fact of a diagnostic sex bias (e.g., Brown, 1992; Caplan, 1991, 1995). Widiger (1998) asserts that clinicians tend to apply a sex-biased style of diagnosing personality disorders, particularly when one considers that certain personality disorders are more common in women than in men. For example, many features of BPD (emotional displays, dependence in relationships) are associated with stereotypical feminine rather than masculine characteristics. Overgeneralizations such as these ultimately can lead to an overrepresentation of women diagnosed with BPD and an underrepresentation of men diagnosed with BPD (even if they meet criteria).

The influence of sex bias was revealed in one study. Becker and Lamb (1994) mailed surveys to a variety of mental health providers, who were asked to assign diagnoses to hypothetical scenarios in which a patient met criteria either for BPD or posttraumatic stress disorder. Half of those surveyed received a "male" case, whereas half received a "female" case. "Female" cases were more frequently diagnosed with BPD than "male" cases, even when the scenarios for both men and women met criteria for BPD. An article by Zanarini and Gunderson (1997) discusses the overlap of symptoms in antisocial personality disorder (APD) and BPD. As a result of this overlap, a man presenting with behaviors that meet criteria for BPD is more likely to be diagnosed with APD, which may be a function of assigning diagnoses that are consistent with sex biases related to these disorders. Again, remaining cognizant of the natural inclination to attribute particular behaviors to one gender rather than the other is extremely important when assigning personality diagnoses, such as BPD.

Comorbidity

Axis I Disorders

Substantial evidence exists to support the fact that BPD is comorbid with many Axis I disorders, specifically, mood, panic, substance abuse, impulse discontrol, eating, gender identity, attention-deficit, and posttraumatic stress disorders (Gunderson & Zanarini, 1987; Herman, Perry, & van der Kolk, 1989; van der Kolk, 1987; Widiger & Frances, 1989). Zanarini et al. (1998), for example, compared patients with criteria-defined BPD and

participants with personality disorders to investigate DSM-III-R Axis I disorders. In a sample of 504 participants, it was found that anxiety, mood, and posttraumatic stress disorders were highly comorbid with BPD compared with participants with other personality disorders.

BPD occurs regularly with mood disorders, which is highlighted in the DSM-IV. The DSM-IV points to the fact that many of the symptoms of BPD can mimic an episode of Mood Disorder, and it becomes necessary to differentiate between common symptoms. Despite diagnostic overlap, there has been a considerable amount of research to support the notion that these two disorders are frequently comorbid. Widiger and Trull (1993) compiled all studies (though May 1989) that reported the diagnosis of a mood disorder in individuals diagnosed with BPD. Among 2015 BPD patients, it was found that 32% were diagnosed with major depression, 17% were diagnosed with dysthymic disorder, and 4% were diagnosed with bipolar disorder. As evidenced by this review, it becomes increasingly clear that a significant number of BPD patients also present with a mood disorder during the diagnostic phase.

Some concern has been raised about the comorbidity of BPD and affective disorders. As a matter of fact, some researchers have suggested that BPD is best understood as a subsyndrome or form of depression (Akiskal, Yerevanian, Davis, King, & Lemmi, 1985). Although a detailed review of the relevant literature on the overlap between BPD and affective disorders is beyond the scope of this chapter, Gunderson and Phillips (1991) provided a comprehensive review of the disorders that examined data on phenomenology, family history, comorbidity, psychopharmacology, biological markers, and pathogenesis. Briefly, the data failed to confirm a close or specific relationship between affective disorder and BPD (Gunderson, 1994). Moreover, as noted by Widiger and Trull (1993, p. 383), "what makes BPD a personality disorder is the course and phenomenology of the symptomatology, not whether there is an underlying biogenetic etiology shared by another disorder."

In addition to the comorbidity between BPD and mood disorders, evidence regarding the co-occurrence of BPD and posttraumatic stress disorder (PTSD) has surfaced in recent years. Research has indicated that a vast number of psychiatric patients with histories of childhood trauma often meet criteria for BPD (Herman, Perry, & van der

Kolk, 1989). In a study by Bryer, Nelson, Miller, and Kroll (1987), it was found that child sexual abuse was reported by 86% of inpatients diagnosed with BPD. It has been found that a history of trauma is usually common among inpatients populations, but the severity of trauma tends to be more pronounced in BPD patients (Herman & van der Kolk, 1987). Given the commonality of childhood sexual abuse in both PTSD and BPD, it becomes apparent why these disorders might be comorbid.

Dissociation is a common feature that is often associated with both BPD and PTSD. Dissociation is correlated with both the intensity of BPD symptomatology and the severity of childhood trauma (Kluft, 1990; Putnam, 1989). Given this commonality, the issue of overlapping symptomatology again becomes important in considering the comorbidity between BPD and PTSD. Considering this issue, appropriate use of criteria for both disorders is essential for determining if an individual clearly meets diagnostic standards, because the possibility for misdiagnosis can be great.

Axis II Disorders

BPD coexists with other Axis II disorders, specifically, Cluster B disorders (Zittel & Westen, 1998). Intuitively, this makes sense considering that a common element underlying Cluster B disorders (antisocial, histrionic, and narcissistic personality disorder) is impulsive and dramatic or erratic behavior. Widiger and Trull (1993) reviewed a number of studies and found that many individuals who received a diagnosis of BPD also received a diagnosis for another personality disorder. Although clinicians routinely differentiate between Axis II disorders, researchers have continually struggled with issues of diagnostic validity (e.g., high rates of comorbidity and diagnostic overlap between Axis II categories) (Zanarini & Gunderson, 1997; Zittel & Westen, 1998). Some have argued that validity problems might be resolved by replacing categories with a dimensional classification system (Widiger, 1993). In a categorical system, prototypical cases of personality disorders are relatively easy to differentiate overlapping symptomatology (Gunderson, 1984; Gunderson & Zanarini, 1987; Widiger & Frances, 1989). However, difficulty increases considerably in cases that do not present with clearly defined behavioral patterns consistent with a particular disorder. In an attempt to remedy this situation, a

great deal of time was spent clarifying diagnostic criteria for Axis II disorders during the revision of the DSM-III-R to the DSM-IV. The available evidence indicates an improvement in reliability and divergence among the DSM-IV Cluster B categories, although issues of diagnostic efficiency and convergence of criteria sets remain a problem (Blais, Hilsenroth, & Castlebury, 1997; Blais, Hilsenroth, & Fowler, 1999; Fossati et al., 1999).

Zanarini and Gunderson (1997) highlighted the overlap between BPD and other Axis II disorders and devoted specific attention to the comorbidity between BPD and antisocial personality disorder (ASPD). In an analysis of all studies that investigated the relationship between BPD and ASPD, they found that "in studies focusing on criteria-defined BPD samples, rates of ASPD comorbidity ranged from 0% to 60%, with most studies reporting rates of co-occurrence between about 10% to 25%" (p. 85). Impulsivity and instability in interpersonal relationships, common features of both disorders, may account, in part, for the high degree of comorbidity between the disorders. As Zanarini (1993) demonstrated, converging lines of evidence (reviewed later) link BPD with other psychiatric disorders that have impulsivity as a predominant feature (e.g., ASPD, substance abuse).

In addition to Cluster B disorders, BPD co-occurs with other Axis II disorders, and specific attention is given to its co-occurrence with schizotypal personality disorder (STP) (Zittel & Westen, 1998; Widiger & Trull, 1993). Research has indicated that diagnostic criteria for both STP and BPD can often be applied to the same individual (Rosenberger & Miller, 1989; Widiger, Frances, & Trull, 1987). However, with careful consideration and specific attention to subtle differences (e.g., cognitive functioning and affect), the ability to differentiate the two disorders becomes less troublesome. For example, Widiger and Trull (1993) noted that the correlation between DSM-III-R BPD and STP criterion sets was often minimal, suggesting that the two disorders represent distinct dimensions or categories. Moreover, although the inclusion of stress-induced, quasi-psychotic symptoms in the DSM-IV definition of BPD was vociferously debated mainly because of the possibility of increasing diagnostic overlap with STP, the weight of the available empirical evidence suggests that the two disorders remain readily distinguishable (Blais et al., 1997). In general, STP belongs along a spectrum of schizophrenia pathology (Meehl, 1989), whereas BPD occurs along a

spectrum of impulsivity and affective pathology (Siever & Davis, 1991; Zanarini, 1993).

This issue of comorbidity obviously presents itself when considering the diagnosis of Axis II disorders, given the commonality of personality characteristics within this subset of disorders. With this in mind, the importance of accurate assignment of personality characteristics in diagnosis becomes germane. Thorough assessment of personality characteristics is an essential component in accurately distinguishing Axis II disorders. Assessment will allow adequately diagnosing comorbid personality disorders when required. Given the evidence of high comorbidity between BPD and other Axis II disorders, appropriate consideration should be given during diagnosis to avoid incorrectly assigning diagnostic labels.

Course and Outcome of BPD

When reviewing the data on the outcome and course of the disorder, it is important to remember that the majority of studies has followed borderline patients in treatment, and thus little is known about the natural history or course of the disorder (Stone, 1989; Widiger & Trull, 1993). BPD usually begins in adolescence and peaks in young adulthood (Paris, 1999). If borderline individuals survive their 20s and early 30s, the symptoms tend to "burn out" by age 40 or 50 (Zittel & Westen, 1998).

Short-term follow-up studies (e.g., Barasch et al., 1985; Stevenson & Meares, 1992) indicate that 60–70% of individuals who are diagnosed with BPD continue to meet diagnostic criteria 2 to 3 years after the initial assessment. Intermediate outcome studies (e.g., Pope, Jonas, Hudson, Cohen, & Gunderson, 1983) indicate that 57–67% of BPD patients continue to meet diagnostic criteria 4 to 7 years after the index assessment (Linehan & Heard, 1999). At 5-year follow-up, most patients show little to no improvement in functioning (e.g., Paris, 1988; Stone, 1989; Zanarini, Chauncey, Grady, & Gunderson, 1991). However, more recent studies (e.g., Linehan, Armstrong, Suarez, Allmon, & Heard, 1991; Najavitz & Gunderson, 1995) indicate that borderline patients can show functional improvement in 1 to 3 years, which may reflect advancements in treatment.

Long-term outcome studies (e.g., McGlashan, 1986; Paris, Brown, & Nowlins, 1987; Plakun, Burkhardt & Muller, 1985; Stone, 1990) indicate

that diagnosable BPD usually remits by middle age. Both Stone (1990) and Paris et al. (1987) found that 75% of patients diagnosed as borderline during early adulthood no longer met criteria at 15-year follow-up. Nonetheless, considerable variability exists in functional outcome, and long-term recovery was rarely complete (Paris, 1999; Widiger & Trull, 1993). For example, 10 to 30 years after initial diagnosis, about one in five patients in Stone's (1990) sample were living normal symptom-free lives, whereas about one in three still showed major symptoms. Prognosis was better for patients who were intelligent, attractive, had artistic talents, or who were described as more likable, whereas prognosis was poorer for patients who had alcohol or substance abuse problems, histories of physical or sexual abuse, severe problems with impulsive behavior, and comorbid antisocial or schizotypal personality features. McGlashan (1992), who conducted a review of the literature on the course of BPD, concluded that better long-term outcome was associated with higher intelligence; lower-affective lability; less chronicity; and an ability to experience pleasure, contain aggression in relationships, and tolerate psychological pain.

Suicide is one of the major risks for borderline patients observed in these and other studies (Zittel & Westen, 1998). In general, BPD patients have a high rate of suicide completion. Although McGlashan (1986) found a suicide rate of 3%, both Paris (1993) and Stone (1990) found completed suicide rates of 8 to 9%. Based on a review of eight outcome studies, Linehan and Heard (1999) estimated the average suicide rates at 7.8%. Breaking this down over time periods, the average suicide rate among patients followed in short-term studies (i.e., 3 years after the index point) was 4.22%, whereas for studies that estimated suicide rates from 4 to 7 years and 13 to 20 years, the average rates were 7.53 and 7.65%, respectively. A consistent finding among all of these studies is that most suicides occur within the first 5 years of the index assessment (Linehan & Heard, 1999; Paris, 1999; Zittel & Westen, 1998).

Etiology

When examining etiologic factors associated with BPD, it is important to note that biological and psychological factors interact in multiple ways to shape the course of the disorder. Paris

(1999) distinguished between necessary and sufficient conditions for BPD. He applied a diathesis-stress model (Monroe & Simmons, 1991) to explain the etiology of the disorder. In his biopsychosocial model (Paris, 1994, 1999), biological factors are considered necessary for borderline psychopathology to take particular form, but genetic vulnerabilities by themselves are not sufficient causes of the disorder. Psychological and social factors, although insufficient causal factors, probably best determine which vulnerable individuals develop BPD. Therefore, psychological conditions may be necessary but not sufficient causes for developing BPD (Paris, 1999). With this biopsychosocial model in mind, we review the empirical literature on biological and psychological factors implicated in BPD.

Biological Factors

There has been limited genetic research on BPD. To date, there are no adoption studies of BPD. The only twin study was conducted by Torgersen (1984), who did not find any concordance for BPD among seven monozygotic pairs, although his original sample was too small to make definitive conclusions. In subsequent work, Torgersen (1986) examined a larger sample of twins and established that BPD has a particularly low index of heritability, compared with most of the other personality disorders. Paris (1999) noted that studies of normal twin populations (e.g., Jang, Livesley, Vernon, & Jackson, 1996; Livesley, Jang, Schroeder, & Jackson, 1993) provide support for the heritability of certain personality traits seen in BPD (e.g., impulsivity, affective instability, and cognitive symptoms) (see also Plomin, Defries, McClearn, & Rutter, 1997). However, evidence for the genetic heritability of the specific disorder is essentially nonexistent, which makes BPD no different from other Axis II disorders (McGuffin & Thapar, 1992; Nigg & Goldsmith, 1994; Paris, 1994).

Family history studies (e.g., Akiskal et al., 1985; Androlonis & Vogel, 1984; Links, Steiner, & Huxley, 1988; Zanarini et al., 1988) examined the prevalence of psychiatric disorders among the first-degree relatives of individuals with BPD. One of the most consistent findings is that BPD tends to "breed true" (Links et al., 1988; Zanarini & Frankenberg, 1997) because borderline individuals are five times more likely to have first-degree relatives with BPD than by chance alone (Gunder-

son, 1994; Zittel & Westen, 1998). Some have suggested that this represents genetic transmission of the disorder (e.g., Baron, Risch, Levitt & Gruen, 1985), although only twin and adoption studies can separate genetic from environmental influences. In addition, family history studies have documented a higher frequency of relatives with other impulse spectrum disorders, namely, alcoholism, substance abuse, and antisocial behavior (Paris, 1999; Zanarini et al., 1993). There is also a greater frequency of unipolar major depression, but only in the relatives of BPD patients with concurrent major depression (Pope et al., 1983; Gunderson & Phillips, 1991; Paris, 1999).

Research has yet to reveal any biological markers that are specific to BPD (Gunderson & Phillips, 1991; Paris, 1999). For example, biological markers for depression, such as abnormal dexamethasone suppression (DST) or decreased REM latency, occur only in BPD patients who are also depressed (Gunderson & Phillips, 1991; Gunderson, 1994). Zanarini and Frankenburg (1997), who summarized the results of EEG studies, arrived at a similar conclusion. At least two studies reported a significantly higher rate of abnormal EEG findings among BPD patients relative to depressed controls (Cowdry, Pickar, & Davies, 1985–1986; Snyder & Pitts, 1984). However, two other studies found that the rates of abnormal EEG findings in BPD patients and Axis II control patients were roughly comparable (Cornelius, Brenner, Soloff, Schulz, & Tumuluru, 1986; Zanarini, Kimble, & Williams, 1994). Paris (1999) noted that a more sophisticated EEG study, which examined “P-300” event related potentials (Kutcher, Blackwood, Clair, Gaskell, & Muir, 1987), revealed that BPD patients had abnormal EEG findings resembling those seen in schizophrenia. However, it should be underscored that biological markers, even when found, do not necessarily demonstrate a biological etiological factor (Paris, 1994, 1999). Moreover, research strategies that attempt to localize specific brain deficits may be far too simplistic because the causes of BPD, it is thought, are multidimensional, complex, and interactive.

Thus, it is not surprising that studies that have used neuroimaging techniques with BPD patients have also produced mixed findings. Two studies found that BPD patients had normal CT scans (Schulz et al., 1983; Snyder, Pitts, & Gustin, 1983). By contrast, two other studies found that a small

percentage of borderline patients had abnormal CT scans, although the rates of abnormal scans were not significantly different from those seen in normal participants or patients with other personality disorders (Lucas, Gardner, Cowdry, & Pickar, 1989; Zanarini, Kimble, & Williams, 1994). To date, only two studies examined PET scans in BPD patients (Goyer, Konicki, & Schulz, 1994; Leyton et al., 1997), although the sample sizes were rather small. Goyer et al. (1994) found reduced brain activity in the frontal and parietal lobes of BPD patients. The strongest findings link brain metabolism with aggressive and impulsive traits, suggesting that biological markers are more specific to borderline traits than the disorder *per se* (Paris, 1994, 1999).

Similar conclusions were reached from biochemical studies that examined markers associated with impulsivity (Coccaro et al., 1989; Hollander et al., 1994; Martial et al., 1997). In these studies, that typically assess serotonergic activity by the flenfluramine challenge test, BPD patients show decreased serotonergic activity relative to control subjects. However, this deficit is more specific to those patients who score high on traits of impulsivity and aggression than BPD *per se*. Moreover, levels of the serotonin metabolite 5-HIAA in the cerebrospinal fluid are not significantly lower in BPD than in control patients unless the BPD patients also have histories of suicide attempts (Gardner, Lucas, & Cowdry, 1990; Paris, 1999).

Additionally, some evidence supports the notion of a biological relationship between affective instability and increased sensitivity of the cholinergic and noradrenergic systems, although there are no clear biological markers related specifically to BPD or other personality disorders (Figuroa & Silk, 1997; Steinberg, Trestman, & Siever, 1994). Finally, several researchers (Andrulonis, Blueck, Stroebel, & Vogel, 1982; Gardner, Lucas, & Cowdry, 1987; van Reekum, Links, & Boiago, 1993) found that individuals with BPD have a significantly greater number of soft neurological signs, compared to normal controls. However, these markers are rather nonspecific (e.g., they occur in other patient populations as well) (Zanarini et al., 1994).

In summary, existing evidence implicates a number of biological systems that may play a role in BPD, although no biological markers are spe-

cific to BPD. Some BPD patients, particularly those with comorbid depression, may share some of the hypothalamic-pituitary-adrenal (HPA) abnormalities of depressed patients, as revealed by the DST and REM-latency onset studies (Figuroa & Silk, 1997). Other BPD patients, mainly those with impulsive traits, may have abnormalities in the serotonergic system. There are also nonspecific abnormalities in the cholinergic and adrenergic systems, which may be related to symptoms of dysphoria, emotional lability, and hyperreactivity to environmental stimuli (Figuroa & Silk, 1997).

Psychological Factors

There is a substantial amount of evidence that psychological factors play a role in the development of BPD (Paris, 1994, 1999). The risk factors tend to be related to a variety of childhood experiences and fall into three broad categories: childhood trauma, early parental separation and loss, and disturbed family environment and abnormal parental bonding (Paris, 1994, 1999; Zanarini & Frankenburg, 1997).

Childhood Trauma

Research findings suggest that borderline individuals report a high rate of childhood trauma. A number of studies showed that childhood physical abuse is more commonly reported by BPD patients than by controls (Herman et al., 1989), but some researchers have not found such associations (Ogata, Silk, Goodrich, et al., 1990). The most consistent finding is the association between childhood sexual abuse (CSA) and BPD. Approximately 50 to 70% of BPD patients report CSA (Paris, 1994; Zanarini et al., 1993; Zittel & Westen, 1998). Additionally, CSA has a strong association with BPD independent of other factors such as neglect or loss (Ogata et al., 1990; Paris et al., 1994a). In the light of these findings, childhood trauma has been proposed by some (Herman & van der Kolk, 1987) as an explanation for the etiology of BPD. However, Paris (1999) identified several problems in interpreting findings on CSA.

First, CSA lacks specificity as an etiologic risk factor for BPD. For example, childhood trauma is frequently reported in both BPD patients and patients with other personality disorders (Paris et al.,

1994a,b). More fundamentally, many individuals who experience childhood trauma, including sexual abuse, do not go on to develop BPD. In fact, there is a wide range of clinical outcomes in individuals with CSA (e.g., depression, PTSD, substance abuse, normal presentation). Thus, childhood trauma, it is thought, represents a general risk factor for psychopathology rather than a cause of any one specific disorder (Browne & Finkelhor, 1986; Paris, 1999).

Another problem is that most studies have not systematically examined that parameters or characteristics of sexual abuse (e.g., the identity of the perpetrator and the severity, frequency and duration of the abuse), which are better predictors of clinical outcome than sexual abuse alone (Browne & Finkelhor, 1986; Paris, 1999). In a series of studies, Paris et al. (1994a,b) measured parameters of CSA severity in a sample of BPD patients. Severity of sexual abuse was much more strongly related to BPD than abuse alone. Thus, it appears that the long-term outcome of sexual abuse partially depends on these parameters.

Additionally, Paris (1999) noted that most research has not systematically teased apart the relationship between CSA and concomitant risk factors. For example, CSA frequently occurs in a chaotic and pathological family environment (Finkelhor, Hotaling, Lewis, & Smith, 1990). In community studies, the long-term effects of CSA were explained by their intercorrelations with abnormalities in family functioning (Nash et al., 1993). Additionally, research has not considered how CSA might interact with biological risk factors, such as childhood temperament and personality features (Paris, 1999). Finally, the effect size of the association between CSA and BPD is not very large. Fossati et al. (1999) conducted a meta-analysis of twenty-one published studies and found only a moderate pooled correlation (.279) between CSA and BPD.

In summary, childhood trauma, and sexual abuse in particular, represent psychological risk factors in the development of BPD. However, the magnitude of their effects are not specific and probably depend on multiple interacting factors, such as the parameters or characteristics of the abuse, the presence or absence of a supportive family environment, the temperament of the child, and the existence of additional biological and psychological risk factors. Future research needs to

sort out these interactions by examining the impact of childhood trauma using a multidimensional framework (Paris, 1997). Additionally, longitudinal studies need to be carried out to examine changes in functioning over time.

Parental Separation and Loss

Several studies examined the prevalence of early separations and losses in the childhood histories of BPD patients (e.g., Akiskal et al., 1985; Links, Steiner, Offord, & Eppel, 1988; Soloff & Millward, 1983; Zanarini, Gunderson, Marino, Schwartz & Frankenburg, 1988). Zanarini and Frankenburg (1997) summarized the major findings of these studies. First, early separations and losses are common among patients with BPD (approximately 37–64% of BPD patients report early parental separation or loss, depending on the study). Second, prolonged separations and early losses tend to discriminate BPD patients from other psychiatric patients, including those with psychotic, affective, or other personality disorder diagnoses.

However, Paris (1999), who also reviewed studies on parental separation and loss, reached a somewhat different conclusion. He noted that most studies that supported a relationship between BPD and parental separation/loss compared borderline patients with depressed patients. Moreover, some studies failed to confirm these differences (Ogata et al., 1990). For example, Paris et al. (1994a,b) compared BPD patients with patients who had other personality disorders. Although early separation and losses were frequent in BPD patients, they occurred just as frequently in individuals with other Axis II disorders. Indeed, Paris (1999) noted that a history of early separation and loss is quite frequent in normal populations (Tenant, 1988) and is not specific to any type of psychopathology. Most likely, if early separation and loss does play an etiological role in BPD, it does not lead to the disorder by itself (Paris, 1999; Rutter, 1989).

Disturbed Family Environment and Parental Bonding

Although the data on family environment and parental bonding are largely based on retrospective accounts of childhood experiences, if we are to believe the reports of BPD patients, then malig-

nant family experiences cannot be overlooked. The early clinical literature suggested that BPD arose out of overinvolved, hostile-dependent, and separation-resistant families (Gunderson, 1994). However, empirically studies indicated that rather than overinvolvement, there was significant emotional neglect of children who later developed BPD (Gunderson, Kerr, & Englund, 1980). Family history studies consistently documented the fact that many borderline individuals grew up in severely dysfunctional family environments characterized by neglect, conflict, hostility, and chaotic unpredictability (Links, 1990; Gunderson & Zanarini, 1989). In addition to living in chaotic and unpredictable home environments, many BPD patients perceive having had abnormal bonding with their parents that involve both neglectful and overprotective responses (Frank & Paris, 1981; Soloff & Millward, 1983; Zanarini et al., 1993). These findings are consistent with environmental and biosocial theories of BPD (Adler, 1985; Linehan, 1993) that emphasize the etiological significance of chaotic and unpredictable environments in the development of BPD.

Adler (1985), for example, postulated that parents who fail to provide a supportive and protective environment do not allow their children to develop the skills necessary to regulate emotions and buffer emotional distress. One consequence of emotional neglect is that children learn to regulate negative emotions through impulsive behavior (Paris, 1999). According to Linehan (1993), an “invalidating environment” consistently communicates to the individual that his or her behaviors and reactions are not appropriate or valid responses to events. Children who are raised in an “invalidating environment” never receive adequate training or parental modeling to learn necessary skills to regulate arousal and tolerate emotional distress. Children instead learn that drug abuse, promiscuity, and self-injurious behavior produce temporary relief from stress. Additionally, children do not learn to trust their own reactions as valid, and consequently may have to rely on the environment to provide information about how to feel, think, and act (Linehan, 1993). BPD, it is thought, arises from a combination of these malignant environmental influences (e.g., chaotic and unpredictable family environments, sexual abuse, neglect, etc.) interacting with biologically based deficits in emotional processing and their transaction over time (Linehan, 1993). For a com-

prehensive review of the theories of BPD, the interested reader is referred to Millon (1992) and Paris (1999).

Treatment

Few clinicians would disagree that individuals with BPD represent one of the most challenging and difficult to treat populations. Although various psychosocial treatments have been developed (e.g., psychodynamic, interpersonal, behavioral, and cognitive treatments), few enjoy strong empirical support. Pharmacotherapy has proven useful as an adjunctive treatment of BPD. These treatments are briefly described and evidence supporting their efficacy is reviewed.

Dialectical Behavior Therapy

Dialectical Behavior Therapy (DBT) is a form of cognitive behavioral therapy that was originally developed as a treatment for chronically suicidal individuals who meet criteria for BPD (Linehan, 1993). DBT uses a combination of directive, problem-solving, and behavioral change strategies, coupled with nondirective techniques that promote acceptance and empathy. DBT includes individual and group therapy. The group component involves psychoeducation and teaching patients behavioral coping skills, including distress tolerance, interpersonal effectiveness, emotion regulation, and mindfulness (Linehan, 1993). Individual therapy focuses on six goals addressed in hierarchical priority: suicidal behavior, therapy-interfering behavior, behaviors that interfere with quality of life, behavioral skill acquisition, post-traumatic stress symptoms, and self-respect behaviors.

DBT is one of the only treatments for BPD that has been subjected to careful empirical scrutiny. Linehan et al. (1991) conducted the first randomized controlled clinical trial with BPD patients. Forty-four women diagnosed with BPD and histories of parasuicidal behavior were randomly assigned to either 1-year DBT or treatment as usual (TAU) in the community. At the end of 1 year of outpatient treatment, women who received DBT were significantly less likely to attempt suicide or drop out of therapy than women in the TAU group. Women who received DBT also spent significantly less time in psychiatric inpatient hospi-

tals, had fewer and less medically severe episodes of parasuicidal behavior, were better adjusted interpersonally, and reported less anger (Linehan et al., 1991, 1994). However, the groups did not differ on measures of depression, hopelessness, or suicidal ideation at the completion of the trial.

DBT has also proven effective for treating more severely dysfunctional BPD patients. For example, Barley et al. (1993) found that BPD inpatients who received DBT in conjunction with standard inpatient treatment (SIT) had significantly fewer incidents of parasuicidal behavior than inpatients who received only SIT. Moreover, Linehan et al. (1999) demonstrated that DBT is more effective than treatment as usual in reducing drug use among women with BPD and comorbid substance abuse problems. Future empirical studies are needed to determine the long-term effectiveness of DBT.

Psychodynamic Treatment

Psychodynamic approaches enjoy a long-standing history in treating BPD. Many studies reported significant improvements in patient functioning following psychodynamic treatment (e.g., Adler, 1985, 1989; Buie & Adler, 1982; Kernberg, 1984, 1987; Masterson, 1976, 1981; Stevenson & Meares, 1992). Unfortunately, most psychodynamic clinicians have supported claims of effectiveness on the basis of data from case studies and uncontrolled outcome or longitudinal studies (Linehan & Heard, 1999).

The exceptions are two independent groups of investigators who evaluated psychodynamic treatment approaches using controlled outcome designs. The first studies were conducted by Marziali and colleagues (Clarkin, Marziali & Munroe-Blum, 1991; Munroe-Blum & Marziali, 1988, 1995) who compared psychodynamic group therapy with individual psychodynamic therapy (control condition). The psychodynamic group treatment, called relationship management therapy (RMT), is a time-limited approach that uses a cotherapist model and focuses on interpersonal transactions and their outcomes. Within the group setting, individuals are encouraged to express internalized conflicts around self-attributes, and feedback is provided by cotherapists and other group members. At 12- and 24-month follow-up, the investigators found no significant differences between the treatment groups on major outcome measures.

However, both groups demonstrated significant improvements on all major outcomes at follow-up, which suggests that psychodynamic group therapy may be a more cost-effective method of delivering services than individual psychodynamic therapy (Linehan & Heard, 1999).

In a more recent randomized clinical trial, Bate-man and Fonagy (1999) compared the efficacy of a psychodynamically oriented partial hospitalization treatment (PHT) with standard psychiatric care for patients with BPD. PHT included both individual and group psychodynamic treatment and occurred for a maximum of 18 months. At the end of 18 months, patients who were partially hospitalized were significantly less likely to attempt suicide, engage in self-mutilatory acts, or to be admitted inpatient for psychiatric hospitalization, compared to patients who received standard psychiatric care. Additionally, patients who were partially hospitalized reported significant reductions in anxiety, depression, and general distress, and improvements in interpersonal functioning and social adjustment, whereas patients who received standard psychiatric care demonstrated either limited changes or deterioration during the 18-month period. For most outcomes, improvements in the partial hospitalization group began at 6 months and were maintained at 18 months. Although replication is needed with larger groups, these findings suggest that partial hospitalization may represent an effective alternative to standard inpatient treatment, especially for severely dysfunctional BPD patients.

Pharmacotherapy

A number of pharmacotherapeutic studies were conducted using randomized controlled procedures (for reviews, see Brinkley, 1993; Dimeff, McDavid, & Linehan, 1999; and Soloff, 1994). The four major BPD symptoms at which pharmacotherapy has been targeted are affective instability, impulsive behavior, transient psychotic symptoms, and anxiety (Soloff, 1994). The effects of a number of drugs have been tested, including neuroleptics (Cowdry & Gardner, 1988; Goldberg et al., 1986), antidepressants (Cornelius, Soloff, Perel, & Ulrich, 1990; Parsons et al., 1989), anti-convulsants (Cowdry & Gardner, 1988), and lithium carbonate (Links, Steiner, Boiago, & Irwin, 1990). In general, pharmacotherapeutic agents have proven effective in decreasing depression,

anger, impulsive behavior, psychosis, and other forms of cognitive disturbance (Linehan & Heard, 1999); however, treatment effects are generally considered modest, and most agents have been tested only during short periods of time (Soloff, 1994). Additionally, medications should be monitored carefully in this population because of the potential for misuse, drug abuse, or use for suicide attempts (Linehan, 1993). Pharmacotherapy should be considered a useful adjunct to psychotherapy in treating BPD (Linehan & Heard, 1999; Soloff, 1994).

Summary

The overview of the borderline personality disorder literature reveals that this category continues to evolve, despite its relative recent history in the DSM. Perhaps the most significant improvements will come from systematic research that attempts to resolve the controversy whether the disorder is best conceptualized as a category or personality dimension. Nonetheless, the DSM-IV diagnosis describes a reliable and valid construct. Additional research is also needed to gain a better understanding of the etiology of the disorder, including systematic investigations of the interplay among biological factors, genetic vulnerabilities, and psychological and social risk factors. The use of prospective, longitudinal designs studying large cohorts of children will provide a better understanding of the development, etiology, course, and prevention of the disorder. It is expected that advances in basic research will also translate into breakthroughs in treatment, which ultimately may improve the quality of life for BPD patients.

Histrionic, Narcissistic, and Dependent Personality Disorders

Thomas A. Widiger and Robert F. Bornstein

Introduction

All of the DSM-IV personality disorders share at least some features in common (e.g., impaired interpersonal relationships, distortions in self-concept). Numerous classification systems have been proposed to organize personality disorder pathology into categories, dimensions, or clusters that would share certain underlying commonalities and would be distinguished with respect to others. Only a few of these systems have been widely accepted, and most have been widely criticized. Perhaps any grouping of personality disorders, and particularly any categorical distinctions, will create certain difficulties, even as it resolves others.

This chapter is concerned with histrionic, narcissistic, and dependent personality disorders. The inclusion of these disorders within the same chapter does not necessarily suggest a common issue or unifying theme that naturally joins them or distinguishes them from other disorders of personality. All three have their roots within psychodynamic

theory, but this can also be said for other personality disorders (e.g., obsessive-compulsive and borderline). All three disorders may also be characterized by high levels of dependency needs (including the histrionic and the narcissistic, if one includes implicit needs), but the same may again be equally true for other personality disorders (e.g., borderline). Histrionic, narcissistic, and dependent personality disorders also share some common issues and controversies (e.g., gender and cultural biases), but whatever issues they share will apply as well to the other personality disorders. Historically, they have been among the less frequently researched personality disorders, but now there is a substantial amount of research supporting their validity, particularly for the dependent and narcissistic personality disorders. Each will be discussed in turn, and each presentation is organized with respect to its diagnosis, assessment, epidemiology, etiology, and pathology.

Histrionic Personality Disorder

Histrionic personality disorder is defined in the 4th edition of the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as "a pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts" (APA, 1994, p. 657). The

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

diagnosis was not included in the first edition of the DSM (APA, 1952), although some of the persons who were given the DSM-I diagnosis of emotionally unstable personality were probably given the DSM-II diagnosis of hysterical personality (APA, 1968). The narrative description of the disorder provided in DSM-II is still applicable today:

These behavior patterns are characterized by excitability, emotional instability, over-reactivity, and self-dramatization. This self-dramatization is always attention-seeking and often seductive, whether or not the patient is aware of its purpose. These personalities are also immature, self-centered, often vain, and usually dependent on others. (APA, 1968, p. 43)

The DSM-III-R diagnostic criteria referred to such traits as constantly seeking reassurance, approval, or praise; inappropriately sexually seductive; overly concerned with physical attractiveness; exaggerated emotional expression; uncomfortable when not the center of attention; rapidly shifting and shallow expression of emotions; self-centeredness; and impressionistic speech (APA, 1987). These diagnostic indicators were consistent with the descriptions provided within the recent and past clinical literature (Pfohl, 1991), but significant concerns have also been raised regarding their validity, consistency with clinical theory, and consistency with clinical practice (Blashfield & Davis, 1993; Bornstein, 1999).

Blashfield and Breen (1989) presented the 142 DSM-III-R personality disorder diagnostic criteria to sixty-one clinicians and asked them to indicate the personality disorder "with which [they] believe this criterion is associated" (p. 1576). The histrionic criteria were assigned to the histrionic personality disorder only 41% of the time, consistent with an earlier study by Blashfield and Haymaker (1988). Five of the eight criteria were misassigned more than half of the time. The worst criterion from this perspective was self-centeredness. This criterion was assigned to the histrionic diagnosis by only 8% of the clinicians; assigned instead to the narcissistic by 66%. Blashfield and Breen (1989) concluded that "these results strongly suggest that the DSM-III-R definition of histrionic does not match the definition for this category that is used by contemporary American clinicians [and] this category needs a major change in definition in DSM-IV" (p. 1578).

Blashfield and Herkov (1996) asked 320 clinicians to select one of their patients whom they knew well and was considered to have a person-

ality disorder. They were asked to indicate the personality disorder diagnosis they had assigned to the patient and to indicate on a scrambled list which of the DSM-III-R personality disorder diagnostic criteria were present. Thirty-nine of the patients had been given a clinical diagnosis of histrionic personality disorder, but sixty-five were assigned a sufficient number of histrionic diagnostic criteria to be given the diagnosis. Kappa for the agreement between their clinical diagnoses and the diagnoses that would be provided on the basis of their own assessments of the diagnostic criteria was only .30, consistent with the kappa of .27 in a comparable study by Morey and Ochoa (1989) with the DSM-III criteria sets. "Our study supports the Morey and Ochoa finding that there is a poor correspondence between the clinicians' diagnoses of patients and what DSM-III-R disorders these patients would meet if the clinicians strictly adhered to the DSM-III-R rules" (Blashfield & Herkov, 1996, p. 223).

When diagnosticians do adhere to the rules, the histrionic criteria set does not identify a qualitatively distinct personality disorder. Widiger and Rogers (1989) summarized the results across prior published studies and indicated that at least 80% of the persons who met the DSM-III-R criteria for histrionic personality disorder were likely to meet the criteria set for another personality disorder. Widiger and Trull (1998) reported the percentage of co-occurrence for the diagnosis of DSM-III-R histrionic personality disorder averaged across unpublished data sets involving more than 1000 patients obtained from six independent research teams. A singular diagnosis was rare, and "at least a third of those with histrionic personality disorder met the criteria for borderline and narcissistic" (Widiger & Trull, 1998, p. 362). Stuart et al. (1998) reported the co-occurrence rates obtained from data for 1116 patients pooled from several research sites that had administered the same semistructured interview. Ninety-three of the patients (8.3%) met the DSM-III-R criteria for histrionic personality disorder, and more than 40% met the criteria for the paranoid, narcissistic, borderline, dependent, and passive-aggressive personality disorders. Consistent with Widiger and Trull, the greatest overlap was with the borderline and narcissistic personality disorders (51% met the criteria for borderline, and 73% met the criteria for narcissistic).

Table 1 provides the DSM-IV diagnostic criteria

**Table 1. DSM-IV Criteria
for Histrionic Personality Disorder^a**

A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) is uncomfortable in situations in which he or she is not the center of attention
- (2) interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
- (3) displays rapidly shifting and shallow expression of emotions
- (4) consistently uses physical appearance to draw attention to self
- (5) has a style of speech that is excessively impressionistic and lacking in detail
- (6) shows self-dramatization, theatricality, and exaggerated expression of emotion
- (7) is suggestible, i.e., easily influenced by others or circumstances
- (8) considers relationships to be more intimate than they actually are

^aAPA (1994, pp. 657–658).

for histrionic personality disorder. A major intention of the revision was to increase the criteria set's specificity and its consistency with clinical theory (Pfohl, 1991). The two most problematic DSM-III-R criteria, as suggested by the psychometric data, were (1) constantly seeks or demands reassurance, approval, and praise; and (2) self-centeredness (Pfohl, 1991). Both were deleted. Constantly seeking or demanding reassurance, approval, and praise was replaced by the DSM-IV seventh criterion of suggestibility; self-centeredness was replaced by the DSM-IV eighth criterion of considering relationships more intimate than they really are. The latter criterion was obtained from the clinical literature and from suggestions by consultants to DSM-IV who were experts in the diagnosis of histrionic personality disorder (Pfohl, 1991, 1995). Pfohl (1995) has suggested that DSM-IV suggestibility was simply a rewording of DSM-III-R constantly seeking or demanding reassurance, approval, or praise. However, it is perhaps better understood as a new criterion because it was obtained from the World Health Organization's (1992) research criteria set and was included in

large part to increase the congruence of DSM-IV with the international nomenclature (Widiger et al., 1995). Being suggestible or easily influenced by others is consistent with clinical descriptions of the disorder (Pfohl, 1991), but these traits are unlikely to correlate highly with constantly seeking or demanding approval or praise (Schooler & Loftus, 1986).

The order in which the personality disorder diagnostic criteria are provided in DSM-IV is consistent with their validity in the diagnosis of the disorder, based largely on psychometric research using the DSM-III-R criteria sets (Widiger et al., 1995). The exceptions to this rank ordering are the new diagnostic criteria. They are typically placed at the end of the list not because they might be less diagnostic of the disorder, but simply because there was inadequate data to justify placing them above any of the other diagnostic criteria. Suggestibility and misperceiving the intimacy of relationships are placed at the end of the list in DSM-IV because they are new diagnostic criteria. Being uncomfortable in situations in which they are not the center of attention and inappropriately sexually seductive behavior are placed at the beginning of the list because they are considered the most highly diagnostic indicators. DSM-IV also provides substantially more discussion and explication of the meaning and application of each diagnostic criterion within the text than was provided in DSM-III-R (Frances, First, & Pincus, 1995). Further discussions of each diagnostic criterion are provided by Widiger et al. (1995), and additional experimental criteria for histrionic personality disorder are provided by Pfohl (1995) and Shedler and Westen (1998).

It is unclear whether the revisions to the histrionic criteria set will appreciably affect those who now receive the diagnosis. Morey (1988) indicated that the DSM-III-R and DSM-III criteria sets for histrionic personality diagnosed the same percentage of persons (22%) in their sample of 291 patients, but not necessarily the same persons. Kappa for the agreement between the two criteria sets was .66, which was significant and was the third highest of the criteria sets. Blashfield, Blum, and Pfohl (1992) obtained a comparable rate of agreement ($\kappa = .55$) but they indicated that they had expected much more disagreement, given the substantial revisions to the DSM-III criteria set provided by DSM-III-R (Widiger, Frances, Spitzer, & Williams, 1988). Blais, Hilsenroth, and Castlebury

(1997) reported a substantial decrease in the number of persons likely to receive the histrionic diagnosis using DSM-IV in comparison to DSM-III-R, from 14% in their sample of ninety-four patients with DSM-III-R to only 4% with DSM-IV ($\kappa = .34$).

Linde and Clark (1998) replicated the methodology of Blashfield and Breen (1989), using the DSM-IV criteria set and providing a comparison to criteria sets for various Axis I mental disorders. Linde and Clark indicated that 71% of the DSM-IV histrionic criteria set were correctly assigned (compared to only 41% for DSM-III-R). They also indicated that misassignment occurred significantly less often for the personality disorder criteria sets, compared to the criteria sets for childhood, mood, and anxiety disorders. If one of the goals of DSM-IV was to generate a more clinically meaningful criteria set, "our results suggest that the goals of the most recent Task Force have been met to a large degree" (Linde & Clark, 1998, p. 132). The improvement in face validity might be due in part to the increasing familiarity with and acceptance of the APA diagnostic nomenclature, but the weak findings obtained earlier by Blashfield and Breen (1989) might also be attributed to a lack of understanding or adequate appreciation of the APA diagnostic nomenclature.

Blais, Benedict, and Norman (1996) administered the DSM-III-R and initial drafts of the DSM-IV criteria sets for histrionic personality disorder to a sample of thirty-three clinicians at their medical center and to thirty college students, along with the DSM-III-R criteria set for major depressive disorder. They asked each participant to rate the clarity and understandability of each criterion on a 1- to 5-point scale. The professional clinicians rated the major depressive criteria as more understandable than the histrionic criteria (3.88 vs. 3.16, respectively), but the nonprofessionals rated the histrionic criteria more understandable than the professionals (4.36 vs. 3.16, respectively) and more understandable than the major depressive criteria (4.36 vs. 3.81, respectively). A mean rating of 3.16 indicated that the professional clinicians considered the criteria set at least "fairly clear" and "this finding can be interpreted as indicating that the personality disorder criteria sets are adequately clear" (Blais et al., 1996, p. 20). However, the rating of 3.16 was the lowest for any personality disorder. The fact that the histrionic criteria are less clear than the criteria set for major depres-

sive disorder is an inevitable requirement when describing personality compared simply to an episode of major depression. The lower rating of clarity by the professionals compared to the college students may suggest that the professional clinicians have a better appreciation of this complexity, that they might be reading too much complexity into the criteria, or that they might have higher standards than college students for clarity within diagnostic criteria (Westen, 1997).

Blais, Hilsenroth, and Castlebury (1997) and Blais and Norman (1997) reported initial psychometric studies on the DSM-IV criteria set for histrionic personality disorder. Blais and Norman indicated that the DSM-IV histrionic criteria set obtained relatively weak internal consistency, with Cronbach's $\alpha = .66$, and many of the items continued to correlate with the narcissistic and borderline criteria sets. They also noted that the impressionistic speech and suggestibility criteria failed to correlate appreciably with the other histrionic criteria. "Our findings indicate that DSM-IV personality disorders will continue to demonstrate high comorbidity rates" (Blais & Norman, 1997, p. 175). Blais et al. (1997) were more complimentary. "For example, in the present study the DSM-III-R histrionic personality disorder was significantly correlated with both the narcissistic and borderline personality disorders ... while the DSM-IV version ... showed no significant correlations with [these] other [personality disorders]" (Blais et al., 1997, pp. 275-276). They also indicated that there had been an improvement in the internal consistency of the histrionic criteria set (from .61 to .67) that was well above a coefficient of .35 that would be obtained by nine randomly selected diagnostic criteria of personality disorder. Blais et al. (1997) did indicate relatively weak correlations for the criteria concerned with discomfort when not the center of attention, rapidly shifting emotions, and suggestibility. The poor results for discomfort when not the center of attention is particularly surprising because it was the most diagnostic in prior research (Pfohl, 1991). The criterion that had the highest correlation with the other diagnostic criteria was the new criterion of considering relationships more intimate than they really are.

It is stated in DSM-IV that "in the common situation in which an individual has more than one Axis II [personality disorder] diagnosis, all should be reported" (APA, 1994, p. 26). If a histrionic

person meets the DSM-IV diagnostic criteria for a borderline, dependent, or antisocial personality disorder, then these additional diagnoses should be provided. These personality disorders do overlap, but a histrionic person with only a few borderline or antisocial traits will be much different from a histrionic person with many borderline and antisocial traits. Nevertheless, most practicing clinicians provide only one diagnosis of personality disorder per patient, perhaps finding the presence of multiple diagnoses theoretically and clinically problematic (Gunderson, 1992; Widiger & Sanderson, 1995b). An implicit hierarchical structure occurs in general clinical practice, and the presence of one personality disorder trumps the presence of others (Herkov & Blashfield, 1995). DSM-IV provides suggestions within the text for differentiating among the individual personality disorders. This additional information will be useful at times to clinicians who are attempting to determine which personality disorder would provide the most valid diagnosis. For example, it is stated that "individuals with antisocial personality disorder and histrionic personality disorder share a tendency to be impulsive, superficial, excitement seeking, reckless, seductive, and manipulative, but persons with histrionic personality disorder ... are manipulative to gain nurturance, whereas those with antisocial personality disorder are manipulative to gain profit, power, or some other material gratification" (APA, 1994, p. 657). This additional information goes significantly beyond the individual diagnostic criteria because an assessment of the underlying motivation for a manipulation is not required within the diagnostic criteria for antisocial or histrionic personality disorder. Further discussion of the individual diagnostic criteria and differential diagnosis is also provided in many of the manuals that accompany semistructured interviews (e.g., Widiger et al., 1995).

Problematic differential diagnosis and excessive co-occurrence, however, might be an inevitable result of the attempt to construct qualitatively distinct diagnostic categories from constellations of maladaptive personality traits (Bornstein, 1998b; Tyrer & Johnson, 1996; Widiger, 1993). The empirical fact is that many histrionic patients will have other clinically significant personality traits (e.g., Oldham et al., 1992; Stuart et al., 1998). Providing only one diagnosis to these patients might eliminate this complexity only by ignoring

its existence. "Although clinicians and researchers can describe prototypic personality disorder symptom patterns that reflect different diagnostic ideals, in real-life clinical settings most personality disorder patients show an array of symptoms from several (or even many) different categories" (Bornstein, 1998b, p. 336).

Assessment

There are four primary methods for assessing a personality disorder: an unstructured clinical interview, a semistructured clinical interview, a self-report inventory, and/or a projective test (Widiger & Saylor, 1998). There are advantages and disadvantages to each approach that will apply to each of the personality disorders considered in this chapter (Perry, 1992; Westen, 1997; Widiger & Sanderson, 1995a; Zimmerman, 1994).

The single most popular method for assessing personality disorders within general clinical practice is an unstructured interview (Watkins, Campbell, Nieberding, & Hallmark, 1995; Westen, 1997), whereas the preferred method for clinical research is the semistructured interview (Rogers, 1995; Segal, 1997; Widiger & Saylor, 1998; Zimmerman, 1994). The reluctance to use semistructured interviews in general clinical practice is understandable because they are constraining, may at times be impractical, and can appear superficial. However, they are advisable when questions regarding the reliability or validity of an assessment are likely to be raised (Widiger & Saylor, 1998). Semistructured interviews are helpful in ensuring that the interview will be systematic, comprehensive, replicable, and objective. Unstructured clinical interviews are problematic because they tend to be unreliable, idiosyncratic, and more susceptible to attributional errors and false assumptions (Garb, 1997; Rogers, 1995; Segal, 1997). Minimally, semistructured interviews will provide the clinician with a set of useful suggestions regarding alternative inquiries to assess each diagnostic criterion.

A recommended approach in clinical practice would be to administer first a self-report inventory to identify a subset of personality disorders whose diagnoses are then confirmed by administering a semistructured interview. There are currently five semistructured interviews for assessing the DSM-IV personality disorders: (1) Diagnostic Interview for DSM-IV Personality Disorders (DIPD; Zana-

rini, Frankenburg, Sickel, & Yong, 1996), (2) International Personality Disorder Examination (IPDE; Loranger, Sartorius, & Janca, 1997), (3) Personality Disorder Interview-IV (PDI-IV; Widiger et al., 1995), (4) Structured Clinical Interview for DSM-IV Axis II Personality Disorders (SCID-II; First, Gibbon, Spitzer, Williams, & Benjamin, 1997), and (5) Structured Interview for DSM-IV Personality Disorders (SIDP-IV; Pfohl, Blum, & Zimmerman, 1997). The SIDP-IV, SCID-II, and IPDE have the most empirical support (Segal, 1997; Zimmerman, 1994), but the PDI-IV has the most extensive manual (Rogers, 1995), including a detailed discussion of the history, rationale, and assessment issues for each of the 94 DSM-IV personality disorder diagnostic criteria.

The single most popular method for assessing personality by researchers of normal personality functioning is a self-report inventory (Butcher & Rouse, 1996). The advantages of a self-report inventory are self-evident. It is relatively less expensive and time-consuming to administer, it is systematic, comprehensive, and reliable in its assessment, and it will often be supported by a substantial amount of normative and clinical research that will facilitate interpreting it (Widiger & Saylor, 1998). There are six self-report inventories that can be and have often been used for assessing the DSM-IV personality disorders: (1) Minnesota Multiphasic Personality Inventory-2 (MMPI-2) personality disorder scales developed originally by Morey, Waugh, and Blashfield (1985); (2) Millon Clinical Multiaxial Inventory-III (Millon, Davis, & Millon, 1997); (3) Personality Diagnostic Questionnaire-IV (PDQ-IV; Hyler, 1994); (4) Personality Assessment Inventory (PAI; Morey, 1991); (5) Wisconsin Personality Inventory (WISPI; Klein et al., 1993); and (6) Coolidge Axis II Inventory (CATI; Coolidge & Merwin, 1992). The MMPI-2 and the MCMI-III have the most empirical support; the CATI and WISPI might be comparably valid but are more recent instruments that need further research; the PAI assessment of personality disorders is confined largely to the borderline, antisocial, and paranoid personality disorders; and the PDQ-IV is the least valid but most commonly used due to its brevity and close coordination with the DSM-IV diagnostic criteria (Widiger & Saylor, 1998; Zimmerman, 1994).

A potential disadvantage of self-report inventories and semistructured interviews is their relative emphasis on self-report (Bornstein, 1995; Perry,

1992; Westen, 1997). Personality disorders are characterized in part by characteristic distortions in self-image and self-presentation, which may not be assessed adequately simply by asking respondents if they have each diagnostic criterion. However, many of these instruments can also be administered to persons who know the patient well and have observed firsthand the maladaptive personality traits. In addition, self-report inventories and semistructured interviews do not necessarily rely on accurate self-description. Many of the inquiries within these instruments are subtle and indirect. Most projective tests depend less on the ability or willingness of the person to provide an accurate self-description, although there is currently only limited empirical support for using projective techniques to assess histrionic personality traits (Blais, Hilsenroth, & Fowler, 1998).

Epidemiology

Approximately 1 to 3% of the general population would be diagnosed with histrionic personality disorder (Maier et al., 1992; Nestadt et al., 1990; Zimmerman & Coryell, 1989), and approximately 10 to 15% of patients within clinical settings (Pfohl, 1991). This disorder is typically diagnosed more frequently in females, but this gender ratio has been highly controversial (Bornstein, 1999; Kaplan, 1983; Widiger, 1998). The diagnostic criteria for histrionic personality disorder include behaviors or traits that are significantly correlated with stereotypically feminine behavior (Sprock, Blashfield, & Smith, 1990), clinicians will at times overdiagnose histrionic personality disorder in female patients (Ford & Widiger, 1989; Hamilton, Rothbart, & Dawes, 1986), and some studies that used semistructured interviews failed to obtain a differential sex prevalence rate (Corbitt & Widiger, 1995; Nestadt et al., 1990; Pfohl, 1991). It is even suggested in DSM-IV that the differential sex prevalence rate might be an illusory artifact of a higher base rate of females within clinical settings, biased clinical assessments, or perhaps even biased diagnostic criteria. "Histrionic personality disorder as defined in DSM-IV may continue to represent an exaggerated version of stereotypical feminine traits and may place too little emphasis on items and examples that would tap the parallel 'macho' male version expressing exaggerated masculine traits" (Frances et al., 1995, p. 373). The text discussion of the disorder in

DSM-IV emphasizes the consideration of masculine variants of the diagnostic criteria. "For example, a man with this disorder may dress and behave in a manner often identified as 'macho' and may seek to be the center of attention by bragging about athletic skills" (APA, 1994, p. 656).

If "a healthy woman automatically earns the diagnosis of histrionic personality disorder" (Kaplan, 1983, p. 789), the diagnosis would indeed be invalid and sex-biased. Funtowicz and Widiger (1995, 1999), however, indicated that the diagnostic criteria for histrionic personality disorder (with perhaps one exception) do not diagnose women who are actually lacking in clinically significant impairments in social or occupational dysfunction or personal distress. Some of the women might be only mildly impaired, but they will be at least as impaired as men who meet the criteria for personality disorders that are diagnosed more frequently in males (e.g., antisocial, obsessive-compulsive, and narcissistic). To the extent that personality disorders are extreme maladaptive variants of commonly occurring personality traits (Livesley, Schroeder, Jackson, & Jang, 1994; Widiger & Costa, 1994), differential sex prevalence rates consistent with the normative differences between men and women (Feingold, 1994) would be expected (Corbitt & Widiger, 1995). Some personality disorders may indeed involve maladaptive variants of gender-related traits; some personality disorders occur more often in males (e.g., antisocial and narcissistic), and others occur more often in females (e.g., histrionic and dependent). It has even been suggested that histrionic and antisocial personality disorders are complementary gender-related variants; the antisocial male tends to manipulate others through antagonistic intimidation, and the histrionic female manipulates others through extraverted, seductive flirtation (Hamburger, Lilienfeld, & Hogben, 1996). However, the presence of these gender-related traits substantially complicates the development of gender-neutral, or at least unbiased, diagnostic criteria (Widiger, 1998). A more valid diagnosis of histrionic personality disorder might not be achieved by revising the criteria to be more masculine or to diagnose an equal number of males and females with the disorder. A more valid diagnosis might be obtained by revising "the criteria to decrease the likelihood that there will be false positive errors in their application to women, perhaps by increasing (for example) their behavioral specificity to re-

duce their ambiguity, misinterpretation, and misapplication" (Widiger, 1998, pp. 114–115).

Concerns may also be raised with respect to other demographic variables. For example, histrionic personality disorder is likely to be diagnosed in some cultural groups more than others. For example, the disorder might be seen less frequently in Asian cultures, where overt sexual seductiveness is less frequent (Johnson, 1993), and more frequently within Hispanic and Latin American cultures, where more overt and uninhibited sexuality is evident (Padilla, 1995). However, it will be unclear at times whether adjustments to the diagnostic criteria should be made within these different cultural contexts because the DSM-IV criteria may also reflect biases or assumptions regarding seductiveness that are not shared within other societies (Alarcon, 1996; Rogler, 1996).

Histrionic personality disorder and the validity of the diagnostic criteria may also change across the life span. As the disorder is currently described in the DSM-IV, it is most appropriate for a young adult (Bornstein, 1999). Sexual seductiveness will become less apparent as a person ages or at least may become a less effective means of capturing the attention of or manipulating others. On the other hand, histrionic psychopathology might become more evident as a person ages because the histrionic person continues to rely on an increasingly ineffective means of obtaining attention. In the only study to assess the relationship of age to diagnosis, Nestadt et al. (1990) reported no differential sex prevalence rate for the disorder within younger adults. A differential sex prevalence rate did not emerge until the persons were older than 45. It is possible that many of the behaviors were considered more normative within the younger females (Sprock, 1996) and contributed to an underdiagnosis of the disorder at this time.

Etiology and Pathology

There is some limited support for the heritability of histrionic personality traits, although there has not yet been a familial aggregation, twin, or adoption study of this disorder (McGuffin & Thapar, 1992; Nigg & Goldsmith, 1994). Substantial data suggest that the disorder is a constellation of maladaptive variants of common personality traits within the broad domains of neuroticism and extraversion (e.g., Trull, 1992; Trull et al., 1998). For example, extraversion includes the disposi-

tions to be outgoing, talkative, and affectionate; to be convivial, to have many friends, and to seek social contact; to be energetic, fast-paced, and vigorous; to be flashy, seek stimulation, and take risks; and to be high-spirited. Costa and McCrae (1992) organized these traits of extraversion into facets of warmth, gregariousness, activity, excitement-seeking, and positive emotionality (respectively). Traits of extraversion are, for the most part, desirable and adaptive. However, persons who are at the most extreme variants of these traits of extraversion are likely to experience a number of maladaptive consequences and would be characterized as being histrionic. "Histrionic individuals express emotions with an inappropriate exaggeration (excessively high positive emotions); they crave excitement and stimulation (high excitement seeking); they are quick to form numerous, generally superficial relationships (high gregariousness); and they display inappropriate affection, intimacy, and seductiveness (high warmth)" (Widiger et al., 1994, p. 47). To the extent that histrionic personality disorder does indeed include maladaptively extreme variants of traits of extraversion, there would be support for its heritability (Jang et al., 1998; Nigg & Goldsmith, 1994).

The pathology of the disorder is to some extent evident by the diagnostic criteria provided in DSM-IV (APA, 1994). Persons with this disorder are said to have a pathological need to be loved, desired, and intensely involved with others intimately, and they will use a variety of means to get this involvement (Horowitz, 1991). They will use their physical appearance to draw attention to themselves, they will be melodramatically emotional, and they will be inappropriately seductive. They may even perceive that a relationship is more intimate than is really the case, in part because of their need for and fantasies of close intimacies. They will be highly suggestible or easily influenced by others because they want to be closely involved and engaged within an intense personal relationship. An extreme example of this suggestibility would be the development of symptoms or memories suggested by a clinician to develop a special, significant relationship.

This description of the disorder is largely consistent with psychodynamic descriptions of oral-dependent pathology (Bornstein, 1999), and a variety of parent-child relationships may contribute to its development. The excessive needs may de-

velop in part through an overly eroticized parent-child relationship. For example, a father might repeatedly indicate through a variety of verbal and nonverbal communications that his love and attention for a daughter are largely contingent upon her being attractive, desirable, and provocative to him. Her sense of self-worth and meaning might depend in large part on the way he relates to her, and she might then value herself primarily in terms of the way she is valued by men (Stone, 1993). She may learn that to get what she needs from others, she must be highly provocative, intrusive, and manipulative (Millon et al., 1996).

Neurochemical models of the disorder have emphasized a hyperresponsiveness of the noradrenergic system. This dysregulation in catecholamine functioning may contribute to a pronounced emotional reactivity to signs of rejection (Klein, 1999). There may be a naturally occurring neurochemical mechanism for regulating mood in response to signs of social applause and rejection. This regulatory mechanism would be helpful sociobiologically in making a person appropriately responsive to cues of social interest. "Perhaps in hysteroid dysphoric patients this mechanism had become overresponsive and . . . monoamine oxidase inhibitors [are] reparative for this dysfunction" (Klein, 1999, p. 425).

Cognitive theorists have emphasized irrational schemata associated with these interpersonal dynamics. Horowitz (1991), for example, describes how histrionic persons view themselves as a "sexy star, wounded hero [or] worthy invalid" (p. 6), and the rest of the world plays the supporting roles of "interested suitor [or] devoted rescuer" (p. 6). Beck and Freeman (1990) address what they consider are irrational core beliefs, such as "Unless I captivate people I am nothing" or "If I can't entertain people they will abandon me." Complicating the treatment of persons with this disorder is their impressionistic and diffuse cognitive style, described well by Shapiro (1965): "hysterical cognition in general is global, relatively diffuse, and lacking in sharpness. . . . The hysterical person tends to respond quickly and is highly susceptible to what is immediately impressive, striking, or merely obvious" (pp. 111-112). This diffuse, impressionistic cognitive style will contribute to their suggestibility, and also in part results from their excessive emotionality. The histrionic person relies primarily on feelings rather than rationality to make decisions. This might be in part bioge-

netic in origin, but it may also be encouraged through social learning because impressionistic suggestibility can be appealing to and can be reinforced by others.

Narcissistic Personality Disorder

Narcissistic personality disorder is described in DSM-IV as “a pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts” (APA, 1994, p. 661). This disorder was not included in the first or second editions of the APA DSM, nor is it included in the current, 10th edition of the World Health Organization’s (1992) international nomenclature. Its inclusion in DSM-III (APA, 1980) “was suggested by an increasing psychoanalytic literature and by the isolation of narcissism as a personality factor in a variety of psychological studies” (Frances, 1980, p. 1053).

The criteria set for DSM-III consisted of a grandiose sense of self-importance or uniqueness; preoccupation with fantasies of success, power, brilliance, beauty, or ideal love; exhibitionism; indifference, rage, shame, humiliation, or emptiness in response to criticism or defeat; feelings of entitlement; interpersonal exploitativeness; overidealization and devaluation of others; and lack of empathy (APA, 1980). The revisions for DSM-III-R added feelings of envy and the belief that one’s problems are unique; the alternation between feelings of idealization and devaluation was deleted due to its overlap with borderline personality disorder (Widiger et al., 1988). The revisions for DSM-III-R were not intended to be substantial, but Morey (1988) suggested that the revisions did change the recipients of the diagnosis. Only 6% of the 291 patients in his study met the DSM-III criteria, compared to 22% with the DSM-III-R criteria that contributed to a kappa of only .38 across the two editions (the third lowest rate of agreement). Blashfield et al. (1992), however, reported a better agreement rate of .57 across the two editions. They concluded that “the concordance of the DSM-III and DSM-III-R was relatively high” (Blashfield et al., 1992, p. 250).

The face validity studies of the DSM-III-R criteria set by Blashfield and Breen (1989) and Blashfield and Haymaker (1988) suggested that there were only a few problematic criteria. In the

study by Blashfield and Breen, the diagnostic criteria were correctly assigned 69% of the time, and there was no consistent misassignment to an alternative diagnostic category. Interpersonal exploitativeness and preoccupation with feelings of envy, however, were misassigned by a majority of the clinicians. Blashfield and Haymaker (1988) indicated that interpersonal exploitativeness was consistently misassigned to the antisocial personality disorder. Morey and Ochoa (1989) reported a kappa of only .31 between the narcissistic personality disorder diagnoses provided by clinicians and the diagnoses that would be provided by their own assessments of the DSM-III criteria. Blashfield and Herkov (1996), however, reported a substantial improvement to .54 for the DSM-III-R criteria set, the third highest among the personality disorders.

A narcissistic personality disorder diagnosis tends to co-occur with other personality disorder diagnoses, particularly the paranoid, borderline, and histrionic (Stuart et al., 1998; Widiger & Rogers, 1989; Widiger & Trull, 1998). There has been surprisingly little co-occurrence with the antisocial personality disorder, despite the presence of the criterion concerned with interpersonal exploitativeness (Blashfield & Breen, 1989; Blashfield & Haymaker, 1988) and the presence of features included within Hare’s (1991) checklist for psychopathy (i.e., lack of empathy, glib charm, and arrogance).

Gunderson, Ronningstam, and Smith (1991) summarized the results of a number of psychometric studies of the DSM-III-R criteria set. They concluded that the most problematic criteria were (1) reactions to criticism with feelings of rage, shame, or humiliation, even if not expressed; (2) lack of empathy; and (3) preoccupation with feelings of envy. Gunderson et al. (1991) did not suggest that these items should be deleted but argued that they needed substantial revision. The first criterion occurred frequently in persons with borderline and paranoid personality disorders. Gunderson et al. suggested that feelings of disdain might be more specific to narcissism than feelings of rage. Subsequent recommendations included the deletion of unexpressed feelings because unexpressed feelings can be quite difficult to assess reliably (Widiger et al., 1995). Lack of empathy is often described in narcissism, but it is also difficult to assess reliably (Ronningstam & Gunderson, 1990) and often occurs in persons with antisocial

personality disorder. Gunderson et al. (1991) concluded that feelings of envy were “not found that often and . . . [are] not necessarily found in [narcissistic] subjects” (p. 173). Ronningstam and Gunderson (1990) suggested that a belief that others envy them would be more diagnostic than feeling envious of others. Advisors to the DSM-IV Personality Disorders Work Group also suggested including feelings of resentment for the privileges or achievements of others (Gunderson et al., 1991).

Table 2 provides the DSM-IV diagnostic criteria. The reaction to criticism with feelings of rage, shame, or humiliation, even if not expressed, was deleted. DSM-III-R preoccupation with feelings of envy was also revised to include a belief that others envy them. A new criterion was added that generally described arrogant, haughty behaviors or attitudes (Ronningstam & Gunderson, 1990). Significant revisions were also made to five of

**Table 2. DSM-IV Criteria
for Narcissistic Personality Disorder^a**

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
- (2) is preoccupied with fantasies or unlimited success, power, brilliance, beauty, or ideal love
- (3) believes that he or she is “special” and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
- (4) requires excessive admiration
- (5) has a sense of entitlement, i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations
- (6) is interpersonally exploitative, i.e., takes advantage of others to achieve his or her own ends
- (7) lacks empathy: is unwilling to recognize or identify with the feelings and needs of others
- (8) is often envious of others or believes that others are envious of him or her
- (9) shows arrogant, haughty behaviors or attitudes

^aAPA (1994, pp. 661).

the other diagnostic criteria (Widiger et al., 1995). For example, the DSM-III-R need for constant attention and admiration was confined only to a need for admiration to facilitate the differentiation from the histrionic personality disorder, and lack of empathy was revised to indicate that narcissistic persons may be able to recognize cognitively how others feel but may not be at all concerned with these feelings (Gunderson et al., 1991; Widiger et al., 1995).

Linde and Clark (1998) indicated in their face validity study that the DSM-IV narcissistic criteria were correctly assigned 74% of the time. However, they did indicate that, once again, interpersonal exploitation was misassigned frequently to antisocial personality disorder. “Indeed, [interpersonal exploitation] appears closer to this antisocial core concept [disregard for the rights of others] than to the narcissistic personality disorder core concept of ‘grandiosity and lack of empathy,’ which was appropriately assigned to narcissistic personality disorder by 97% of clinicians” (Linde & Clark, 1998, p. 134).

Blais and Norman (1997) reported a Cronbach’s alpha of .82 for the DSM-IV narcissistic personality disorder criteria set, the highest obtained by any personality disorder. Many of the narcissistic criteria, however, obtained significant correlations with the antisocial and histrionic criteria sets (e.g., interpersonal exploitation correlated .48 with the antisocial). The lowest internal consistency coefficient was obtained by envy (.35) and the highest by a grandiose sense of self-importance (.64). These findings are consistent with the rank order of the diagnostic criteria because the prior research indicated that grandiosity was the most diagnostic criterion and feelings of envy was the least diagnostic (Gunderson et al., 1991). Blais et al. (1997) found weak agreement between the DSM-III-R and DSM-IV criteria sets with respect to who received the diagnosis ($\kappa = .44$), but they also concluded that “the changes to the narcissistic personality disorder criteria set appear beneficial, as the alpha coefficient for the DSM-IV versions was substantially improved over that obtained by the DSM-III-R version” (p. 276). Further discussions of each diagnostic criterion and additional experimental criteria are provided in Cooper (1998), Ronningstam and Gunderson (1990), Shedler and Westen (1998), and Widiger et al. (1995).

Assessment

All of the semistructured interviews and self-report inventories cited earlier (except the PAI; Morey, 1991) include scales for assessing the narcissistic personality disorder (Morey & Jones, 1998, however, review how the PAI can be used for assessing narcissism). There is also a semistructured interview devoted to assessing narcissism (Diagnostic Interview for Narcissism; Gunderson, Ronningstam, & Bodkin, 1990); the research with it was highly influential in developing the DSM-IV diagnostic criteria (Gunderson et al., 1991). There are also a number of self-report inventories devoted to assessing narcissistic personality traits, including the Narcissistic Personality Inventory (NPI; Raskin & Terry, 1988), that has been used in a number of personality and social-psychological studies of narcissism (Rhodewalt & Morf, 1995) and has the particularly useful feature of subscales for assessing various components of narcissism (i.e., superiority, vanity, leadership, authority, entitlement, exploitativeness, and exhibitionism).

Hilsenroth, Handler, and Blais (1996) provide an informative overview of the assessment of narcissistic personality disorder, and considerable discussion is devoted to projective instruments. Narcissism is one of the more heavily researched domains of Rorschach assessment, and also one of the more controversial. Nezworski and Wood (1995) provided a thorough critique of the empirical support for Rorschach indicators such as pair responses, reflections, and the egocentricity index. They indicated that the diagnostic criteria for narcissism were unspecified in most studies, and, more importantly, the “diagnosticians were aware of Rorschach scores and incorporated them into their diagnoses” (Nezworski & Wood, 1995, p. 192). Nezworski and Wood also indicated that none of these Rorschach indicators correlated significantly with such well-researched self-report measures of narcissism as the NPI (Raskin & Terry, 1988). “In summary, research has not yet demonstrated that Rorschach measures of narcissism are related to diagnoses or self-report measures of narcissism” (Nezworski & Wood, 1995, p. 193).

Exner (1995) responded in part by indicating that his scoring system “does not and never has contained a formal index of narcissism” (p. 200) and therefore should not be faulted for the failure

to correlate with measures of narcissism. Persons with high scores on the egocentricity index will tend to be self-involved, but self-involvement does not necessarily suggest an inflated sense of self-worth. “It may simply indicate an unusual preoccupation with the self, generated by a sense of dissatisfaction” (Exner, 1995, p. 203). Exner (1995) did suggest that the reflection response “does seem to have a relationship to narcissism” (p. 200), but it would still be considered only a “narcissistic-like feature” (p. 202) rather than a direct indication of narcissism, narcissistic pathology, or a narcissistic personality disorder.

Hilsenroth et al. (1996) cited six studies that “have used the Rorschach in differential diagnostic research for narcissistic personality disorder” (p. 673); only one was cited by Nezworski and Wood (1995), and they concluded “that the Rorschach may be helpful to identify narcissistic personality disorder patients from different clinical groups” (p. 675). Hilsenroth et al. did not address the methodological criticisms raised by Nezworski and Wood (1995), but Hilsenroth, Fowler, Padawer, and Handler (1997) did address them in their own Rorschach study. Hilsenroth et al. (1997) compared the frequency of Rorschach reflection, personalization, idealization, and egocentricity scores in a university clinic and student sample. The personality disorder diagnoses were obtained from systematic reviews of material available in the patients’ charts (excluding the original Rorschach data and clinicians’ diagnoses). The results were particularly strong for idealization and reflection responses. “Narcissistic personality disorder patients had significantly more idealization responses than did the antisocial personality disorder group and more reflection responses than did both the antisocial and the borderline personality disorder groups” (Hilsenroth et al., 1997, p. 116). The number of reflection responses correlated significantly ($r = .33$) with the total number of DSM-IV narcissistic personality disorder diagnostic criteria and correlated significantly with the frequency of the individual narcissistic diagnostic criteria that, it would be predicted, is most closely associated with the disorder, including grandiose sense of self-importance, fantasies of unlimited success, and sense of entitlement. Hilsenroth et al. also correlated the Rorschach scores with the Morey et al. (1985) MMPI-2 narcissistic self-report measure (which could not have been affected by a

knowledge of the Rorschach scores). Both the reflection and idealization scores correlated significantly with the MMPI-2 scale. Hilsenroth et al. (1997) concluded that their "findings reflect converging lines of evidence and support the use of the Rorschach as a valuable instrument in the diagnosis of narcissistic personality disorder as well as contributing to a conceptual understanding of narcissism and narcissistic pathology" (pp. 119-120).

Epidemiology

Narcissistic is among the least frequently diagnosed personality disorders within clinical settings (Gunderson et al., 1991); estimates of prevalence are as low as 2%, but at times as high as 16% (APA, 1994). A curious finding is that none of the published community studies that have used a semistructured interview have identified any cases. In fact, three community studies that used semistructured interviews failed to identify a single case of narcissistic personality disorder, despite interviews of more than 2000 persons (Maier et al., 1992; Nestadt et al., 1990; Zimmerman & Coryell, 1989) and despite the substantial amount of research on maladaptive narcissistic personality traits within normal community and college samples (Rhodewalt & Morf, 1995). Modesty versus conceit is one of the facets of one of the fundamental domains of personality functioning (i.e., agreeableness versus antagonism), and approximately 18% of men and 6% of women might be characterized as excessively immodest, arrogant, or conceited (Costa & McCrae, 1992). DSM-IV narcissistic personality disorder is diagnosed more frequently in males (APA, 1994).

Cross-cultural studies of narcissism and narcissistic personality disorder would be of interest. Narcissistic is the only DSM-IV personality disorder that is not officially recognized within the World Health Organization's (1992) international nomenclature. Loranger et al. (1994) demonstrated that the DSM-IV can be applied within a wide variety of cultures and suggested that there were few difficulties with the application. With only a few minor exceptions, "the clinicians viewed the [DSM-IV] as applicable to their particular cultures" (Loranger et al., 1994, p. 223). However, being able to apply a diagnostic criteria set within another culture does not necessarily mean that the disorder diagnosed is valid or even

meaningful within that culture (Alarcon, 1996; Rogler, 1996). Theorists have suggested that narcissistic personality disorder is distinctly cultural and that pathological narcissism is the manifestation of a modern, Western society that has become overly self-centered and materialistic, coupled with a decreasing importance of familial (interpersonal) bonds (Cooper & Ronningstam, 1992; Lasch, 1978).

A life-span developmental model for the disorder would also be of interest for future research. Persons with this disorder might be seemingly well adjusted and even successful as young adults, based on substantial achievements in education, career, and perhaps even within relationships (Ronningstam & Gunderson, 1990). However, their relationships with their colleagues, peers, and intimates might become strained as their lack of consideration for and even exploitative use of others becomes more evident across time. Successes might also become more infrequent as their inability to accurately perceive or address criticism and setback contributes to a mounting number of failures. Persons with this disorder may at times not recognize their pathology until they have had a substantial number of setbacks or have finally recognized that the excessive importance they have given to achievement, success, and status has led to an emptiness and loneliness in their older age (Stone, 1993). As a result, mid-life and late-life transitions may be particularly difficult for persons with this disorder.

Etiology and Pathology

There has not yet been a familial aggregation, twin, or adoption study of the narcissistic personality disorder (McGuffin & Thapar, 1992). The central construct of arrogance (versus modesty) is one of the facets of the broad domain of antagonism (versus agreeableness) that, it has been shown, are closely related to narcissistic personality disorder (Trull, 1992; Trull et al., 1998), and there has been consistent empirical support for the heritability of this broad domain of personality functioning (Nigg & Goldsmith, 1992). Jang et al. (1998), for example, estimated its heritability at .48 in a German and Canadian study. Jang et al. also explored the heritability for each facet of each broad domain after the common heritable component had been removed. Whereas the antagonism facets of mistrust, manipulativeness, oppositional-

ism, and tough-mindedness demonstrated unique heritability (.25 to .31), arrogance versus modesty did not. Much of its unique variance was attributed to shared and nonshared environmental influences.

The predominant psychosocial models for the etiology of narcissism have been largely social learning or psychodynamic (Auberbach, 1993; Cooper & Ronningstam, 1992). One model proposes that narcissism develops through an excessive idealization by parental figures, which is then incorporated by the child into his or her self-image (Benjamin, 1993; Millon et al., 1996). Narcissism may also develop through unempathic, neglectful, inconsistent, or even devaluing parental figures who have failed to adequately mirror a child's natural need for idealization (Kernberg, 1998). The child may find that the attention, interest, and perceived love of a parent are contingent largely on achievements or successes. The child may fail to perceive that the parents value or love them for their own sake, but may instead recognize that the love and attention are largely conditional on successful accomplishments. The child might then develop the belief that its own feelings of self-worth depend on continued recognition by others of such achievements, status, or success.

Conflicts and deficits with respect to self-esteem are central to the pathology of the disorder (Gabbard, 1994; Kernberg, 1998; Stone, 1993). Narcissistic persons must continually seek and obtain signs and symbols of recognition to compensate for conscious or perhaps even unconscious feelings of inadequacy (Auerbach, 1993). Empirical support for the validity of hypotheses concerning narcissistic pathology are being provided by social-psychological and personality, as well as clinical, research. Rhodewalt, Madrian, and Cheney (1998), for example, indicated how narcissism is more highly correlated with instability in self-esteem, rather than simply a consistently high self-confidence. Narcissistic persons may not consider themselves persons who are valued for their own sake because their own worthiness depends on a success, accomplishment, or status, and the value of others is measured as well in terms of the contributions they can make to a success or status. Their feelings of insecurity may at times be masked by disdainful indifference to criticism or by overt expressions of arrogance and conceit. Narcissism is perhaps a maladaptive process of regulating or protecting fragile self-

esteem (Morf & Rhodewalt, 1993; Raskin, Novacek, & Hogan, 1991) in part through gaining the approval and admiration of others. Narcissistic persons may at times claim that it is not narcissism if they are in fact brilliant, talented, and successful. However, the pathology would still be evidenced by an excessive need for and reliance on recognition of their achievements. They are not persons who are comfortable when they are not adequately appreciated for their accomplishments, brilliance, or talent and may feel grossly insulted or enraged when they feel unjustly slighted (Stone, 1993).

In this context, in a series of studies Baumeister and his colleagues have been exploring the contribution of narcissistic conflicts to the occurrence of aggressive, violent behavior (Baumeister, Smart, & Boden, 1996). Bushman and Baumeister, for example demonstrated empirically that neither low nor high self-esteem was predictive of reacting aggressively to threat. It was "the combination of narcissism and insult [that] led to exceptionally high levels of aggression toward the source of the insult" (Bushman & Baumeister, 1998, p. 219). "It is not so much the people who regard themselves as superior beings who are the most dangerous but, rather, those who have a strong desire to regard themselves as superior beings" (Bushman & Baumesiter, 1998, p. 228). Some narcissistic persons may (perhaps appropriately) envy persons who are truly indifferent to success and who can enjoy a simple, modest, and unassuming life.

Dependent Personality Disorder

The dependent personality disorder is described in DSM-IV as "a pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts" (APA, 1994, p. 668). A diagnosis of dependent personality disorder was included in the 1st edition of the DSM, but as a subtype to the passive-aggressive personality disorder, "characterized by helplessness, indecisiveness, and a tendency to cling to others as a dependent child to a supporting parent" (APA, 1952, p. 37). It was not included in DSM-II (APA, 1968; Hirschfeld, Shea, & Weise, 1991).

The DSM-III criteria for dependent personality disorder were grossly inadequate and were confined to the requirement of the three criteria of

passively allowing others to assume responsibility for major areas of life because of an inability to function independently, subordinating own needs to avoid any possibility of having to rely on themselves, and lacking in self-confidence (APA, 1980). Morey and Ochoa (1989) reported a kappa agreement of only .23 between diagnoses of dependent personality disorder provided by clinicians and the presence of the three diagnostic criteria assessed by the same clinicians.

The criteria set was expanded substantially in DSM-III-R to include feelings of submissiveness and fears of separation (Widiger et al., 1988), and it is not surprising that the revisions for DSM-III-R did substantially change those who received the diagnosis. Whereas only 14% of the 291 patients studied by Morey (1988) met the DSM-III criteria, 22% met the criteria set for DSM-III-R (kappa = .54). Blashfield et al. (1992) reported a comparably low kappa of agreement between the two editions ($k = .47$), but they indicated that the DSM-III-R criteria resulted, in a reduction in the prevalence of the diagnosis (from 22 to 17%). "Given the substantial change in definitions, the low diagnostic concordance ($k = .471$) and the relatively low correlation ($r = .622$) were expected" (Blashfield et al., 1992, p. 250).

The face validity study of Blashfield and Breen (1989) indicated that 73% of the criteria were correctly assigned; this was the third highest rate obtained (after the paranoid and obsessive-compulsive criteria sets). Only one of the diagnostic criteria was not assigned to the dependent personality disorder by a majority of the clinicians: easily hurt by criticism or disapproval. This criterion also obtained the weakest results in the earlier face validity study by Blashfield and Haymaker (1988). Blais et al. (1996) indicated that the DSM-III-R criteria set for dependent personality disorder obtained the highest rating of clarity by their college students, 4.48 on a scale of 1 to 5 (where 5 = very clear). The ratings by the clinicians were significantly lower (3.35) but still well within the "fairly clear" range.

However, despite their apparent face validity, Blashfield and Herkov (1996) reported no improvement in the agreement between the diagnoses of dependent personality disorder provided by clinicians and their own assessment of the presence of the nine diagnostic criteria. The clinicians and the criteria set diagnosed approximately the same percentage of patients (61% and 57%,

respectively), but the kappa value for agreement with respect to those who received the diagnosis was only .29, the second lowest for any personality disorder in this study. Blashfield and Herkov indicated that an allowance of others to assume responsibility for major areas of life was given particular weight in the clinicians' diagnoses.

Most of the patients who meet the criteria for dependent personality disorder will meet the diagnostic criteria for other personality disorders, particularly the borderline, histrionic, and avoidant (Stuart et al., 1998; Widiger & Rogers, 1989). Widiger and Trull (1998) indicated (in their summary of the findings for more than 1000 patients obtained from six unpublished data sets that were analyzed for DSM-IV) that 48% of the dependent patients met the DSM-III-R criteria for borderline personality disorder and 57% met the DSM-III-R criteria for avoidant. The most problematic item with respect to differentiating among these personality disorders was being easily hurt by criticism or disapproval. This diagnostic criterion occurred in more than 85% of the avoidant patients and in more than 70% of the borderline at four of the six research sites (Widiger & Trull, 1998). Feeling devastated or helpless when a close relationship ended was the second most problematic criterion because it was the next most frequent dependent criterion among borderline patients at four of the six sites and was the third most frequent symptom at the remaining two sites.

Hirschfeld, Shea, and Weise (1991) based their recommendations for DSM-IV on this prior research and on clinical and theoretical literature concerning attachment and dependency. Table 3 provides the DSM-IV diagnostic criteria. Being easily hurt by criticism or disapproval was deleted because it "is not specific to dependent personality disorder" (Hirschfeld et al., 1991, p. 147). No item was added to the criteria set to replace this deletion, but all of them were revised significantly (Hirschfeld et al., 1991; Widiger et al., 1995). Feeling devastated or helpless when a close relationship ends was revised to "urgently seeks another relationship as a source of care and support when a close relationship ends" (APA, 1994, p. 669). "Avoidant and dependent persons may act quite similarly when they have someone, but not when they are alone" (Widiger et al., 1995, p. 116). Avoidant and dependent persons are often clinging, insecure, and dependent when they are involved with someone, but when the relationship

Table 3. DSM-IV Dependent Personality Disorder Criteria^a

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has difficulty making everyday decision without an excessive amount of advice and reassurance from others.
2. Needs others to assume responsibility for most major areas of his or her life.
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval (Note: Do not include realistic fears of retribution).
4. Has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than to a lack of motivation or energy).
5. Goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant.
6. Feels uncomfortable or helpless when alone, because of exaggerated fears of being unable to care for himself or herself.
7. Urgently seeks another relationship as a source of care and support when a close relationship ends.
8. Is unrealistically preoccupied with fears of being left to take care of himself or herself.

^aAPA (1994, pp. 668–669).

ends, avoidant persons are slow to find replacements, whereas in “dependent persons, the history of negligent, abusive, unreliable, or exploitative partners is due, in large part, to their failure to be careful, selective, or discriminating” (Widiger et al., 1995, p. 116) in selecting new partners. Many of the other revisions were made to emphasize attachment issues and an emotional reliance on others, rather than simply feelings of low self-confidence (Benjamin, 1993; Hirschfeld et al., 1991; Livesley, Schroeder, & Jackson, 1990). This is evident in the references to need for or a seeking of nurturance and, most significantly, in the revision to the definition of the disorder from simply a “pervasive pattern of dependent and submissive behavior” (APA, 1987, p. 354) to “a pervasive and excessive need to be taken care of that leads to

submissive and clinging behavior and fears of separation” (APA, 1994, p. 665).

Linde and Clark (1998) reported that the DSM-IV criteria for dependent personality disorder were correctly assigned by their participants 78% of the time; this was the fourth highest rate obtained among the personality disorders and was higher than the average rate of 69% obtained for the Axis I disorders. Blais and Norman (1997), however, suggested that some of the diagnostic criteria are still problematic. They reported an internal consistency (Cronbach’s alpha) coefficient of .67; this was among the second lowest but still well above the coefficient of .35 obtained by nine randomly selected diagnostic criteria. The two weakest criteria were going to excessive lengths to obtain nurturance and support and urgently seeking another relationship as a source of care and support when a close relationship ends. The latter item, however, was only one of three dependent criteria that was uncorrelated with the avoidant criteria.

Assessment

All of the semistructured interviews and self-report inventories cited before (except the PAI; Morey, 1991) include scales for assessing the DSM-IV dependent personality disorder. There are also a number of self-report inventories devoted to assessing dependent personality traits, including the Interpersonal Dependency Inventory (Hirschfeld et al., 1977), the dependency scale from the Blatt Depressive Experience Questionnaire (Blatt & Zuroff, 1992; Santor, Zuroff, & Fielding, 1997), and the sociotropy scale from the Beck Sociotropy-Autonomy Scale (Robins, Hayes, Block, Kramer, & Villena, 1995).

Bornstein (1993, 1995) provides a thorough overview of the assessment of dependent personality traits, including the use of projective techniques. The Rorschach Oral Dependency (ROD) scale developed by Masling, Rabie, and Blondheim (1967) “is far and away the most widely used projective dependency measure” (Bornstein, 1993, p. 25). The ROD is a content scoring system for the Rorschach, including explicitly dependent or dependency-related imagery or oral imagery. Interrater reliability is typically quite high; agreement ranges from 85 to 95%, correlation in total score is typically greater than .90, and kappa coefficients for cutoff point classifications often exceed

.80 (Bornstein, 1996a). Significant correlations have been obtained with thematic apperception measures of dependency ($r = .58$; Masling et al., 1967) and with the Hirschfeld et al. (1977) self-report IDI, ranging from .32 to .67 in women and .37 to .48 in men. Behavioral correlates of ROD dependency have included increased yielding in Asch-type conformity experiments, completing introductory psychology research requirements earlier in the semester, and difficulty terminating psychotherapy. "Laboratory, clinical, and field studies confirm that the ROD scale does, in fact, predict dependency-related behavior in a variety of participant groups" (Bornstein, 1996a, p. 203). There has not yet been a published study on the correlation of the ROD scale with any measure of dependent personality disorder. "The relationship between ROD scores and Axis II psychopathology remains unexamined" (Bornstein, 1996a, p. 204), and Bornstein (1995) does suggest that self-report inventory and semistructured interview assessments of dependency are probably better predictors of a DSM-IV dependent personality disorder diagnosis than projective measures. However, clinicians who prefer to assess implicit, perhaps even unconscious, dependency needs might prefer a projective assessment rather than a self-report inventory or a semistructured interview (Bornstein, 1998a; Westen, 1997).

Epidemiology

Dependent personality disorder is among the most frequently diagnosed personality disorders (APA, 1994); it occurs in 5 to 30% of patients (Hirschfeld et al., 1991) and 2 to 4% of the general population (Maier et al., 1992; Nestadt et al., 1990; Zimmerman & Coryell, 1989). It is diagnosed more frequently in females than in males, although this differential sex prevalence rate is controversial in a manner comparable to histrionic personality disorder (see earlier discussion), and it is again suggested in DSM-IV that the differential sex prevalence rate might be an illusory artifact of biased clinical assessments and the base rate of females within clinical settings (APA, 1994).

A few studies that used semistructured interviews have failed to identify a differential sex prevalence rate for dependent personality disorder (e.g., Glolomb, Fava, Abraham, & Rosenbaum, 1995; Grilo et al., 1996). However, most studies that used semistructured interviews indicated that

more women than men are likely to have dependent personality disorders (Corbitt & Widiger, 1995). Bornstein (1996b) conducted a meta-analysis of studies that assessed for dependent personality traits. "All dependent personality disorder prevalence rate studies published before 1993 that (a) used structured interviews to derive dependent personality disorder diagnoses and (b) involved random samples of psychiatric inpatients, outpatients, or community subjects were included in this analysis (n of studies = 18)" (Bornstein, 1996b, p. 4). He found "a highly significant difference that indicates that a woman is nearly 40% more likely than a man to receive a dependent personality disorder diagnosis" (Bornstein, 1996a, p. 4).

It should be noted, however, that Bornstein (1996b) did not suggest that the differential sex prevalence rate obtained with semistructured interviews is necessarily correct. On the contrary, he suggested that instruments of assessment with high face validity (e.g., semistructured interviews or self-report inventories whose questions obviously assess for dependent personality traits) will tend to underestimate the prevalence of the disorder in males given the higher likelihood that they unconsciously or consciously deny the extent of their dependency needs. Bornstein (1995) also conducted a meta-analysis of all studies published since 1950 that provided data on sex differences in dependency. A total of ninety-seven studies was identified, and the findings "revealed that (a) women of all ages consistently obtain higher dependency scores than do men on objective dependency tests; and (b) adult men obtain slightly higher scores than do adult women on projective dependency tests" (Bornstein, 1995, p. 319). These results suggest that although women almost invariably obtain higher scores than men on measures of self-attributed (i.e., overt or conscious) dependency needs, women and men might not differ with respect to their levels of implicit (underlying or unconscious) dependency needs.

The prevalence and diagnosis of dependent personality disorder may also vary across cultures (Foulks, 1996) because there are profound differences in the extent to which societies encourage and value dependency-related behaviors. Many Western societies place more emphasis and value on expressions of autonomy and self-reliance and might then be prone to overdiagnose the disorder (Bornstein, 1992, 1993). In some cultures, such as

the Japanese (Johnson, 1993) or Indian (Singh & Ojha, 1987), interpersonal connectedness and interdependency are more highly valued, and what is considered dependency within the American culture might not be considered pathological within another culture.

The controversies concerning gender may also interact with issues concerning culture. Within many societies, females are encouraged to be more dependent than males and are diagnosed as disordered for having conformed to this sex role (Kaplan, 1983). It is not always clear whether this diagnosis represents an accurate assessment of a pathology created by maladaptive socialization of women (Widiger & Spitzer, 1991) or a masculine bias with respect to these judgments (Kaplan, 1983). Some researchers have even suggested that there might not be many dependent females if there were more dependable males (Coyne & Whiffen, 1995). Dependent behavior in females is often in reaction to irresponsible, indifferent, or negligent behavior of the persons with whom they are involved. If males, including fathers, were more consistently dependable, there might indeed be less dependency in females.

There is also substantial need for research on the relationship of aging to the presence and the diagnosis of this disorder (Abrams & Horowitz, 1996; Segal, Hersen, Van Hasselt, Silberman, & Roth, 1996). Dependent personality disorder is one of the more commonly discussed and researched personality disorders among the aged (Baltes, 1996; Loranger, 1996). However, it is not always clear if this dependency results from the aging process (e.g., secondary to a deterioration in capacity to care for oneself and loss of supportive relationships) or if it represents the characteristic manner in which the person functioned throughout life. Studies have suggested that the increased dependency levels in older adults are due primarily to increases in instrumental dependency (i.e., reliance on others for assistance in daily living), rather than to increases in an emotional dependency (as suggested by a clinging insecurity). Emotional dependency is more closely linked with the diagnosis of a dependent personality disorder (Baltes, 1996; Bornstein, 1993). In any event, one cannot currently diagnose a personality disorder with DSM-IV unless the disorder was evident since late childhood or early adulthood. DSM-IV does recognize adult-onset personality change if it is the direct result of a neurochemical change

secondary to a medical disorder (i.e., personality change due to a general medical condition), but not if the change is the direct result of social-environmental experiences or is an indirect result of a medical incapacitation.

Etiology and Pathology

There has been a study of the heritability of dependent personality disorder, but the methodology was too weak to be adequately conclusive (Nigg & Goldsmith, 1994). O'Neill and Kendler (1998) reported the results of a longitudinal study of 2230 twins to whom an interpersonal dependency subscale of the IDI had been administered (Hirschfeld et al., 1977). The results suggested a modest genetic influence and a large specific environmental contribution. Dependent personality disorder may also involve maladaptive variants of common personality traits within the broad domains of neuroticism and agreeableness (Mongrain, 1993; Widiger et al., 1995; Zuroff, 1994). Facets of agreeableness that are closely involved with dependency are excessive trust (gullibility), altruism (self-sacrificing), compliance (submissiveness), modesty (self-effacing), and tender-mindedness (Widiger et al., 1995). These traits appear to be heritable (Nigg & Goldsmith, 1992). A closely related dimensional model of personality pathology is provided by Livesley and his colleagues; included within it is a dimension of insecure attachment that may represent a fundamental pathology of dependent personality disorder (Bornstein, 1992, 1993) that, it has been shown, is heritable within both clinical and nonclinical populations (Livesley, Jang, & Vernon, 1998).

Dependent personality disorder may represent an interaction of an anxious, fearful temperament with an insecure attachment to an inconsistent or unreliable parental figure (McGuffin & Thapar, 1992). Dependent persons may turn to parental figures to provide reassurance and a sense of security that they are unable to generate for themselves. This empirically supported etiologic model (Rothbart & Ahadi, 1994) is consistent with current object relations theory in which dependent personality traits are considered an internalization of the mental representation of the self as weak and ineffectual and contribute to a disposition to look to others to provide protection and support, to become preoccupied with fears of abandonment, and to develop feelings of helplessness and insecurity

(Blatt, Cornell, & Eshkol, 1993; Bornstein, 1992, 1993).

Parental figures might exacerbate genetically based dispositions toward feelings of anxiousness and insecurity by not encouraging the development of interpersonal skills and coping strategies and by validating an inadequate, powerless, or ineffectual self-image through authoritarian or overprotective behavior (Bornstein, 1993, 1999). Efforts toward autonomy and individuation might be discouraged, whereas continued infantilization and dependency are encouraged. In an intriguing cross-generational laboratory study, Thompson and Zuroff (1998) demonstrated how dependent mothers tended to reward mediocre rather than excellent performance by their daughters. Positive regard by parental figures might not be unconditional, but conditional instead the continued (and perhaps inconsistent) communication of their value or worth to them. Persons with this disorder might then develop the belief that their worth is contingent on their worth or importance to another person.

Cognitive theorists describe an irrational schema that conveys this pathological sense of self-worth. Beck and Freeman (1990) suggest that the core belief is that "I am completely helpless," coupled with the sense that "I can function only if I have access to somebody competent" (p. 290). "They conclude that the solution to the dilemma of being inadequate in a frightening world is to try to find someone who seems able to handle life and who will protect and take care of them" (Beck & Freeman, 1990, p. 290). However, their neediness and desperation will often prevent them from carefully selecting people who will indeed be protective and nurturant. They often choose indiscriminately and become quickly attached to persons who are unreliable, unempathic, and even exploitative and abusive. They might feel that either they deserve inadequate partners or may even select inadequate partners to try to work through or resolve their long-standing interpersonal conflicts and feelings of inadequacy (Stone, 1993).

A substantial number of studies has now confirmed that the dependent person's self-image as weak and ineffectual and the excessive need to please others contributes to a variety of interpersonal problems and maladaptive consequences (Bornstein, 1999; Overholser, 1996). Bornstein, Riggs, Hill, and Calabrese (1996), for example, demonstrated in a series of experiments how de-

pendent persons might do whatever is necessary when competing with peers to please an authority figure, even if it means acting aggressively. Santor and Zuroff (1997) demonstrated how dependent persons were excessively concerned with maintaining interpersonal relatedness, adopting the responses of friends who outperformed, minimizing disagreement with disagreeing friends, and praising friends even when they disagreed with them. A number of studies have also indicated that dependent personality traits provide vulnerability to the development of clinically significant episodes of depression, particularly in response to interpersonal rejection or loss (Blatt & Zuroff, 1992). Valid methodological concerns are often raised with respect to this research (e.g., Coyne & Whiffen, 1995; Widiger, Verheul, and van den Brink, 1999), but a sufficient number of replicated, well-designed prospective studies support the hypothesis that dependency does indeed provide vulnerability to episodes of depression (Robins et al., 1995). For example, Hammen et al. (1995) obtained 6-month and 12-month follow-up assessments of 129 high school senior women. They conducted multiple regression analyses to predict depression on the basis of dependency cognitions, prior interpersonal stress, and the interaction between them, controlling for initial levels of depression. All of the young women experienced stressful life events during this period of their lives, including moving away from home, separating from an important relationship, and losing a romantic partner, but most of them did not become depressed. "It was the women with cognitions about relationships representing concerns about rejection or untrustworthiness of others who were especially challenged by normative changes" (p. 441). Hammen et al. (1995) concluded that "overall, the results suggest that dysfunctional attachment cognitions contribute to both onset and severity of symptomatology" (p. 441).

Conclusions

A substantial amount of clinical, personality, and social-psychological research has been conducted on histrionic, narcissistic, and dependent personality disorders since the last edition of this text (Blashfield & Davis, 1993). It is no longer the case that these are weakly validated diagnostic constructs. Much is now known regarding their

diagnosis, assessment, epidemiology, etiology, and pathology.

Many issues, of course, remain to be resolved. For example, additional studies are needed to understand more completely the myriad ways in which gender, ethnicity, and age influence the likelihood of actually having or simply receiving a diagnosis of histrionic, narcissistic, or dependent personality disorder. For each disorder, the interaction of hypothesized genetic and neurochemical diatheses with early environmental influences that may exacerbate or minimize these predispositions needs to be more carefully examined. Many issues of excessive diagnostic co-occurrence and inadequate differentiation must also be addressed, and future revisions of the diagnostic system will have a substantial amount of clinical, theoretical, and empirical literature that will be of substantial help in these deliberations. Finally, it would also be useful to consider adaptive consequences of histrionic, narcissistic, and dependent personality traits. These personality traits are present in part because they have adaptive consequences and useful benefits. Individuals who select (or perhaps modify) environments that accommodate their vulnerabilities and value their strengths may experience substantially fewer consequences of the maladaptive nature of the personality disorder symptomatology. This chapter has hopefully been helpful in highlighting some of the more significant findings that have occurred since the prior edition of this text and also in stimulating the development of useful research for future editions of this text.

Disorders Associated with Social and Situational Problems

This page intentionally left blank.

Paranoid, Schizoid, and Schizotypal Personality Disorders

Michael B. Miller, J. David Useda, Timothy J. Trull, Rachel M. Burr, and Christa Minks-Brown

Introduction

Our personalities are collections of behavioral, mental, and social characteristics that define us as individuals. Characteristics that are not temporally stable cannot establish replicable individual differences and therefore are not considered aspects of personality. For some of us, our personalities interfere with our abilities to form relationships, to control our impulses or emotions, to perceive ourselves and others accurately, and to enjoy life or to function at work. When such problems reach a sufficiently pathological extreme, personality is said to be disordered.

According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV; American Psychiatric Association [APA], 1994), Personality Disorders (PDs) are characterized by inflexible, pervasive, stable, and enduring patterns of inner experience and behavior that deviate markedly from the expectations of the individual's

culture and lead to clinically significant distress or impairment in important areas of functioning. The maladaptive patterns of thought or behavior must be present at least by early adulthood, they must not be manifestations or consequences of other mental disorders, and they must not be caused by drug use or by medical conditions (see DSM-IV, p. 633, for general diagnostic criteria for a Personality Disorder).

In the DSM system of psychiatric diagnosis, PDs are grouped into three clusters (called A, B, and C) based on phenotypic similarity. Cluster A disorders include Paranoid, Schizoid, and Schizotypal PDs. The major commonality for these disorders is that affected individuals generally have very weak or nonexistent social attachments and odd or eccentric behavior. A second source of similarity for these disorders is that all three of them are found at higher rates in the families of schizophrenia patients, so that all three disorders may be alternative expressions of a similar genetic predisposition.

In this chapter, we focus on three Cluster A disorders. Seven major topics are presented: (1) a historical overview of both the schizophrenia spectrum concept and of the Cluster A personality disorders; (2) detailed descriptions of the disorders based on their modern (DSM-IV) diagnostic criteria; (3) epidemiology, including preva-

lence rates and intercorrelations (comorbidity rates) of the disorders; (4) methods of assessment; (5) dimensional (continuous) alternatives to diagnostic classification; (6) major theories of etiology; and (7) leading treatments for Cluster A disorders.

Historical Overviews

History of the Schizophrenia Spectrum of Disorders

It has been observed for many years that the family members of psychotic patients often exhibit symptoms similar to those of their psychotic relatives, but of lesser severity. Nineteenth-century American psychiatrist Isaac Ray was one of the first to write on this topic. According to Ray (1863), “the current philosophy ... supposes that the hereditary affection must appear in the offspring in precisely the same degree of intensity which it had in the parent.... Such views are not warranted by the present state of our knowledge respecting the hereditary transmission of disease” (p. 30). Ray believed that subtler aspects of mental disorder deserved more attention than they were receiving. He believed that mentally sound and unsound elements could coexist in one individual and he wrote of persons who “may get on very well in their allotted part, and even achieve distinction, while the insane element is often cropping out in the shape of extravagancies or irregularities of thought or action, which, according to the standpoint they are viewed from, are regarded as gross eccentricity, or undisciplined powers, or downright insanity” (Ray, 1863, p. 31).

Psychiatrists of the early part of the twentieth century, such as Eugen Bleuler, Emil Kraepelin, and Ernst Kretschmer, also described individuals who were not frankly psychotic but had features of psychotic illness. Bleuler and Kretschmer described the family members of those with schizophrenia by using terms such as schizoid, shut in, or suspicious (Kendler, 1985). Bleuler coined the term *schizophrenia* for what he believed was a *group* of psychotic disorders, and he also coined the term *latent schizophrenia* to describe cases where features of schizophrenic illness were present but in attenuated form. Gregory Zilboorg’s (1941) *ambulatory schizophrenia* was merely schizophrenia that was not striking enough to be easily recognizable. Paul Hoch and colleagues

developed the diagnostic category of *pseudoneurotic schizophrenia* (Hoch & Cattell, 1959; Hoch & Polatin, 1949; Hoch et al., 1962), whose primary clinical symptoms were similar to the symptoms of today’s Schizotypal PD. Rado (1953) coined the term *schizotypal*, and Meehl (1962) introduced the concept of *schizotypy* to define a condition with an underlying inherited neural integrative defect that could be manifested as anything from mild distortions of thought and perception to full-blown schizophrenia.

Even though these different writers seemed to be describing very similar individuals, no single term became clearly favored. During the middle of the twentieth century, up to the 1970s, the adjective *schizoid* (noun *schizoidia*) was often used to describe schizophrenic-like individuals (e.g., Heston, 1970; Kallmann, 1938). This often confuses today’s readers because the term *schizotypal* has taken on the meaning once held by *schizoid*, and the diagnostic criteria for Schizotypal PD criteria are much more schizophrenia-like than those for Schizoid PD.

In the late 1960s, Paul Wender, Seymour Kety, and David Rosenthal used Danish adoption and psychiatric records to undertake a series of studies of the genetics of schizophrenia. Their research methods were impeccable, and the published results of their “Danish adoption studies” were extremely influential—truly a watershed in the history of psychiatric research. Like the clinicians and researchers who preceded them, these researchers observed that biological relatives of schizophrenic patients, even those who were not schizophrenic themselves, sometimes exhibited schizophrenic behaviors. The researchers interpreted the range of psychopathology in the family members as evidence of a continuum or spectrum of schizophrenic-like disorders with a similar genetic basis:

We had recognized certain qualitative similarities in the features that characterized the diagnoses of schizophrenia, uncertain schizophrenia, and inadequate personality, which suggested that these syndromes formed a continuum; this we called the schizophrenia spectrum of disorders. If schizophrenia were to some extent genetically transmitted, there should be a higher prevalence of disorders in the schizophrenia spectrum among the biological relatives of the index cases than in those of their controls. (Kety, Rosenthal, Wender, & Schulzinger, 1968, p. 353)

In later papers, the same authors used the term “borderline schizophrenia” for individuals who

did not meet their criteria for schizophrenia but had some schizophrenic personality features. The term “schizophrenia spectrum” is still widely used, but which disorders should be included in the spectrum is still not fully resolved.

The DSM-II was published in 1968, but it did not include reference to personality types with schizophrenic features. It contained terse descriptions (three sentences each) of Paranoid and Schizoid PDs, but no formal diagnostic criteria, and Schizotypal and Borderline PDs were not listed. Psychiatrists of the day used the term “borderline” inconsistently to refer to either an unstable “borderline personality” or to “borderline schizophrenia.” Some psychiatric researchers of the 1970s wisely sought to clarify the meanings of the diagnostic labels by refining the DSM diagnostic approach to include explicit criteria and more complete descriptions. The DSM-III, which appeared in 1980, marked a dramatic change in diagnostic rigor. The addition of Schizotypal PD and Borderline PD in DSM-III was influenced greatly by the work of Spitzer, Endicott, and Gibbon (1979). Spitzer et al. sought to clarify the meaning of the term “borderline” as it was being used by psychiatrists at that time. Spitzer mailed letters to a randomly selected sample of 4000 APA members asking for their help in developing the criteria for DSM-III borderline personality disorder and requesting that they use items developed by Spitzer et al. to rate two of their patients, one “who warrants a diagnosis of borderline personality, borderline personality organization or borderline schizophrenia” (p. 20) and one who is “moderately to severely ill but [does] not have a diagnosis of psychosis or any of the borderline categories” (p. 20). Exactly 808 psychiatrists responded, and statistical analysis of their data showed that the two types of borderline patients could be partially distinguished from each other (but with a 54% overlap!) and readily distinguished from the non-borderline controls. The items used to rate patients in the Spitzer et al. (1979) study were later developed into the DSM-III criteria for Borderline PD (corresponding to the unstable personality) and Schizotypal PD (corresponding to borderline schizophrenia).

History of Schizotypal PD

Schizotypal PD is the major schizophrenia-spectrum personality disorder, so much of the his-

tory of Schizotypal PD was covered in the preceding section, but we will add a discussion of the historical development of the terms *schizotype* and *schizotypal*. The term *schizotype* was used by Kretschmer early in the twentieth century (Brueel, 1936), but most of today’s scholars attribute the term to Rado (1953). Rado created *schizotype* by combining *schizophrenia* and *phenotype*. Paul Meehl (1962, 1964, 1990) elaborated extensively on Rado’s concepts and developed a complex theory of a trait he called *schizotypy*. In Meehl’s theory, a single dominant gene carried by 10% of the population causes, in every carrier, a “neural integrative defect” which he called *schizotaxia* (combining *schizo-* with *ataxia*). He did not specify the exact nature of the defect. In addition, Meehl (1962) stated that “All schizotaxics become, *on all actually existing social learning regimes*, schizotypic in personality organization” (p. 231, italics in original). Meehl’s schizotype (an individual with a schizotypic personality organization) is characterized by cognitive slippage (mild thought disorder), anhedonia or hypohedonia (lack of pleasure), ambivalence, and interpersonal aversiveness (social fear). It follows that, in our world, every carrier of the dominant gene will have a schizotypic personality organization; also, according to Meehl (1990), 10% of such individuals will develop frank schizophrenia, and the remaining 90% will have varying degrees of personality psychopathology. Individuals who do not carry the gene are protected from developing schizophrenia, but they might very rarely develop a psychotic disorder that mimics schizophrenia. Meehl’s (1964) descriptions of schizotypic personality traits were very clear and detailed, and they have played an important role in research (viz., the psychometric scales developed by the Chapmans and described in the section of this chapter on dimensional approaches).

Meehl’s concepts and terminology were not adopted by the DSM when the category of Schizotypal PD was added in 1980. In fact, Spitzer et al. (1979) cited neither Meehl nor Rado and simply claimed to adopt the term *schizotypal* because “the term means ‘like schizophrenia’” (p. 18). Meehl’s theory of *schizotaxia*, *schizotypy*, and *schizophrenia* has inspired a tremendous amount of research in the decades since it was published. Some of the findings of that research will be discussed later in this chapter. We should add that the single-gene aspect of Meehl’s theory, while per-

haps not refuted outright, seems unlikely to be correct in the face of a large number of genetic linkage analysis studies of schizophrenia that have failed to find evidence of a strong single-gene effect.

History of Paranoid PD

The study of paranoid phenomena has a long and rich history within philosophy, psychiatry, and psychology. The literature has focused on the existence and description of distinct subtypes of paranoia, the relation of paranoid states to other diagnostic entities, as well as the etiology and course of the various paranoid diagnoses. The definitions and terms used to describe paranoid disorders have varied and evolved over time. The evolution of the Paranoid PD construct will be described briefly (see Millon & Davis [1996] for a more in-depth discussion).

Early descriptions of paranoia do not resemble contemporary conceptualizations of this phenomenon. In Greek literature, paranoia was often used to describe madness in general or thinking amiss (Akhtar, 1990; Lewis, 1970; Manschreck, 1979). Various formulations through the 1700s attempted to define conditions which had exhibited some aspects of paranoia, but none received the attention that was accorded to Heinroth's (1818) conceptualization (Akhtar, 1990; Lewis, 1970; Tanna, 1974). Heinroth's description included four types of paranoia: a gross distortion of an individual's reality due to a single misconception; delusions of the supernatural; megalomania; and a mixture of cognitive, emotional, and volitional problems (Lewis, 1970). Heinroth believed that paranoia predominantly affected understanding and rarely occurred in a pure form, a nineteenth-century observation that still rings true today. He asserted that paranoia usually co-occurs with disorders of the will or affect or both (i.e., delusions and bizarre behavior, mood disturbance).

Kahlbaum's 1863 definition of paranoia is widely regarded as resembling a modern-day conceptualization of this phenomenon (Tanna, 1974). Yet, the classification of paranoid syndromes posed a challenge for diagnosticians of the nineteenth-century. Turn-of-the-century German diagnosticians, particularly Emil Kraepelin and Eugene Bleuler, continued to examine paranoia and its subtypes, and delusions of persecution figured prominently in

their conceptions of the various paranoid disorders. The greatest challenge in classifying paranoia lay in the nineteenth-century observation that paranoid states were seen in many different psychiatric conditions, an observation that is still valid today (Manschreck & Petri, 1978). Central to the diagnostic dilemma of the time was whether to classify paranoia as a separate disorder that could co-occur with schizophrenia (or dementia praecox, as it was then called) or to classify paranoia as a subtype of schizophrenia (Lewis, 1970; Manschreck, 1979), a controversy that continues to this day (Coryell & Zimmerman, 1989; Kendler & Gruenberg, 1982; Kendler, Masterson, & Davis, 1985; Maier, Lichtermann, Minges, & Heun, 1994).

By the end of the nineteenth century, Emil Kraepelin's classification of psychiatric disorders recognized three forms of paranoia; (1) a subtype of dementia praecox (like modern Schizophrenia, Paranoid Type); (2) a form associated with a milder type of dementia praecox which did not display the deterioration of personality Kraepelin expected to see in dementia praecox (like modern Delusional Disorder, Persecutory Type); and (3) most importantly for this discussion, another form of paranoid disorder described was an insidious, chronic illness characterized by a fixed delusional system, without hallucinations or deterioration of personality (see Manschreck, 1979). This third form most closely resembles the present-day Paranoid PD.

Paranoid PD has been recognized formally in the U.S. psychiatric nomenclature since 1942 and has been included in every edition of the DSM since its inception in 1952. In this century, the defining features of Paranoid PD, as described in the clinical literature, have included a pervasive and unwarranted mistrust of others (Kraepelin, 1921), hypersensitivity to criticism (Cameron, 1943, 1963; Kretschmer, 1925), antagonism and aggressiveness (Sheldon, 1940; Sheldon & Stevens, 1942), an excessive need for autonomy (Millon, 1969, 1981), hypervigilance (Cameron, 1963; Millon, 1981; Shapiro, 1965), and rigidity (Shapiro, 1965). Although Paranoid PD had already been a part of the DSM system, this body of literature was the basis for the formulation of explicit diagnostic criteria for Paranoid PD in the DSM-III (APA, 1980). The DSM-III criteria were meant to be representative of the clinical literature; yet not all have agreed to the comprehensiveness of the con-

struct as defined by the DSM and have described additional criteria for assessing Paranoid PD (Akhtar, 1990; Millon, 1983, 1987; WHO, 1992).

History of Schizoid PD

The term *schizoid* was coined by Bleuler (1922), but descriptions of individuals who would meet today's criteria for Schizoid PD preceded Bleuler by many years. Millon and Davis (2000) note that Ribot (1890) coined the term *anhedonia* for the lack of physical and social pleasure that is central to the schizoid experience. August Hoch (1910) described a "shut-in" personality that he saw as highly vulnerable to dementia praecox (schizophrenia). Hock's shut-ins were seclusive and quiet, stubborn, rigid, and prone to fantasy. Bleuler's concept of the schizoid was similar to Hoch's, but Bleuler focused more on the indifference of schizoid individuals and on their self-absorption—their autistic focus on an inner world. Kretschmer (1925) interpreted the inner focus of schizoid persons as a necessary consequence of their detachment from other human beings.

The Schizoid personality has been included in the DSM diagnostic system since its inception in 1952. The earliest description noted that "Inherent traits in such personalities are (1) avoidance of close relations with others, (2) inability to express directly hostile or even ordinary aggressive feelings, and (3) autistic thinking" (APA, 1952), DSM-II (APA, 1968) retained a similar description, but DSM-III (APA, 1980) introduced diagnostic criteria in place of mere descriptions and added an emphasis on the emotion in the Schizoid PD. Rather than simply avoiding interpersonal relationships, the schizoid is said to show "(A) Emotional coldness and aloofness, absence of warm, tender feelings for others; (B) indifference to praise or criticism or to the feelings of others" (APA, 1980, p. 311). A new diagnostic category called Avoidant PD was added in the DSM-III. The Avoidant PD was said to be socially withdrawn, like the schizoid, but the avoidant was hypersensitive to rejection and derogation instead of being indifferent like the schizoid. So the fundamental distinction among these disorders was that the *cause* of social isolation differed among them: The avoidant was isolated because of social anxiety, whereas the schizoid was isolated because of

social aloofness and indifference. DSM-III-R enhanced this difference in emotionality by adding "rarely, if ever, claims to experience strong emotions, such as anger and joy" (APA, 1987, p. 340) to the list of symptoms of Schizoid PD and simultaneously more strongly emphasized the neurotic emotionality of the Avoidant PD. The DSM-IV (1994) has deemphasized the emotionality issue for both PDs, and the DSM-III-R schizoid symptom shown in the previous sentence was removed in DSM-IV.

The vacillation in DSM criteria for Schizoid and Avoidant PDs reflects a controversy that dates to Kretschmer's (1925) writings on schizoid personality. Kretschmer distinguished between two schizoid types: the anesthetic and the hyperaesthetic. This dichotomy was revised and elaborated by Millon (1969) in his theory of personality, and it became the basis for the schizoid (anesthetic) and avoidant (hyperaesthetic) PDs. According to Kretschmer (1925), hyperaesthetic individuals tend to feel their isolation strongly and "they seek as far as possible to deaden all stimulation from the outside" (p. 161). Anesthetic individuals were considered indifferent and withdrawn because they were so lacking capacity for affective responsiveness: "He draws back into himself . . . because all that is about him can offer him nothing" (p. 162). This dichotomization of socially withdrawn individuals into schizoid and avoidant PDs has always been controversial and remains so. Several writers (e.g., Akhtar, 1987) have doubted that individuals with schizoid personalities are truly unemotional, even though they appear so to observers. Gunderson (1983) questioned the need for the Avoidant PD category in DSM-III on the grounds that empirical support for the schizoid/avoidant distinction was weak and the theoretical rationale for the distinction was not widely accepted.

Today, we are left in the awkward position of having two DSM personality disorders—schizoid and avoidant—that are similar enough that some experts feel that they are not distinct disorders, but these same two disorders are grouped in different DSM personality disorder clusters because of their theoretical dissimilarity. Bleuler originally conceived of schizoid individuals as schizophrenic-like and, despite relatively weak empirical affirmation for the relationship of Schizoid PD to schizophrenia, Schizoid PD is grouped with Schizo-

Table 1. DSM-IV Diagnostic Criteria for Schizotypal Personality Disorder

A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) ideas of reference (excluding delusions of reference)
- (2) odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or "sixth sense"; in children and adolescents, bizarre fantasies or preoccupations)
- (3) unusual perceptual experiences, including bodily illusions
- (4) odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped)
- (5) suspiciousness or paranoid ideation
- (6) inappropriate or constricted affect
- (7) behavior or appearance that is odd, eccentric, or peculiar
- (8) lack of close friends or confidants other than first-degree relatives
- (9) excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self

B. Does not occur exclusively during the course of Schizophrenia, a Mood Disorder With Psychotic Features, another Psychotic Disorder, or a Pervasive Developmental Disorder.

typal and Paranoid PDs in DSM-IV's Cluster A. Following Kretschmer (1925) and Millon (1969), the DSM-IV Avoidant PD is marked by feelings of inadequacy, hypersensitivity, and fear of rejection. So it is grouped with the anxious/inhibited Dependent and Obsessive-Compulsive PDs in Cluster C.

Descriptions of Cluster A PDs

Description of Schizotypal PD

Schizotypal PD is characterized by a pervasive pattern of acute discomfort in close relationships, cognitive or perceptual distortions, and eccen-

tricitities of behavior which begins by early adulthood and is present in a variety of situations. At least five of nine criteria listed in Table 1 must be evident for this diagnosis to be given (American Psychiatric Association, 1994). These criteria include ideas of reference (Criterion A1) that are incorrect interpretations of events as having a particular and unusual meaning specifically meant for the individual. Ideas of reference must be distinguished from delusions of reference, which may be similar in content but are held with greater conviction. For example, a person who exhibits ideas of reference may have the *feeling* that strangers are talking about him/her, but if challenged, acknowledges that the people may be talking about something else. In contrast, individuals with delusions of reference would consistently *believe* that people are talking about them and could probably give specific examples of what those people are saying. Individuals with Schizotypal PD may have odd beliefs or magical thinking that influence their behavior and are inconsistent with subcultural norms (Criterion A2). For example, they may be superstitious and/or believe in clairvoyance, telepathy, or a "sixth sense." Unusual perceptual experiences, such as feeling the presence of another person or hearing someone call their name when no one is there, may be present as well (Criterion A3).

In addition, individuals with Schizotypal PD may exhibit odd thinking and speech (Criterion A4). Speech patterns may be vague, circumstantial, metaphorical, over elaborate, or stereotyped. Suspiciousness or paranoid ideation (Criterion A5) may also be characteristic of these individuals. For example, they may believe that their co-workers are trying to undermine their reputations with their boss. They frequently lack close friends or confidants other than first-degree relatives (Criterion A8). This may be due, in part, to their interactional style. They often experience excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears (Criterion A9). At social events, schizotypal people tend to become more uncomfortable rather than relaxed as time passes. In addition, they often are unable to express the full range of affects and thus may seem to interact with others in an inappropriate, stiff, or constricted manner (Criterion A6). These individuals' behavior or appearance may seem odd, eccentric, or peculiar (Criterion A7) which, again makes maintaining relationships difficult.

It is important to note that Schizotypal PD should not be diagnosed if these behaviors occur only during the course of Schizophrenia, other psychotic conditions (e.g., mood disorder with psychotic features), or a pervasive developmental disorder (APA, 1994). The following is a vignette of a person with schizotypal PD.

Although Jim was viewed by his high school teachers as “bright” and “creative,” he never seemed to live up to his potential. Further, at times his “creativity” seemed to border on the bizarre. For example, he made it clear to several people that he believed in “fairies” who were invisible but did good deeds. According to Jim, you can sometimes “feel” their presence, and these fairies may in fact be responsible for day-to-day events that transpire. Fairly mundane or routine happenings seem to take on personal significance to Jim. For example, thunderstorms might be interpreted by Jim as a message not to shower for one day. Discussions with Jim about fairies or otherwise tend to be hard to follow. Jim often is quite vague, and he frequently uses metaphors that are difficult to connect to the topic at hand. Another “odd” feature of Jim’s behavior is that he frequently breaks out into a silly grin and laughs for no apparent reason. This makes those around him feel very uncomfortable. For the last ten years, Jim has had no real friends, lives by himself, and prefers to be alone. He “lives off the land” and is much more comfortable being “out in nature” rather than around people.

Description of Paranoid PD

Nearly anyone can describe an individual who would be called “paranoid” or who has acted “paranoid” to some degree at some time. Nearly everyone has experienced fleeting feelings of suspicion, felt unduly criticized, or felt the need to be alone. We all know what is means to “read between the lines” of what someone is saying for other meanings, such as implied criticisms. Perhaps, we have sometimes have been unwilling to be flexible about what we think, or we have reacted angrily to a mild insult. These experiences are at the core of the way a person with Paranoid PD experiences the world, and they carry these feelings, thoughts, and actions to such an extreme, and so consistently, across a wide variety of circumstances that their lives are full of threat, anger, and interpersonal problems.

Table 2. DSM-IV Diagnostic Criteria for Paranoid Personality Disorder

-
- A. A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
- (10) suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her
 - (11) is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
 - (12) is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
 - (13) reads hidden demeaning or threatening meanings into benign remarks or events
 - (14) persistently bears grudges, i.e., is unforgiving of insults, injuries, or slights
 - (15) perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack
 - (16) has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner
- B. Does not occur exclusively during the course of Schizophrenia, a Mood Disorder With Psychotic Features, another Psychotic Disorder and is not due to the direct physiological effects of a general medical condition.

Note: If criteria are met prior to the onset of Schizophrenia, add “Premorbid,” e.g., “Paranoid Personality Disorder (Premorbid).”

According to the DSM-IV (see Table 2), “The essential feature of Paranoid Personality Disorder is a pattern of pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent. This pattern begins by early adulthood and is present in a variety of contexts” (p. 634). Paranoid PD is comprised of maladaptive variants of six personality traits: mistrust/suspicion, antagonism, autonomy, hypersensitivity, hypervigilance, and rigidity. It is differentiated from transitory suspicious states that we all may experience, as well as from systematized paranoid delusional states associated with certain Axis I disorders (e.g., schizophrenia, delusional disorder). Paranoid PD individuals experience transitory psychotic symptoms during periods of extreme

stress. Paranoid PD is considered among the more severe PD in terms of the defensive style employed (e.g., projection, acting out) and the level of dysfunction (Millon & Davis, 1996; Shapiro, 1994; Vaillant, 1994). Paranoid PD is rarely diagnosed alone (Morey, 1988; Weissman, 1993; Widiger & Rogers, 1989; Widiger & Trull, 1998). The comorbidity with other Axis II disorders observed in these individuals may, in part, also explain the severity associated with this diagnosis (Weissman, 1993). A “pure” Paranoid PD case is rarely, if ever, seen (Millon & Davis, 1996). Thus, what is described herein is a prototype of the disorder. As this list of traits indicates, the term “paranoid” as applied to Paranoid PD is not just feelings or thoughts of persecution. The diagnosis describes individuals who lack trust, are hypersensitive to criticism, are prepared to act in a hostile manner to defend their sense of autonomy, incessantly seek out examples to confirm their maladaptive beliefs, are intensely preoccupied with suspicions about others’ intent to harm or threaten them, and are rigid in their beliefs about others. In addition, Paranoid PD individuals tend to be tense and affectively inhibited.

Interpersonal Style

The DSM-IV’s General Diagnostic Criteria for a Personality Disorder indicate that interpersonal dysfunction is a defining characteristic of PDs. It is stated that the interpersonal dysfunction must be observed in a variety of personal and social situations. This is particularly true of Paranoid PD. Paranoid PD individuals suffer from problematic interpersonal relationships primarily due to their propensity for suspiciousness, mistrust of others, and hostile reactions to perceived threat. A vicious cycle occurs in the interpersonal lives of Paranoid PD individuals. Their lack of trust and expressed hostility tend to push people out of their lives. Expressions of hostility may provoke hostile reactions, which in turn only confirm the Paranoid PD individual’s maladaptive belief that the world is generally threatening and hostile. They do not tend to check with others whether their beliefs are sensible.

Individuals with Paranoid PD are impaired in their ability to examine their own beliefs. Their rigid style of thinking often restricts their ability to take another perspective. They will often act on their suspicious ideas regarding others’ intentions, reasoning that others are “out to get them.” They

often look for examples of their suspicious ideas in the actions of others and are reluctant to interpret events differently. This interpersonal style typically leads to problems in initiating or maintaining romantic relationships and is associated with lack of trust and pathological jealousy, divorce, intolerance of indifference, difficulties keeping a job, and recurrent litigation for perceived injustices (Auchincloss & Weiss, 1994; DSM-IV, APA, 1994; Meissner, 1995; Millon, 1981; Sullivan, 1932/1965; Turkat, 1985). Paranoid PD individuals have an excessive need for autonomy and lack trust in others, which disrupts the formation of stable interpersonal relationships. The following is a vignette of a person with Paranoid PD.

George is a 30-year-old single man with a long history of problems with co-workers at the small high-tech company where he works. He keeps to himself at work, does not confide in others about his work or personal life, and is viewed by most as very difficult to get along with. It is not unusual for George to lash out verbally at others, accusing them of lying or trying to make him look bad. This has led to an extremely tense work environment. Co-workers frequently complain to work supervisors about George’s hostility and uncooperativeness. George’s immediate supervisor has tried to talk to him about these issues, but George maintains that the problem lies with his co-workers, not himself. Most recently, George has begun to accuse his supervisor of trying to make him look bad as well. George has threatened to sue his supervisor and the company because of “harassment.” Although very little is known about George outside of the workplace, it does not appear that he has any long-standing friendships. Previous acquaintances have complained that George soon became hostile and accusatory, leading to the end of the relationship.

Cognitive Style. According to Shapiro (1965), the paranoid type is hyperalert and possesses a rigid attentional style to environmental stimuli. This cognitive style is representative of a cognitive mode that “is not merely occasionally or sporadically characteristic of paranoid people, but is continuous,” (p. 59) and confirms a paranoid’s anticipations. Magaro (1980, 1981) also discussed cognitive distortions displayed by paranoid individuals such as intolerance for ambiguous stimuli; rigid response styles; and distortions of perceptions, attention, and encoding. Although Magaro (1981) argues for a distinct paranoid cognitive style that differentiates the paranoid from the schizophrenic (as mentioned before, a focus of

historical controversy), this work relied on the study of paranoid psychotics (i.e., delusional and/or hallucinating). Unfortunately, Magaro's (1981) information-processing perspective has not received empirical attention in relation to the cognitive style of those with Paranoid PD. It is unclear to what extent paranoid thought processes in the more severe paranoid disorders (i.e., the paranoid subtype of Schizophrenia and Delusional Disorder) can be generalized to the less severe but chronic form of paranoia in Paranoid PD. Munro (1982, 1992) has also argued for a distinct paranoid dimension as well, but Paranoid PD is not firmly established as part of this dimension within this perspective. The study of Paranoid PD from an information-processing perspective warrants further research.

Beck and Freeman (1990) offer the most extensive theory on the cognitive style of individuals with Paranoid PD. They postulate that the paranoid behaviors themselves are not at the center of the disorder. According to Beck and colleagues, beliefs and feelings of inadequacy and the inability to cope effectively in interpersonal situations are essential features of Paranoid PD. The resulting anxiety associated with these negative self-perceptions is reduced when one searches for an explanation external to oneself and blames others. From this perspective, the terms schemas and misattributions replace the theoretically cumbersome term "projection" (to be discussed later), often described in a variety of other theoretical perspectives. Paranoid individuals will search incessantly for reasons in their environment to confirm their maladaptive beliefs; this self-perpetuating cycle reinforces their maladaptive ideas even further. Any sign of criticism or mistreatment confirms their cognitions and feelings regarding the disloyalty and threatening stance of others (Beck et al., 1990). Unfortunately, there is little empirical data for a cognitive profile representative of Paranoid PD (Schmidt, Joiner, Young, & Telch, 1995).

The defense mechanism of projection must be discussed in any discussion of the cognitive nature of paranoia or Paranoid PD. The clinical utility of using projection as a diagnostic indicator of Paranoid PD has been demonstrated empirically (Drake & Vaillant, 1985). Defense mechanisms refer to innate involuntary regulatory processes that allow individuals to reduce cognitive dissonance and to minimize sudden changes in internal and external environments by altering the way these events are perceived. Defense mechanisms can alter our perception of any or all of the following: subject

(self), object (other), idea, or feeling (Vaillant, 1994, p. 44).

The terms projection, introjection, and projective identification have long been widely accepted to describe the paranoid's intrapsychic processes, and the use of projection as a defense mechanism is a defining characteristic of Paranoid PD (Vaillant, 1994). The psychoanalytic writings on the defense mechanism of projection are vast and often complicated theoretically (Freud, 1911/1963; Klein, 1946/1986; Meissner, 1978). Summarizing these psychoanalytic viewpoints on projection is beyond the scope of this chapter. Briefly, the construct entails recognizing characteristics in another individual that are in conflict within the Paranoid PD individual's own self-esteem, but out of conscious awareness. This is experienced by Paranoid PD individuals as something wrong with the other, not with themselves. From the Paranoid PD individual's perspective, the other is faulty, threatening, or critical. The Paranoid PD individual often acts on this perception.

Projection in the clinical literature is often synonymous with paranoid conditions. This view of projection may be a limited interpretation of this defense mechanism (see Shapiro, 1994). More recent psychodynamic and interpersonal perspectives offer assistance in clarifying the description of projection (O'Leary & Watson, 1995; Shapiro, 1994). Briefly, similar to the description by Beck et al. (1990) and broader than more traditional views, the process of projection in Paranoid PD can be simply stated as the attribution of self-blame and anxiety associated with negative self-concepts (I feel shame) to external sources (I am being humiliated). The rigidity of Paranoid PD individuals' cognitive processes inclines them to perceive threat from external sources (as opposed to from within) and direct anger outward to alleviate internal anxieties. Projection or substitution of blame is central to understanding the cognitive style of Paranoid PD. Unfortunately, empirical investigation of defense mechanisms has only recently become systematic (Morey, 1993).

Note that social psychologists have systematically studied the constructs known as self-serving biases, attribution, and schemas as well as their moderation by motivation. The process of projection could easily be encompassed within this literature. These constructs may provide a more parsimonious theoretical foundation, as well as established empirical evidence for the cognitive processes involved in the individuals' tendencies to blame others for their problems (for a review of

these classic social psychology constructs, see Fiske & Taylor, 1991). The applicability of these constructs to a clinical sample of Paranoid PD individuals may be fruitful in the empirical investigation of projection. In summary, although the clinical literature has consistently regarded projection as a hallmark of Paranoid PD and there is indication as to this construct's clinical utility, the empirical study of projection in Paranoid PD remains to be conducted systematically.

Affective Style. The DSM-IV does not include Paranoid PD criteria that refer specifically to affect or mood. However, the Associated Features section of the manual describes correlates of the disorder such as being cold to others or having restricted affect with little sense of humor. Paranoid PD individuals have also been described as tense and nervous (DSM-II-R; APA, 1987, p. 337). This criterion refers to the Paranoid PD individual's proclivity to appear to others as guarded, generally cold, emotionally reserved, and as noted before, uses the ability to blame others to defend against anxieties. Evidence presented by Trull (1992) found significant positive correlations between the NEO-Personality Inventory-Revised (NEO-PI-R; Costa & McCrae, 1992), the Neuroticism domain (regarded as an index for the proclivity to experience negative affect-depression/anxiety), and Paranoid PD symptom counts. Thus, despite appearing emotionally reserved to others generally, the Paranoid PD individual experiences anxiety and is prone to angry outbursts in response to perceived slights. This apparent contradiction between the external presentation of those with Paranoid PD and their internal emotional state has been a characteristic common to Paranoid PD within the clinical literature (Akhtar, 1990).

Description of Schizoid PD

According to the Diagnostic and statistical manual of mental disorders, 4th ed. (DSM-IV; APA, 1994), Schizoid PD is characterized by a "pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings" (p. 638; see Table 3). Individuals with Schizoid PD do not seem to enjoy interpersonal contact and derive little or no pleasure from close personal relationships. They demonstrate little interest in sexual experiences with another person and rarely marry. Individuals with Schizoid PD tend to lack emotional attachment and do not seek out close friendships, except pos-

Table 3. DSM-IV Diagnostic Criteria for Schizoid Personality Disorder

-
- A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
- (1) neither desires nor enjoys close relationships, including being part of a family
 - (2) almost always chooses solitary activities
 - (3) has little, if any, interest in having sexual experiences with another person
 - (4) takes pleasures in few, if any, activities
 - (5) lacks close friends or confidants other than first-degree relatives
 - (6) appears indifferent to the praise or criticism of others
 - (7) shows emotional coldness, detachment, or flattened affectivity
- B. Does not occur exclusively during the course of Schizophrenia, a Mood Disorder with Psychotic Features, another Psychotic Disorder, or a Pervasive Developmental Disorder and is not due to the direct physiological effects of a general medical condition.
-

sibly with a first-degree relative. Persons with Schizoid PD typically prefer to spend time in solitary pastimes rather than engaging in social activities. Therefore, these individuals tend to perform better in those occupations that require minimum interpersonal contact.

Those interactions in which persons with Schizoid PD do engage do not seem to provide these individuals with much pleasure or satisfaction. They appear indifferent and unaffected by typically pleasurable or emotional experiences (e.g., "walking on a beach at sunset or having sex;" APA, 1994, p. 638). In fact, Schizoid PD individuals usually have a difficult time expressing emotion, especially anger, and may report never having experienced a strong emotional response. Their lack of subjective emotional experience and paucity of expression may cause individuals with Schizoid PD to appear cold and detached. They seem to be affected by neither criticism nor commendation, and they appear generally unaware of social nuances, such as body language and facial expressions. Due to their lack of social acuity, Schizoid PD individuals tend to be socially inept

and are perceived by others as impassive and self-absorbed.

Finally, individuals with Schizoid PD may also experience brief psychotic episodes, especially under stress. In fact, according to DSM-IV, Schizoid PD may be present premorbidly in individuals with Delusional Disorder or Schizophrenia. Table 3 presents the DSM-IV criteria for Schizoid PD.

In summary, Schizoid PD is a pattern of emotional detachment and social isolation. Individuals with Schizoid PD do not appear to need, nor do they seem to desire close interpersonal relationships with other people, including sexual experiences. It is necessary to differentiate individuals with Schizoid PD from those who are considered "loners." Although behaviorally these individuals may appear quite similar, it is "only when these traits are inflexible and maladaptive and cause significant functional impairment or subjective distress do they constitute Schizoid Personality Disorder" (APA, 1994, p. 640). The following vignette is typical of Schizoid PD.

Sandy is a 28-year-old single woman who has always been viewed as a "loner." Even as a child and as a teenager, she had little interest in being around or interacting with others, including her own family members. Her school record was unremarkable, and she moved away from home as soon as she finished high school. Her parents have been concerned about her for some time. She rarely leaves her small apartment, does not have any hobbies or interests, and only occasionally works at "odd jobs." Her financial situation is bleak, and her parents pay her rent, so that she is not evicted. This all goes on without Sandy's knowledge; if left up to her, it is likely she would lose her apartment. Although the threat of loss of one's apartment would concern most people, Sandy does not seem to care one way or another. This is typical of her. She shows very little emotion regardless of the situation. Those who come into contact with her see her as "cold" and "detached."

Epidemiology of Cluster A PDs

Epidemiology of Schizotypal PD

According to DSM-IV, Schizotypal PD has a prevalence of approximately 3% of the general population (APA, 1994), but DSM cites no empirical support for that claim. Prevalence rates for

Schizotypal PD in clinical samples range widely from 2 to 31%, and higher rates are found in inpatient samples (Widiger & Trull, 1998). The 3% prevalence for the general population presented by DSM-IV seems high, given that systematic studies of psychiatric patients and their relatives have found lower values (Loranger, 1990; Zimmerman & Coryell, 1990). Some evidence suggests a higher rate for Schizotypal PD in men than in women (Essen-Möller, et al., 1956), and the same may be true of schizophrenia (Iacono & Beiser, 1992).

Epidemiology of Paranoid PD

Despite the general paucity of empirical research on Paranoid PD, estimates of the prevalence rates of Paranoid PD across a variety of settings have been offered. The prevalence rates of Paranoid PD in clinical samples, it has been noted, have increased since the revisions of DSM-III to DSM-III-R (Bernstein et al., 1993b; Morey, 1988). Prevalence estimates available from nonpsychiatric control subjects of the New York High-Risk Project range from 0–1.1% for DSM-III-R Paranoid PD (Erlenmyer-Kimling et al., 1995; Squires-Wheeler et al., 1993). An epidemiological study estimated the prevalence of Paranoid PD at 3.3% in young adults aged 18–21 (Bernstein, Cohen, Velez, Schwab-Stone, Siever, & Shinsato, 1993a). The DSM-IV (1994) reports Paranoid PD prevalence rates of 0.5–2.5% in the general population, 10–30% in psychiatric inpatient settings, and 2–10% in outpatient mental health clinics (p. 636). Unfortunately, there are no recent studies that provide prevalence rates of Paranoid PD according to the DSM-IV criteria set. It has been commonly believed that Paranoid PD is more prevalent in males, and empirical evidence has suggested this as well (Alnaes & Torgersen, 1988a; Reich, 1987).

Comorbidity with Other Personality Disorders

Another challenging area of research that has implications for assessing Paranoid PD involves the high degree of overlap among the PDs defined by the DSM classification system. Zimmerman (1994) reviews the many studies that report the high rate of overlap among the PDs defined by the DSM categorical classification system. It is clear that the DSM system has improved the interrater

reliability (i.e., the concurrence of assessment between two different raters) of the PDs, yet, the diagnostic scheme itself may have some problems of its own. As noted before, the emphasis on behavioral criteria in the DSM-III-R and DSM-IV (an effort that has increased the interrater reliability of the PD diagnoses by reducing the need for inferences when diagnosing these disorders) may cause artifactual overlap among the disorders. Simply put, the same *behaviors* may occur across PDs but for different reasons.

High comorbidity rates among PDs raise the issue of whether present diagnostic categories are clinically discrete or useful (Millon, 1981). Nearly all studies of inpatient samples indicate that those diagnosed with Paranoid PD receive additional PD diagnoses (Widiger & Rogers, 1989; Zimmerman, 1994). The defining characteristics (i.e., "odd and eccentric") of Cluster A PDs (DSM-IV; APA, 1994, p. 629) it has been shown, are poor predictors for inclusion into this cluster (Schopp & Trull, 1993). Morey (1988) refers to the boundary problem in PD diagnosis and reported that 22% of 291 outpatients who were receiving treatment for PDs met the criteria for a Paranoid PD diagnosis. Yet, those diagnosed with Paranoid PD frequently received additional diagnoses of Borderline PD (48%), Narcissistic PD (35.9%), and Avoidant PD (48.4%). Widiger and Trull (1998) in their review of DSM-III-R criteria set's performance across a variety of published and unpublished data sets report problematic co-occurrence (> 41%) among Paranoid PD, Borderline PD, and Avoidant PD. In addition, problematic co-occurrence (> 38%) among Schizoid PD, Schizotypal PD, Narcissistic PD, and Paranoid PD was found as well. Borderline PD, Narcissistic PD, and Avoidant PD are not included in the Cluster A grouping. This indicates that PD overlap is not restricted to cluster membership.

Paranoid PD is viewed as a syndrome of covarying traits that together define the boundaries of this disorder. It is becoming more accepted that Paranoid PD may be viewed as a dimensional construct that spans a continuum of severity and impairment (Auchincloss & Weiss, 1994; Sperry, 1995). Empirical and theoretical support for assessing Paranoid PD from a dimensional perspective is growing (Clark, Livesley, Schroeder, & Irish, 1996; Tien et al., 1992; Trull, 1992; Widiger, Trull, Clarkin, Sanderson, & Costa, 1994). It would serve both clinicians and researchers to assess the

degree of significant maladaptive paranoid traits one possesses, as defined by the DSM-IV, as opposed to simply rating the presence or absence of symptoms associated with Paranoid PD, called for by the DSM-IV categorical diagnostic system. A dimensional approach that takes maladaptive variants of normal personality into account offers more diagnostic information than merely assessing the presence or absence of a PD and its behavioral expressions. An increase in diagnostic information may in turn facilitate the differentiation of PDs. The differentiation of Paranoid PD from other PDs in empirical research could also have the effect of (1) refining both the construct of Paranoid PD, as well as the criteria that assess Paranoid PD; and (2) increasing the reliability of conclusions based on empirical studies of Paranoid PD samples.

Epidemiology of Schizoid PD

Few studies have assessed the prevalence of Schizoid PD, but it is one of the rarest PDs. Bernstein, Cohen, and Velez (1993) assessed PDs in a large, community-based sample of adolescents and diagnosed 1.8% with Schizoid PD. Of course, the diagnostic criteria have changed over the years, and the DSM-IV criteria might yield a different prevalence than observed when DSM-III-R was used. Schizoid PD is somewhat more common in men than in women (Kass, Spitzer, & Williams, 1983). Unfortunately, very few epidemiological studies of personality disorders have been undertaken.

Dimensional Approaches

Psychiatry and the DSM take a medical approach to understanding personality psychopathology. Symptoms are assessed and counted, and individuals are classified either as "disordered" if they have sufficient symptoms for a particular PD, or as not disordered if they do not have sufficiently many symptoms. Unfortunately, nearly any symptom can be assessed on a continuum of severity, and the implicit threshold for determining the presence of the symptom is usually arbitrary and vaguely defined. For example, DSM-IV criteria often use phrases such as "has little, if any, interest" and "almost always..." which leave room for interpretation.

Personality psychologists have developed systems for measuring personality along sets of correlated dimensions. Many attempts have been made to use factor analytic techniques to reduce the system to a small number of interpretable dimensions, but no one approach has been satisfactory to all researchers. We will focus on one popular system called the five-factor model (FFM). Using a dimensional system, like the FFM, researchers and clinicians can understand personality pathology as an extreme deviation from normality along some dimension or along some combination of dimensions. In this approach, a set of scores replaces diagnosis as an approach to assessing personality. It should be very appealing to both clinicians and researchers to have an informative collection of numbers that rates a patient or subject instead of a simple yes/no diagnosis.

We distinguish from the preceding general approach to personality measurement by a second dimensional approach that does not attempt to measure every aspect of personality. This second approach, which we will call the *specific-traits approach*, focuses the measurement problem on a single trait dimension, usually one that has an important relationship to psychopathology. For example, one might develop a scale for measuring social anxiety. Perhaps most of the variance of such a scale can be accounted for by dimensions of the FFM (e.g., neuroticism and extroversion), but researchers and clinicians who want to assess social anxiety might prefer a more focused tool. The specific-traits approach has been used extensively in psychopathology research.

Trait Dimensions and the Five-Factor Model

An alternative way to conceptualize and understand PDs is to examine the major personality traits that underlie each disorder. Currently, one of the more popular personality models is the five-factor model of personality (FFM) or Big Five. There are a number of measures of the FFM or Big Five available; most use a self-report format (Widiger & Trull, 1997). As operationalized by Costa and McCrae (1992) in the NEO-Personality Inventory-Revised (NEO-PI-R), the FFM consists of the personality domains of neuroticism (vs. emotional stability), extraversion (vs. introversion), openness to experience (vs. closed to experience), agreeableness (vs. antagonism), and con-

scientiousness (vs. carelessness). Further, each domain of personality consists of six personality trait facets. For example, Costa and McCrae (1992) propose that the facets of neuroticism are anxiety, depression, self-consciousness, vulnerability, impulsiveness, and angry hostility.

On the surface, the scores on FFM measures should demonstrate at least moderate correlations with PD pathology. After all, by definition, PDs are comprised of maladaptive personality traits and represent some of the more commonly encountered variants of personality pathology. In general, studies have demonstrated that the FFM is relevant to the official PD categories. This has held true regardless of the clinical status of the samples examined or the specific FFM instrument employed.

To provide personality trait information on the Paranoid, Schizoid, and Schizotypal PDs, we present FFM trait correlation predictions based on understanding the criteria for these three disorders, as well as some examples of studies that presented data relevant to these predictions.

In their five-factor "translation" of the PDs, Widiger, Trull, Clarkin, Sanderson, and Costa (1994) predicted that Paranoid PD would be characterized primarily by low levels of Agreeableness (low scores of facets of Trust, Straightforwardness, and Compliance), high scores on the Neuroticism facet of Hostility, and low scores on the facet Openness to Actions. Widiger et al. proposed that Schizoid PD is characterized primarily by low levels of Extraversion (low scores on Warmth, Gregariousness, Excitement Seeking, and Positive Emotions), low levels of the Neuroticism facets of Hostility and Self-Consciousness, and low levels of the facet Openness to Feelings. Finally, the authors predicted that Schizotypal PD is characterized primarily by high levels of Neuroticism (especially the facet of Self-Consciousness), high levels of Openness to Experience (especially the facets of Openness to Fantasy and Openness to Ideas), low scores on the Extraversion facets of Warmth and Gregariousness, and low scores on the Agreeableness facet of Trust.

In general, empirical studies have supported these predicted associations in both clinical (Soldz, Budman, Demby, & Merry, 1993; Trull, 1992) and nonclinical samples (Costa & McCrae, 1990; Wiggin & Pincus, 1989). For example, Paranoid PD scores were negatively related to Agreeableness scores (Costa & McCrae, 1990; Trull, 1992; Wig-

gins & Pincus, 1989) and positively related to Neuroticism scores (Costa & McCrae, 1990; Trull, 1992). Further, Schizoid PD scores were negatively related to Extraversion scores (Costa & McCrae, 1990; Soldz et al., 1993; Trull, 1992; Wiggins & Pincus, 1989), negatively related to Warmth and Gregariousness facet scores (Wiggins & Pincus, 1989), and negatively related to Openness scores (Trull, 1992; Wiggins & Pincus, 1989). Finally, Schizotypal PD scores were positively related to Neuroticism scores (Costa & McCrae, 1990; Soldz et al., 1993; Trull, 1992), positively related to Openness scores (Wiggins & Pincus, 1989), negatively related to Extraversion scores (Costa & McCrae, 1990; Soldz et al., 1993; Trull, 1992), and negatively related to Agreeableness scores (Costa & McCrae, 1990; Soldz et al., 1993; Trull, 1992).

One limitation of these early studies is that they all used questionnaire measures of the FFM, and in addition, few facet level relationships were reported. Recently, an interview-based measure of the FFM has been developed, the Structured Interview for the Five-Factor Model of Personality (SIFFM; Trull & Widiger, 1997). The SIFFM provides both domain and facet-level personality trait scores and contains items that tap more maladaptive variants of these personality traits (Trull et al., 1998). Similar to the findings of previous investigators who used questionnaire measures of the FFM, Trull & Widiger (1997) found that Paranoid PD scores correlated positively with Neuroticism scores and negatively with Agreeableness scores, that Schizoid PD scores correlated negatively with Extraversion scores, and that Schizotypal PD scores correlated positively with Neuroticism and Openness scores and negatively with Extraversion scores. Further, Trull & Widiger's (1997) results supported several of the facet-level predictions noted before. For example, Schizotypal PD scores were positively correlated with Self-Consciousness, Openness to Fantasy, and Openness to Ideas scores, and negatively correlated with Warmth and Trust scores. Finally, in a more recent study, Trull, Widiger, and Burr (in press) found that once comorbid personality disorder symptoms were controlled for, Paranoid PD was characterized primarily by low levels of Trust; Schizoid PD was characterized primarily by low Warmth, low Gregariousness, and low Positive Emotions; and Schizotypal PD was characterized by low levels of Openness to Feelings and Trust and high levels of Anxiety, Self-Consciousness, Openness to Fantasy, and Openness to Ideas. Thus, more fine-grained differentiation among these schizophrenia

spectrum personality disorders was possible by considering first-order/facet-level personality traits.

In summary, the FFM is a promising scheme for assessing and conceptualizing the PDs, including Paranoid, Schizoid, and Schizotypal PDs.

Specific-Traits Approach

In the factor analytic approach of the FFM, a relatively small number of dimensions is used to describe all other personality traits and disorders. As an alternative to the actor analytic approach, one might prefer to design scales that focus on specific symptom dimensions. The advantage of this approach, which we are calling the *specific-traits approach*, is that highly refined measurements of the targeted trait dimension can be produced for use in research. The reliability and validity of scale scores can be determined, and individuals at the extremes of trait dimensions can be selected for study. Use of linear combinations of FFM factor scores would probably never produce measures of the desired traits that are as valid as those produced by scales designed specifically for that purpose.

Loren and Jean Chapman and their students at the University of Wisconsin developed several paper and pencil self-report scales for specific dimensions of schizotypal personality described by Meehl in his manual of schizotypic signs (Meehl, 1964). These scales (sometimes called the "Wisconsin scales") include the thirty-item Magical Ideation (MagId) Scale (Eckblad & Chapman, 1983), which measures beliefs in forms of causation that are conventionally regarded as invalid and magical; the thirty-five item Perceptual Aberration (PerAb) Scale (Chapman et al., 1978), which measures schizophrenic-like distortions in the perception of one's own body (twenty-eight items) and other perceptual distortions (seven items); the forty-item Social Anhedonia (SocAnh) Scale, first developed by Chapman et al. (1976) and revised by Eckblad et al. (1982), which measures schizoid indifference to other people; and the fifty-one item Impulsive Nonconformity (Non-Con) Scale (Chapman et al., 1984), which measures impulsive antisocial behavior like that observed in some premorbid schizophrenics. All of the Wisconsin scales are highly reliable measures of individual differences and have internal consistency reliability coefficients of .80 to .90 (Chapman et al., 1982). College students identified by high scores on these scales are schizophrenic-like in many aspects of cognitive and social behavior

(Edell, 1993) and psychophysiology (Miller & Yee, 1993). Chapman, Chapman, Kwapil, Eckblad, and Zinser (1994) conducted 10-year follow-up interviews of a sample of several hundred college students selected for high scores on one or more of the scales or for moderately low scores on all of the scales (a control group). They found that former students selected for high scores on MagId or PerAb were significantly more likely than control participants to have experienced a psychotic episode during the follow-up period and to have heightened schizotypal and psychotic-like symptoms. In addition, participants in the MagId/PerAb group with elevated scores on SocAnh were at especially high risk for schizotypal symptomatology, and this was replicated by Kwapil et al. (1997). Furthermore, Kwapil (1998) has shown that high SocAnh scores are specifically related to schizophrenia-spectrum disorders and not to mood disorders.

The Chapman approach has been influential, and the Wisconsin scales have been used widely by psychopathology researchers. Much of the research has used individuals (usually college students) with high scores on the PerAb and/or MagId scales (usually placing them in the upper 3–5% on those scales). Few of these selected individuals meet criteria for PD diagnoses, but they often have multiple PD symptoms, psychotic-like symptoms, or mood disorders. The approach is popular partly because it is inexpensive to screen and select college students for research. The studies of selected college students are not studies of PDs per se, but they certainly tell us something about the nature of the schizophrenia-spectrum PDs.

Etiological Theories of Cluster A Personality Disorders

Etiological Theories of Schizotypal PD

Genetic influences are important in the etiology of Cluster A PDs. Adoption studies have shown that biological relatives of schizophrenic probands are at higher risk of Schizotypal PD than control subjects, even when they have had no contact with the schizophrenic relative (see Kety et al., 1994). This is a strong indication that Schizotypal PD and schizophrenia share some common genetic risk factors.

Less is known about environmental etiological factors. Mednick, Parnas, & Schulsinger (1987)

suggested that schizophrenia would emerge in high-risk individuals (e.g., children of mothers with schizophrenia) who were exposed to a “deleterious environment.” They found that high-risk children who later developed schizophrenia had more often endured traumatic births than those who developed Schizotypal PD and that those who developed Schizotypal PD experienced even fewer birth complications than children of normal mothers who never developed a mental disorder. These findings suggest that schizotypal PD might be caused by a schizophrenia-prone genotype in an especially salutary environment.

Etiological Theories of Paranoid PD

As with other pertinent nosological issues that surround Paranoid PD, etiological factors such as associated risk factors or developmental processes have been based on case studies, clinical consensus, and speculation. Many theorists from different perspectives (e.g., psychoanalytic, interpersonal, behavioral-cognitive) provide etiological conjectures of Paranoid PD. Yet, most do not explicate the connection between a risk factor and the development of maladaptive personality traits or provide empirical support for their assertions. There is a consensus in clinical literature as to what the antecedents of Paranoid PD should be. In the psychosocial realm, parental neglect or domination, abuse, isolation, exposure to violent adults, and infliction of pain have been cited as risk factors.

Limited empirical support has been found for a relationship between DSM-III-R Paranoid PD and retrospective self-reported ratings of a negative paternal relationship during childhood (e.g., criticism, rejection, lack of confiding, rarely feeling loved) as well as childhood traumatic experiences (e.g., physical/sexual abuse) (Modestin, Oberson, & Erni, 1998; Norden, Klein, Donaldson, Pepper, & Klein, 1995). There is evidence suggesting a relationship between parental aggressiveness and later development of aggression and hypervigilance (two core traits of Paranoid PD) in offspring (Lewis, 1992). Yet, these relationships were found for other PDs as well. Overall, these findings point to the nonspecificity of trauma and problems with parental bonding as possible antecedents of PD pathology in general. There is no empirical evidence suggesting that early home environmental factors are associated *specifically* with the development of Paranoid PD (Modestin et al., 1998; Norden et al., 1995). Furthermore, the studies that have been conducted on early home environments

or abuse in childhood and the development of PDs are plagued by methodological issues (e.g., small sample sizes, use of retrospective report, differing treatment settings, lack of normal controls, not accounting for the effects of comorbidity between Axis-I and Axis-II disorders, or selection and response biases) and limit the conclusions that can be drawn (Crowell, Waters, Kring, & Riso, 1993; Ruegg & Frances, 1995). There are presently no prospective empirical studies that have examined familial factors in the development of Paranoid PD.

Genetic Relationship to Schizophrenia.

Paranoid PD (along with Schizotypal and possibly Schizoid PD) is believed to be genetically related to schizophrenia and therefore is considered a schizophrenia-spectrum disorder. The hypothesis of a common genetic mechanism(s) underlying schizophrenia-spectrum disorders has been tested extensively. A major diagnostic question pervading this research is the relationship of Paranoid PD to schizophrenia disorders and to Axis I Delusional Disorder (Kendler et al., 1985b; Kendler & Gruenberg, 1982; Siever & Davis, 1991; Winokur, 1985, 1986). The schizophrenic-delusional disorder dichotomy has become increasingly controversial. Researchers have attempted to study the familial rates of Paranoid PD, Schizotypal PD, and Schizoid PD in those identified with a schizophrenic or delusional disorder (Baron et al., 1985; Coryell & Zimmerman, 1989; Dorfman, Shields, & DiLisi, 1993; Frangos, Athanassenas, Tsitourides, Katsanou, & Alexandrakou, 1985; Kendler & Gruenberg, 1982; Kendler et al., 1985a,b, 1993; Lowing, Mirsky, & Pereira, 1983; Parnas et al., 1993; Yeung, Lyons, Wateraux, Farone, & Tsuang, 1993) or alternatively and to a lesser degree, the familial rates of Paranoid PD, Schizotypal PD, and Schizoid PD in those identified with the same Cluster A disorders (Fulton & Winokur, 1993; Kendler et al., 1993; Siever et al., 1990; Thaker, Adami, Moran, Lahti, & Cassady, 1993). These studies have demonstrated an inconsistent, weak relationship of Paranoid PD to schizophrenia as well as a weak relationship to delusional disorder (for reviews of these studies see Nigg & Goldsmith, 1994; Ruegg & Frances, 1995; Webb & Levinson, 1993). Some empirical data have supported the contention that Paranoid PD may lie on a continuum of paranoia and Axis I delusional disorder (paranoid psychosis) in its most severe form (Kendler et al., 1985b; Winokur, 1985) and is distinct from schizophrenia (Kendler et al., 1985b).

Methodological issues in this literature limit the strength of inferences that can be drawn from the body of data gathered to date.

Paranoid PD has also been found at increased rates in families identified through a depressed proband (Alnaes & Torgersen, 1988b), and it may have an etiological relationship to anxiety disorders (Reich & Braginsky, 1994). The reported relationship of Paranoid PD to depressive or anxiety disorders presents evidence contrary to including Paranoid PD as strictly a schizophrenia-spectrum disorder. However, more research is needed to address these hypotheses before conclusions can be drawn.

Siever and Davis (1991) provide the most relevant description of an inherited psychobiological dimension as a risk factor in developing Cluster A disorders. From this perspective, it is hypothesized that attention/selection deficits in Cluster A disorders negatively impact cognitive/perceptual apparatus that results in misunderstandings, social isolation, mistrust, and poor reality testing. Siever and Davis assert that persistent mild disturbances in this dimension could contribute to the development of specific defense mechanisms and adaptive strategies. If these susceptibilities crystallize to define the pervasive characteristic ways in which an individual reacts to others or stress, then a Cluster A PD is possible. Although Siever and Davis bridge the gap between a risk factor and the development of a PD (and the available data suggest that there may be a substantial genetic component to the development of PD), the specific mode of inheritance or what is inherited remains unclear (Weissman, 1993). Furthermore, although the effects of punitive or abusive traumatic experiences are believed to interact with a genetic predisposition toward a paranoid style or core features of Paranoid PD (Siever & Davis, 1991), specific environmental or genetic influences that may moderate or mediate the development of Paranoid PD traits have not been identified (Nigg & Goldsmith, 1994).

Etiology of Schizoid PD

Very little is known about the etiology of Schizoid PD. It has long been believed that Schizoid PD is genetically related to schizophrenia, but the empirical support for that hypothesis is very weak. For example, Kety et al. (1994) found a similar rate of Schizoid PD among the biological relatives of adoptees with chronic schizophrenia (5.7%) as

among the biological relatives of control adoptees (8.1%).

Schizoid PD may be genetically related to autism. Wolff, Narayan, and Moyes (1988) selected twenty-one children with autism and twenty-one control children with other handicaps and compared the parents of the two types of children on schizoid symptomatology. They rated sixteen of thirty-five parents of autistic children (eight of fourteen fathers and eight of twenty-one mothers) as having schizoid traits compared with none of the thirty-nine parents of the control children. Wolff et al. suggested that this effect might be attributable to a genetic influence shared by parent and offspring that is sometimes expressed as schizoid traits and sometimes as autism. An adoption study would help to clarify if the effect is genetic or from other causes.

Millon (1981) noted that schizoid individuals often report that their parents were cold and unaffectionate toward them. This observation has not been confirmed in systematic research, but even if it were, it would not prove a cause–effect relationship between parental warmth and the development of schizoid personality traits. It is possible that parents of schizoid people are schizoid themselves (perhaps due to a genetic effect) and therefore are unaffectionate. Another possibility is that schizoid adults were aloof schizoid children who were so unresponsive to parental affection that their parents learned to be less affectionate. The causal picture is potentially very complex, but we have some suggestive leads.

Treatment of Cluster A Personality Disorders

Treatment of Schizotypal PD

Clinicians should consider patients individually and tailor treatments to match patients' symptom profiles. Patients with extensive thought disorder problems or with transient psychotic experiences might be more responsive to antipsychotic medication. Medication might enhance the patient's responsiveness to other forms of psychotherapy. Few controlled treatment studies of Schizotypal PD exist, but Hymowitz et al. (1986) treated seventeen schizotypal outpatients with haloperidol in a single-blind trial and noted improvement on overall schizotypal symptoms, particularly on the scales that measure ideas of reference, odd com-

munication, and social isolation. Unfortunately, half of their patients dropped out of the study complaining of side effects, particularly sedation. The newer "novel" antipsychotic medications have superior side-effect profiles, are successful in treating schizophrenia, and might also be effective with schizotypal patients.

Cognitive therapy is another appealing approach for treating Schizotypal PD. Cognitive therapies for treating depression and anxiety disorders have empirical support for effectiveness, and similar therapies designed to treat Schizotypal PD might be effective, but we were not able to identify any empirical studies to support that claim. Odd beliefs and magical thinking are common symptoms of the disorder and seem well suited for a cognitive-behavioral approach. Beck et al. (1990) listed four types of cognitive distortions in Schizotypal PD: (1) suspicious or paranoid ideation, (2) ideas of reference, (3) odd beliefs and magical thinking, and (4) illusions. If therapists can develop enough of a relationship with schizotypal patients to gain their compliance with the treatment program, it might be possible to start dialogue about automatic thoughts and cognitive distortions. The difficulty of establishing a productive relationship should not be understated. Schizotypal individuals are often suspicious and socially awkward. They probably do not seek treatment often and may terminate treatment before it is complete.

Psychodynamic therapies generally lack empirical support, and this is certainly true of psychodynamic therapies for treating Schizotypal PD. Stone (1985) reviewed the literature on psychodynamic treatment in Schizotypal PD. Even if the psychodynamic approaches are not effective, reading the literature on such treatments can be helpful to clinicians who are trying to develop working relationships with schizotypal clients.

Treatment of Paranoid PD

The pervasiveness of suspicion and lack of trust in others that is associated with Paranoid PD presents difficulty in assessment and treating it. The therapeutic environment itself, with its emphasis on trust and disclosure, may be overwhelming to the Paranoid PD client (Meissner, 1995; Millon & Davis, 1996; Stone, 1993). In general, very little is known about treating PDs (Shea, 1993). A small number of empirical studies is relevant to treating Paranoid PD, but what is known about this topic

comes primarily from clinical observation. Parnas et al. (1993) noted that 51% of those with a DSM-III-R Cluster A disorder in their sample reported that they had never sought treatment. In a study of 339 Australian psychiatrists given a vignette of a DSM-III-R Paranoid PD case, two-thirds responded that they saw patients like this at a rate of two per year, 62% said that this treatment was beyond their expertise or untreatable, and only 11% thought the case would continue treatment. Almost all thought that supportive therapy that reduced suspicion and hostility was the method of treatment to use, and difficulty in establishing therapeutic relationships with these individuals, as well as noncompliance, were areas of concern (Quality Assurance Project, 1990).

Accurate and efficient assessment of Paranoid PD is essential in treatment. Without an initial understanding of the client's paranoid perception of the world, clinicians who approach Paranoid PD clients in a manner that may threaten their excessive need for autonomy and privacy may never see those clients again after the first session. Clinicians and researchers alike are faced with the often difficult task of attempting to differentiate between relatively transitory mistrustful beliefs, an overly valued belief, and delusions, as well as of ascertaining the level of impairment and dysfunction associated with a suspicious and antagonistic interpersonal style. For this reason, there is often difficulty in initially assessing Paranoid PD features in individuals who suffer from the disorder.

Paranoid PD clients' suspicious and antagonistic interpersonal style often challenges assessment and therapeutic skills. A clinician should not be too warm or friendly or question the validity of claims prematurely without becoming included in the Paranoid PD individual's suspicions. Furthermore, the client may not be capable of distinguishing presenting problems (such as stress, depression, and anxiety) from a paranoid perspective of the world. A lack of insight into the nature of their problems and difficulties with self-disclosure delay the gathering of pertinent information relevant to verifying a Paranoid PD diagnosis. Often, Paranoid PD individuals do not view their perspective of the world as related to their problems; rather, they view it as the way they need to be to survive. It would not be typical of a Paranoid PD client to present with complaints of paranoia. Turkat et al. (1990) report that, "clinically the Paranoid PD [client] may present with symptoms that initially

appear unrelated to DSM-III-R criteria, which leads to misdiagnosis" (p. 264). An assessment of motivation for change and ability to tolerate the therapeutic process is indicated, given the Paranoid PD individual's rigidity and the problems cited before. Those who are coming to therapy to alleviate the symptoms (e.g., depression, anxiety) often associated with stress related to interpersonal problems are believed to be poor candidates for successful therapy, but those who are willing to confront their paranoid styles may fare better (Meissner, 1995). Furthermore, informants could be interviewed and prior psychological and medical history should be reviewed, given the Paranoid PD individual's tendency toward secretiveness, deception, or defensiveness. Ironically, Paranoid PD may be overdiagnosed by inexperienced clinicians who may underappreciate the severity of this disorder and view "normal" suspicious tendencies as meeting criteria for severe maladaptive paranoid traits (The Quality Assurance Project, 1990). Paranoid individuals will often drop out of therapy, will be resistant to self-disclosure, or will resist following treatment regimens (Turkat, 1985; Williams, 1988). Furthermore, they have been characterized as difficult patients who exhibit more dysfunctional behavior relative to other clinical populations and have poorer prognoses (Auchincloss & Weiss, 1994; Meissner, 1995; Millon, 1981). Interpersonalists may not share this negative prognostic view (O'Leary & Watson, 1995).

The psychodynamic and interpersonal literature offers many theoretical perspectives of both the etiology and treatment of paranoid states (e.g., Blum, 1980; Meissner, 1978; O'Leary & Watson, 1995). Only recently, there have been efforts by psychodynamically oriented clinicians to establish time-limited treatment approaches to PDs. It should be noted that these treatments of PDs focus on gaining insight into features of personality (e.g., introversion, misattributions of others' intent, anger control, excessive fear of social evaluation, interpersonal problems) that are relevant to Paranoid PD and thus offer techniques that are applicable (see Luborsky, 1984; Strupp & Binder, 1984). The cognitive-behavioral, interpersonal, and behavioral approaches offer more specific treatment guidelines (e.g., Beck & Freeman, 1990; Benjamin, 1993; Linehan, 1987; Turkat & Maisto, 1985; Turkat, 1990; Williams, 1988). Briefly, these prescriptions include increasing the Paranoid PD individual's sense of self-efficacy, reducing anxi-

ety in response to perceived negative evaluation by others, increasing interpersonal skills (e.g., trust, communication, perspective-taking), and increasing more realistic attributions to the motives of others. It should be noted, however, that there are presently no treatment studies that assess the relative effectiveness of any of the cognitive-behavioral (or of the interpersonal and psychodynamic) interventions for Paranoid PD. It has also been suggested that during periods of extreme stress, anxiolytic medication may be indicated as is the use of antipsychotic medication (Coccaro, 1993; Manschreck, 1992; Quality Assurance Project, 1990), but Paranoid PD individuals may be resistant to taking medications, and the effects of this request on the therapeutic relationship could be negative (Meissner, 1995). The efficacy of medications in alleviating Paranoid PD symptoms is unknown.

Treatment of Schizoid PD

As noted by Millon and Davis (1996, 2000), the prognosis is poor for those with Schizoid PD to make significant changes in their interpersonal styles. Individuals with Schizoid PD typically come to the attention of mental health professionals because of Axis I conditions (e.g., Major Depression). Once these Axis I symptoms have abated, the Schizoid PD patient may not have much motivation to stay in treatment. Further, and most importantly, those with Schizoid PD are unlikely to see their characteristic pattern of passive avoidance and indifference to others as problematic. Schizoid PD patients see little value in increasing social contact or in learning to identify emotional states in themselves and others. However, there may be situations in which the social isolation is so maladaptive or dysfunctional as to suggest to the therapist and hopefully to the Schizoid PD patient that treatment is warranted.

Several general strategies and techniques are recommended in these cases (Beck & Freeman, 1990; Millon & Davis, 2000). The two major overarching treatment goals are to increase social contact and improve social skills and to help the patient begin to identify and differentiate emotional states in self and others. Increased social contact and improved interpersonal skills may be accomplished through homework assignments, role-playing, and ultimately through group therapy (Beck & Freeman, 1990). Group therapy may

be especially useful for Schizoid PD because group members model appropriate self-disclosure, provide a "safe" interpersonal environment, and give feedback regarding interpersonal style. Beck and Freeman (1990) also recommend the use of Dysfunctional Thought Records (DTRs) with Schizoid PD patients. DTRs document patients' thoughts, emotional reactions, and behaviors in specified situations that are tailored to the individual patient. In the case of Schizoid PD, the DTR can be used to challenge maladaptive thoughts and reactions concerning social interactions and to help the patient identify and differentiate emotions and gradations of emotions in self and others (Beck & Freeman, 1990).

Despite their appeal, it is worth remembering that no well-controlled studies of the efficacy or effectiveness of these techniques in treating Schizoid PD exist. Further, the majority of Schizoid PD patients, by virtue of the nature of the disorder, are unlikely to be interested in treatment aimed at increasing social interaction or improving interpersonal skills. Therefore, the treating mental health professional should not expect quick and significant changes and should guard against feeling overly frustrated or discouraged (Millon & Davis, 2000).

General Conclusion

Schizotypal, Paranoid, and Schizoid personality disorders are all marked by serious problems in interpersonal relationships. Because of this, such individuals have been hard to study. They avoid psychotherapy and participation in research. As a result, data on epidemiology, etiology, and treatment for these disorders are sparse. It is not even clear that these three disorders truly belong in the same personality disorder cluster. Future research focused on the causes of variation in the general population in the individual symptoms of these PDs might lead to greater understanding of their natures and causes.

Substance Abuse: An Overview

**Susan F. Tapert, Susan R. Tate,
and Sandra A. Brown**

Introduction

Substance abuse and other addictive behavior disorders are among the most prevalent mental health disorders in our society. Significant health and societal costs are attributed to excessive involvement with alcohol, nicotine, illicit drugs, prescription drugs, industrial solvents, and impulse control problems (e.g., gambling, binge eating, risky sexual behaviors). This chapter will discuss conceptual models, assessment, and treatment of substance abuse, covering alcohol, illicit drugs, misused prescription drugs, and nicotine problems. Gambling disorders will be briefly reviewed. Although eating disorders and compulsive sexual disorders share features of addictive behaviors, these issues will be addressed in other chapters of this volume.

Prevalence

Current substance abuse or dependence is present in 11% of the U.S. population, and nearly 27% percent have met criteria during their lifetime, based on the results of a national survey (Kessler et al., 1994). Alcohol is the most widely used intoxicating substance. National household sur-

veys report that 82% of Americans ages 12 and above have used alcohol and half drank alcohol in the past month (Substance Abuse and Mental Health Services Administration [SAMHSA], 1998), as shown in Table 1. Binge drinking, consuming five or more drinks on a single occasion, is most common among young adults ages 18 to 25, although evident among adolescents (Johnston, O'Malley, & Bachman, 1999). Frequent bingeing (5 times in the past month) indicates unhealthy drinking and was reported by 11% of young adults. Over 13% of the population has met diagnostic criteria for alcohol dependence at some point in their lifetimes, and more than 4% currently meet criteria (Grant, 1997). Alcohol-related economic losses due to decreased productivity, health care costs, and motor vehicle crashes are estimated at \$148 billion annually (Harwood, Fountain, Livermore, & The Lewin Group, 1998). Alcohol is the third most prominent contributor to mortality in the United States (McGinnis & Foege, 1993).

Illicit drug use has increased in recent decades, and prevalence rates of individual substances fluctuate over time. Nearly 36% of the population over age 12, it is estimated, has used an illicit drug in their lifetimes (see Table 1). Marijuana is the most commonly used illicit drug, used by an estimated 9% of the population during 1997. Almost 12% of males aged 18 to 25 years have used marijuana more than fifty times in the past year. In 1997, 1.9% of the U.S. adult population used cocaine, 1.9% used hallucinogens, 1.1% used inhalants (the rate is 4.4% for 12–17-year-olds), 0.3% used heroin, and 2.8% reported nonmedical use of prescription

Table 1. Percent of U.S. Adolescents, Young Adults, and Adults who Used Alcohol, Binge Drank, Used Illicit Drugs, and Used Nicotine in the Past Month^a

Age group	Any alcohol use	Binge drinking ^b	Illicit drug use	Nicotine use
12–17	21%	8%	11%	20%
18–25	58%	28%	15%	41%
26–34	60%	23%	7%	34%
35 and older	53%	12%	4%	28%

^aSAMHSA, 1998.

^bIndicates consumption of five or more drinks on a single occasion.

medications (SAMHSA, 1998). Nearly 8% of the national population, it is estimated, met criteria for drug dependence at some point in their lifetimes, and almost 3% met criteria in the past year (Kessler et al., 1994). Illicit drugs present particular medical risks because the content of any drug obtained on the street is difficult to specify. Drug injectors are at risk for HIV, hepatitis, infections, vein deterioration, and endocarditis (Peterson, Dimmeff, Tapert, & Stern, 1998). Drug use alone costs the United States an estimated \$89 billion annually due to loss in productivity, crime, medical consequences, and treatment services (Harwood et al., 1998).

Nicotine is the most abused addictive substance in our society. More than 70% of the U.S. population over age 12 has smoked at some point, and 30% currently smoke (see Table 1). Approximately three million people start smoking each year at the average age of 15.6 years. Current smokers are more likely to drink heavily and use illicit drugs than nonsmokers (SAMHSA, 1998). Although not considered an intoxicant, nicotine is associated with significant health problems across the lifespan (e.g., Myers & Brown, 1997), and tobacco is the leading preventable cause of mortality in the United States (McGinnis & Foege, 1993).

Gambling is an increasing problem in the United States. The expanding presence of casinos on U.S. Indian reservations and Internet gambling provide easily accessible means of risking monetary loss for a chance at quick winnings. Pathological gambling refers to a diagnosable disorder (American Psychiatric Association [APA], 1994) involving recurrent gambling, preoccupation, gambling with increasing amounts of money, loss of control, unsuccessful attempts to cut back, and jeopardizing

jobs and relationships. A recent epidemiological survey reported that 46% of the population has gambled recreationally, 9% reported at least one gambling-related problem, and 1% met criteria for pathological gambling. Problem gamblers are commonly tobacco- and alcohol-dependent (Cunningham-Williams, Cottler, Compton, & Spitznagel, 1998).

Definitions. Before we discuss theories of substance abuse, we will define key terms in this field of study. *Addictive behaviors* refer to “any compulsive habit pattern in which the individual seeks a state of immediate gratification” (Marlatt, 1985, p. 4). The gratification may be in the form of relief from discomforts such as tension, negative mood, or withdrawal states, or it may be the introduction of pleasure or euphoria. Addiction involves continued involvement with the behavior despite adverse consequences and attempts to stop (Roberts & Koob, 1997). Addictive behaviors include excessive use of psychoactive substances, such as alcohol, nicotine, and other drugs, or excessive, unhealthy levels of other behaviors with compulsive characteristics, such as gambling, eating, or sexual acts.

Substance dependence and substance abuse are clinical disorder diagnoses of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV; APA, 1994) that require fulfilling specific criteria. The diagnostic criteria have changed with each revision of the DSM-IV (see Nathan, Skinstad, & Dolan, Chapter 21, this volume). *Substance dependence* implies an addiction to the drug, whereas *substance abuse* refers to a less severe condition involving continued use of a mind-altering substance despite problems caused by such use (American Psychiatric Association, 1994; Schuckit, 1995). Substance dependence is

diagnosed in individuals who demonstrate at least three of seven criteria within the same year: (1) tolerance to the substance, (2) withdrawal from the substance upon cessation of use, (3) taking more of the substance or over longer periods of time, (4) loss of control over the substance use, (5) loss of time related to use, (6) activities forsaken, and (7) continued use despite knowledge of consequences. A diagnosis of substance abuse applies to maladaptive patterns of substance use that do not meet the more severe criteria for substance dependence. Specifically, a person is diagnosed with substance abuse if one of the four following criterion are met as a result of the substance use: (1) failure to meet role obligations, (2) recurrent use in dangerous situations, (3) recurrent legal problems, or (4) continued use despite persistent social problems, and criteria for substance dependence are not met.

Substance dependence implies a psychological and/or a physical need for the drug. *Psychological dependence* can occur following repeated use of any drug of abuse and refers to users' perceptions that they need the substance to feel or function optimally. For example, regular marijuana smokers who feel they cannot relax at the end of the day without an evening joint have developed psychological dependence on marijuana. *Physical dependence* indicates the physiological adaptation of the body to prolonged exposure to the substance. Two aspects of this adaptation are tolerance and withdrawal. *Tolerance* refers to cellular and metabolic adaptations in response to continued presence of the substance (Koob & Bloom, 1988). As tolerance develops, more of the drug is necessary to obtain the desired effects, and use becomes more frequent. *Cross-tolerance* occurs when tolerance to one drug has developed and more of any drugs in that class is necessary to produce comparable effects, based on the similar organic structure of active ingredients and nervous system response. If a user simultaneously administers multiple drugs of the same class, *potentiation* occurs, and the additive or synergistic effects can result in an overdose.

Withdrawal is experienced when administering a substance to a physically dependent organism is halted. Characteristic withdrawal syndromes ensue, depending on the drug class used, and the withdrawal syndromes tend to involve opposite symptoms as intoxication effects of the substance (Koob & Bloom, 1988). For example, opiate intox-

ication reduces pain sensations, but opiate withdrawal involves increased sensitivity to pain. This neuroadaptation is illustrated by the opponent process model. Positive hedonic effects (e.g., a cocaine rush) are followed by compensatory negative hedonic experiences (e.g., negative mood and withdrawal symptoms after cessation of use; Koob, Caine, Parsons, Markou, & Weiss, 1997).

From a public health perspective, substance use and abuse can be conceptualized along a continuum, in which excessive use of a variety of substances is associated with increasing levels of the risk of negative consequences (Newcomb & Bentler, 1988a). The risk of adverse consequences decreases at moderate use levels and declines further with abstinence (Marlatt & Tapert, 1993).

Models of Addiction

As the substance abuse field has developed during the past several decades, controversies have arisen over the way to conceptualize addiction problems. The first controversy relates to the cause of substance abuse. Is it the fault of the addicted individuals, or is it due to circumstances beyond their control? The second controversy concerns treating substance abuse problems. Is recovery the responsibility of the addicted person, or are external entities responsible for recovery (Marlatt, 1992)? Opposing perspectives on these issues are summarized by four competing models of addiction (Brickman et al., 1982), highlighted here.

Moral Model

The moral model of addictive behaviors refers to movements such as the temperance movement that preceded the prohibition on alcohol and law enforcement approaches in the recent "War on Drugs" (Trebach & Zeese, 1990). In this model, responsibility for developing and resolving the addiction is attributed to the individual with the substance use disorder. Drinking, for example, is viewed as a "sign of weak character" (Brickman et al., 1982), and the only way out is to exert willpower. Genetic and environmental etiological factors do not modify this responsibility. The moral stance can foster guilt for developing the addiction problem and failing to change. From this

perspective, relapse is ascribed to moral weakness (Marlatt, 1992).

Medical Model

The medical or disease model, which is the most common theoretical view employed in the United States, places responsibility for developing the addictive disorder on physiological factors, such as a family history of addiction or pathological metabolism (Jellinek, 1960). Treatment relies on external sources for specialized medical intervention into the pathological process. The addictive process, it is thought, has a deteriorating course, and, if left untreated, may result in death (Miller & Hester, 1995). Total abstinence from all intoxicating substances is the only acceptable treatment outcome and must be maintained life-long to arrest disease progression (McCrary, 1994). Relapses are viewed as triggered by factors beyond the individual's control, often with a physiological basis. Taking a biological perspective, drug properties appear to interact with genetics to determine the reinforcement of drug taking, thereby influencing repeated use (Koob et al., 1998). The advantage of the medical model over the moral model is that addicted individuals are not blamed for the problem and they are encouraged to seek help from specialists, rather than attempt to treat the problem alone. In addition, research on the biological substrates of addictive processes has greatly advanced our understanding of genetic risk and protective factors and enhanced treatment of these disorders.

Spiritual Model

The spiritual or enlightenment model is espoused by twelve-step programs such as Alcoholics Anonymous and Narcotics Anonymous (Alcoholics Anonymous, 1980; Miller, 1998b). The development of addiction is seen as related to a spiritual weakness. The concept of a "higher power" is emphasized for overcoming the addiction problem, and the individual must admit helplessness over the substance of abuse. Attending group meetings is considered imperative to prevent recurrence of the spiritual disease. A major advantage of this model is the social support and supplementary resources that members receive from meetings. Criticisms of the spiritual model include difficulty incorporating nonspiritual indi-

viduals into group processes that rely on religious beliefs and that peers or paraprofessionals with past histories of addiction deliver the intervention in lieu of addiction-trained professionals (Miller & Brown, 1997).

Biobehavioral and Interactionist Models

Several integrative models have been proposed to incorporate the accumulating knowledge base of addictive behaviors from both biological and psychological sciences. The compensatory model (Brickman et al., 1982) posits that people with addiction problems need not be held at fault for developing the problem but are responsible for changing the behaviors, either independently or by seeking assistance. Substance abuse acquisition is conceptualized as a maladaptive response that occurs when stressors overpower appropriate coping strategies (e.g., Windle & Windle, 1996). Physiological, conditioning, social learning, and cultural factors exacerbate this process (Roberts & Koob, 1997; Vogel-Spratt, 1995). A relapse is viewed as a mistake in a new learning process (Marlatt, 1992). Recent refinements of interactionist theories of addictions include behavioral-genetic perspectives on the development of substance use disorders (McGue, 1997; Rose, Kaprio, Winter, Koskenvuo, & Viken, 1999) and behavioral economics views on addictive behavior problem resolution (Tucker, Vuchinich, & Pukish, 1995; Vuchinich & Tucker, 1998). In summary, the accumulating knowledge base of factors involved in developing addiction problems strongly suggests a multifaceted process, involving biological, psychological, and cultural components.

Initiation, Maintenance, and Remission of Addiction

Substances of abuse have unique pharmacological properties and somewhat distinct use consequences, but they also share a great deal in common. A number of risk factors and developmental pathways in and out of addictive behaviors are shared across substances. The initial experimentation with substances of abuse is primarily determined by social and environmental risks. Biological and environmental factors combine to influence decisions to use again, the development

of adverse consequences, and ultimately, efforts to reduce or stop substance involvement.

Genetic Risk

Genetically influenced factors, it has been shown, affect the risk of developing substance use disorders (e.g., Pickens et al., 1991; Schuckit, 1985; Wall & Ehlers, 1995), although the heritability of dependence on drugs other than alcohol is less clear. Sons of male alcoholics are two to four times more likely to develop alcohol problems than sons of nonalcoholics (Cloninger, Bohman, & Sigvardsson, 1981). Approximately a quarter to half of the variability in drug abuse or dependence is attributable to heredity (Grove et al., 1990; Pickens, Svikis, McGue, & LaBuda, 1995), and the genetic risk is greater for male offspring. High rates of comorbidity with antisocial personality disorder complicate determining the genetic risk of drug dependence (Kessler et al., 1997). The risk of behavior control problems are also elevated for offspring of alcoholics (Sher, 1997), whereas risk of depression and anxiety problems has not been demonstrated (Schuckit & Smith, 1996).

Learning Influences

Classical Conditioning. Self-administration of a variety of substances of abuse has been conditioned across several species. Drug-induced euphoria (unconditioned stimulus) over time becomes associated with environmental stimuli present during the euphoric state (conditioned stimuli), such as drug-taking paraphernalia, locations, behavior, and people (Vogel-Sprott, 1995). After continued pairing with the drug-induced euphoria, these associated stimuli may produce intense urges or cravings to take the substance again (Roberts & Koob, 1997). However, not all individuals with substance dependence use drugs in response to cravings (Vogel-Sprott, 1995). Similarly, stimuli associated with unpleasant periods of abstinence may elicit withdrawal-like symptoms. This conditioning principle can be observed in individuals who attempt to quit substance use and are constantly reminded of the addictive substance by a wide range of cues in the environment (Ludwig, Wickler, & Stark, 1974; Vogel-Sprott, 1995).

Instrumental Learning. Any reward following a behavior will increase the chance that the

behavior will occur again. With substance use, both the acute pharmacological impact and social/environmental factors may produce rewards following drug self-administration, which increase the chance that drug taking will recur. For example, if individuals smoked marijuana, then experienced pleasurable pharmacological effects or experienced social approval, they would be likely to smoke marijuana again. Additionally, relief from aversive states, such as withdrawal or distress following drug self-administration also increases the likelihood of repeated drug-taking behaviors (Alexander & Hadaway, 1982). Euphoric sensations associated with drug taking are mediated by specific groups of connected neurons in the brain. Extant research indicates that the brain's reward circuitry involves connections between the ventral tegmental area and the basal forebrain, encompassing the dopaminergic neurotransmitter system, as well as opioid, serotonergic, and gamma-aminobutyric acid (GABA) neurotransmitter systems. These brain regions and systems, it has been demonstrated, subserve reinforcement of using a variety of addictive substances, including repeated alcohol, cocaine, and opiate self-administration, as well as other addiction cycles such as pathological gambling, binge eating, and compulsive sexual behaviors (Koob & Le Moal, 1997).

Environmental factors

Family. Aspects of an individual's environment may act independently or in concert with biological factors to protect or imperil the chance of developing an addiction (Sher, Gershuny, Peterson, & Raskin, 1997). Positive, loving parent-child bonds reduce the risk of substance abuse (Kandel, 1978). Conversely, high levels of parent-adolescent conflict (Needle, Glynn, & Needle, 1983) and lack of familial cohesion (Hundleby & Mercer, 1987) increase this risk. Offspring of substance abusing parents have a significantly increased risk of using substances above and beyond genetic risks because substance use is often a common coping response modeled to offspring (Chassin, Pillow, Curran, Molina, & Barrera, 1993; Holden, Brown, & Mott, 1988). Parental monitoring and attitudes influence teen substance use directly by limiting opportunities to engage in deviant behavior (Forehand, Miller, Dutra, & Chance, 1997) and indirectly by influencing peer selection (Brown, Mott, & Stewart, 1992; Dishion, Patter-

son, & Reid, 1988). In general, three family characteristics elevate the risk of subsequent substance abuse: (1) parental dysfunction (e.g., substance dependence), including antisocial behaviors, alcoholism, and drug abuse; (2) minimal parental involvement with their children; and (3) dearth of affectionate, supportive parent-child interactions (Sadava, 1987). These family climate factors may interact with shared genes to contribute to the development of substance problems (McGue, Sharma, & Benson, 1996). Some studies of adoptees have indicated that siblings may be a greater source of environmental influence than parents for risk of substance use disorder (McGue, 1997; Rose et al., 1999).

Life Stress. Researchers have associated a variety of stressful life circumstances with the onset and progression of substance involvement. Life adversity, such as relationship problems, familial difficulties, legal troubles, and academic failure, increases the risk factors of substance abuse during adolescence (Duncan, 1977; Pandina & Schuele, 1983). Life stress is higher in families with substance abusers, suggesting an interactive mechanism by which positive family histories may increase the risk of substance abuse (Brown et al., 1995; Sher, 1991). Among adults treated for substance use disorders, those experiencing taxing psychosocial stressors appear more vulnerable to rapid posttreatment relapses (Brown, Vik, Patterson, Grant, & Schuckit, 1995).

Cognitions

Expectancies. Expectations regarding the effects of substances are related to consumption patterns in youth and adults. These expectancies mediate initiation of use and progression to problematic use (Brown, 1993; Goldman, Brown, Christiansen, & Smith, 1991; Smith, Goldman, Greenbaum, & Christiansen, 1995). Expectancies develop from both direct and vicarious experiences with substances and reflect culturally held beliefs, as well as personal learning about substances in school, in the media, and from peers and family (Goldman et al., 1991). Research has also linked family histories of substance use disorders, particularly when exposed to abusing models during youth, with increased positive expectancies of certain substance effects (Brown, Tate, Vik, Haas, & Aarons, 1999; Sher, 1993). Although very young

children of substance abusers may hold more negative expectancies for substance effects, these expectancies are more likely to become quite positive as offspring acquire personal substance use experiences (Lundahl, Davis, Adesso, & Lukas, 1997; Wiers, Gunning, & Sergeant, 1998). Expectancies are generally substance-specific, but some (e.g., tension-reduction effects) are common to several classes of substances. Overall, individuals who anticipate that substances will produce positive effects have a greater chance of developing substance-related problems than those who do not hold this belief. In contrast, expectancies of negative substance effects may deter the initiation of involvement with certain substances (Brown, 1993). Expectancies may also result in anticipatory psychological responses of a compensatory nature (Ross & Pihl, 1988) that are linked to behavioral tolerance.

Perceptions of Normative Use. Users of alcohol and other drugs tend to perceive that others use amounts similar to those they use (Baer, Stacy, & Larimer, 1991). Erroneous perceptions of normative use are particularly notable among substance abusing adolescents and college students. These biases preserve cognitions of personal use patterns as nonproblematic and accelerate consumption to conform to perceived normative use levels (Marks & Miller, 1987; Perkins & Berkowitz, 1986).

Personality

Individuals with substance abuse or dependence are quite heterogeneous with regard to lifestyle, social background, and personality characteristics (Babor, Hesselbrock, Meyer, & Shoemaker, 1994). Several personality traits are more common among people with addiction problems. These include rebelliousness, autonomy striving, liberalism, willingness to try new experiences, and independence (Segal, Huba, & Singer, 1980). Similarly, research has linked sensation seeking (Kohn & Annis, 1977; Zuckerman et al., 1994), impulsivity (Vistor, Crossman, & Eiserman, 1973), low self-esteem (Kaplan, 1977), reduced self-efficacy (Schinke, Botvin, & Orlandi, 1991), nonconventionality (Brook, Whiteman, & Gordon, 1983), behavioral undercontrol (Jessor & Jessor, 1977), and aggressive tendencies (Krueger, Caspi, Moffitt, Silva, & McGee, 1996) to high rates of sub-

stance involvement. Children with personalities characterized by deviance, emotional lability, inattention, lack of involvement in activities, and stubbornness are at greater risk of using substances frequently in late adolescence (Shedler & Block, 1990). Although evidence for a unitary "addictive personality" has not received empirical support (Sutker & Allain, 1988), more individuals with substance use disorders meet criteria for antisocial personality disorder and other mental health problems (e.g., anxiety and depressive disorders), even after substance-related pathology is excluded (Verheul, Hartgers, van den Brink, & Koeter, 1998). These personality characteristics that are relatively common among substance abusers appear to be inherited traits which may exacerbate or mediate familial substance abuse or dependence (McGue, 1997; Sher, 1997).

Developmental Issues

In the past decade, increased awareness of the prevalence of youthful substance use and the risks involved has brought about growth in research focused on developmental issues. Experimentation with a variety of socially unapproved behaviors during adolescence is fairly common. Approximately 54% of eighth-grade students in the United States have used alcohol, and 38% have used an illicit drug (Johnston, O'Malley, & Bachman, 1998). This experimentation, especially with alcohol, cigarettes, and marijuana, can be part of the developmental process of individuation (Hawkins, 1982; Schinke et al., 1991). However, age of onset of substance use has recently been linked to lifetime risk of both alcohol abuse and dependence (Grant, 1997).

The relevance of various risk and protective factors for substance abuse fluctuates across developmental stages (Newcomb & Bentler, 1989). For example, the influence of peer behaviors and attitudes is greatest during adolescence (Hawkins, 1982), and spousal support among adults is a significant predictor of successful recovery without treatment (Sobell & Sobell, 1998). Personality traits and substance expectancies stabilize with maturity and play a powerful role in perpetuating substance involvement in young adulthood (Tappert, Stewart, & Brown, 1999). The consequences of adolescent substance use may develop slowly and include physical problems, psychological mal-

adjustment, unstable employment patterns, higher divorce rates (Brown, Myers, Mott, & Vik, 1994; Kandel, Davies, Karus, & Yamaguchi, 1986; Newcomb & Bentler, 1988a), and impaired social development (Baumrind & Moselle, 1985). Troubled life trajectories are particularly associated with multiple drug problems during adolescence (Brown et al., 1994; Newcomb & Bentler, 1988b, 1989).

The natural course of substance abuse involves fluctuating levels of use across time (Schuckit, Tipp, Smith, & Buchholz, 1997), including reductions and cessation without formal treatment. For example, only 12% of opiate-dependent Vietnam veterans continued their addiction after returning to the United States (Robins, Davis, & Nurco, 1974), likely due to major reductions in both stress and drug-related cues (Alexander & Hadaway, 1982; Robins, 1993). Individuals who remedy addictions without professional assistance have become a recent focus of attention, because the majority of adults who develop alcohol problems and resolve them do not seek treatment (Sobell & Sobell, 1998). Several studies of adolescents also demonstrate that many high school students deescalate their alcohol and drug involvement over the course of a school year (Stice, Myers, & Brown, 1998) and that youth routinely make serious attempts to reduce or stop their tobacco, alcohol, and other drug use (Wagner, Brown, Monti, Myers, & Waldron, 1999). The availability of desirable activities other than substance use greatly enhances the chance of natural recovery for adults (Tucker, 1995; Vuchinich, 1998), and youth use multiple strategies simultaneously (e.g., social supports, alternative activities) to sustain their behavior change efforts (Wagner, Brown, Monti, Myers, & Waldron, 1999). Investigations of the natural change process suggest that many individuals initiate behavior change before entering formal treatment and that interventions may assist primarily in maintaining change efforts (Tucker et al., 1995).

Substances of Abuse

The principles underlying development of substance abuse problems are quite similar across different substances of abuse, but substances differ in intoxication effects, withdrawal syndromes, resulting consequences, and the sequence in which experimentation tends to occur.

Sequence of Substance Experimentation

Substance involvement tends to follow a predictable sequence, from the use of "gateway" substances that are legal for adults (i.e., alcohol or cigarettes) to the use of marijuana, hard drugs, and prescribed psychoactives in adulthood (Ellickson, Hays, & Bell, 1992). This common sequence was investigated in more than 1000 high school students followed through young adulthood (Kandel, Yamaguchi, & Chen, 1992). Alcohol use has a stronger link to progression in this sequence for males than for females, whereas cigarette use has a stronger link for females than for males. The use of a substance at a particular stage in the sequence does not necessarily dictate progression to the next stage; rather, entry into a use stage is a prerequisite for the next stage.

The following section details the properties and consequences of specific substances of abuse. It should be remembered that polysubstance use involving multiple substances used concurrently is relatively common (Earleywine & Newcomb, 1997), particularly among adolescents and young adults (Stein, Newcomb, & Bentler, 1987; Stewart & Brown, 1995), complicating acute effects, withdrawal, and clinical course.

CNS Depressants

Central nervous system depressants include alcohol, sedatives, and anxiolytic drugs. These drugs depress excitable tissues at all brain levels, produce a subjective sensation of intoxication, and are physically addictive (Schuckit, 1995).

Alcohol. Properties specific to alcohol are discussed in detail by Nathan and colleagues (this volume). Briefly, intoxication generally involves subjective sensations of relaxation, tension reduction, sociability, disinhibition, and euphoria. Toxic reactions occur at higher doses or with potentiation from other CNS depressants and involve confusion, irritability, slowed pulse, reduced body temperature, low blood pressure, and possible respiratory failure. Some degree of alcohol withdrawal is generally observed in daily drinkers who quit drinking and involves sweating, increased heart rate and respiratory rate, increased body temperature, tremor, nausea, vomiting, depressed mood, and muscle aches. More severe symptoms of seizure and delirium tremens, a condition marked by increased tremor, profound confusion, and hal-

lucinations, appear in 5% of those who experience alcohol withdrawal (for a review, see Schuckit, 1995).

Approximately half of adults with alcohol dependence evidence cognitive impairments in visuospatial functioning, verbal learning and memory, visual memory, psychomotor functioning, or nonverbal abstract reasoning (Beatty, Hames, Blanco, Nixon, & Tivis, 1996; Brandt, Butters, Ryan, & Bayog, 1983) and tend to be more pronounced in older drinkers (Adams et al., 1993). The majority of these cognitive deficits improve with extended abstinence (Reed, Grant, & Rourke, 1992). Neuroimaging studies also demonstrate adverse brain changes associated with alcohol dependence (Jernigan, Pfefferbaum, & Zatz, 1986) that tend to resolve with abstinence (Carlen et al., 1986) and worsen following alcohol relapse (Pfefferbaum et al., 1995).

Depressant drugs. This class of drugs includes hypnotics (e.g., barbiturates, methaqualone, chloral hydrate), anxiolytics, and benzodiazepines (e.g., Xanax[®], Valium[®], Librium[®], Ativan[®]). These drugs are prescribed at high rates (approximately 15% of the U.S. population), and although used effectively for most, misuse is observed in 5–10% of patients for whom these medications are prescribed. Effects experienced after ingestion include euphoria, disinhibition, cognitive impairment, loss of motor coordination, and slurred speech. High doses can produce hallucinations or paranoia, ataxia, sedation, and increased risk of accidents (e.g., vehicular). Very high doses can produce depressed heart rate, respiratory failure, coma, or death. These substances show cross-tolerance and present a high risk of lethal overdose if used simultaneously with alcohol or other CNS depressants. Abrupt cessation can be fatal and is especially dangerous from agents with short half-lives (e.g., Xanax[®]—10 hours). The typical withdrawal syndrome is characterized by anxiety, insomnia, headaches, tremors, muscle aches, increased heart and respiratory rates, fatigue, and, sometimes, disorientation, hallucinations, depression, and convulsions. This withdrawal syndrome can persist for days to weeks. Individuals who withdraw from depressant drugs should receive medical monitoring (Schuckit, 1995). The chronic use of barbiturates is associated with persisting deficits in abstraction, psychomotor processing, and nonverbal learning (Bergman, Borg, Engelbrektsen, & Vikander, 1989).

Stimulants

CNS stimulants include caffeine and nicotine, but the major intoxicating stimulants of abuse are cocaine and amphetamines. Drugs of this class typically produce physiological arousal, euphoria, insomnia, and diminished appetite.

Cocaine. Users can insufflate (snort) or smoke cocaine powder, sprinkle the powder in rolled cigarettes, smoke it in cooked form (“crack” or “rock”), or inject it in a dissolved form. Crack is more potent than powdered cocaine and causes intense effects that diminish rapidly. Cocaine use produces euphoria, expansive mood, loquaciousness, restlessness, mood swings, irritability, aggression, and insomnia. In higher doses, loss of control, paranoia, panic attacks, and hallucinations may occur. Common physical effects include elevated heart rate, dry mouth, sweating, numbness of the mucous membranes, and hand tremors. Tolerance develops rapidly, usually within days of continued use. Withdrawal symptoms include fatigue, depressed mood, craving, agitation, and, in some cases, physical aggression. The half-life of cocaine is 1 hour, and withdrawal lasts for days to months (Kuhn, Swartzwelder, & Wilson, 1998). Chronic cocaine use adversely influences short-term memory (Ardila, Rosselli, & Strumwasser, 1991; Manschreck et al., 1990), verbal recall (Mittenberg & Motta, 1993), speed of information processing, attention (Ardila, 1991; O’Malley & Gawin, 1990), and abstraction (O’Malley, Adamse, Heaton, & Gawin, 1992).

Amphetamines. Amphetamines include pharmaceutically prepared substances (e.g., Benzedrine[®], Dexedrine[®], Ritalin[®], and other drugs prescribed for obesity, attention deficit/hyperactivity disorder, and narcolepsy) as well as substances produced illegally, such as methamphetamine (“crystal meth,” “speed,” or “ice”). Users can snort powder forms of these drugs, dissolve and inject the substances, smoke them, or ingest the drugs orally. Amphetamines produce subjective experiences of euphoria, sociability, hypervigilance, anxiety, stereotyped behaviors, and impaired judgment. As with cocaine, smoked and injected forms are more concentrated, and behaviors are more dramatically altered than with use of other forms. The primary difference between cocaine and amphetamines is the longer half-life of the latter (6 to 12 hours). Physical effects include increased heart rate, pupil dilation, and psychomotor agita-

tion. Withdrawal symptoms involve 1 week to 6 months of depression, irritability, fatigue, and hypersomnia and can involve aggression and hallucinations (Maxmen & Ward, 1995).

Tobacco. Nicotine, the addictive substance in tobacco, is delivered through cigarettes, cigars, and smokeless tobacco products such as chew and snuff. Long-term use of tobacco has been associated with a wide range of health problems, particularly cancers (of the lung, mouth, and esophagus), coronary artery disease, atherosclerosis, cerebrovascular disease, emphysema, compromised immune function, decreased fertility, and low birth-weight offspring (see review by Baer & Brady Murch, 1998). Although a third of smokers attempt to quit each year, less than 5% remain smoke-free longer than 12 months (see review by Haaga & Kirk, 1998). Cigarette smoking is the leading preventable cause of mortality in the United States (McGinnis & Foege, 1993), and elevated rates of respiratory problems have been noted in youth with as little as 2- to 4-year histories of smoking (Myers & Brown, 1997).

The acute effects of nicotine are less dramatic than those of other substances of abuse; intoxication is mild and generally nonimpairing. Nicotine delivery products tend to be used throughout the day: the half-life of nicotine is only 30 to 120 minutes and increases the environmental associations that may cue the user to smoke. Significant withdrawal symptoms of depressed mood, fatigue, irritability, and craving that last 2–3 weeks are reported in youth and adults who stop or cut down nicotine intake and make the quitting process particularly arduous.

Opiates

This drug class includes derivatives of the opium poppy (e.g., opium, morphine), semi-synthetics (heroin), medication preparations synthesized to have morphine-like properties (e.g., codeine, hydromorphone, methadone, oxycodone, meperidine, and fentanyl), and medications with both opiate agonist and antagonist properties (buprenorphine, pentazocine). Opiates are prescribed for pain relief, cough suppression, or to alleviate opiate withdrawal symptoms. Opiate users inject, snort, smoke, and swallow the drug.

Opiate users report the intoxicating effects of euphoria, especially during the “rush” immediately following administration, as well as apa-

thy, dysphoria, impaired judgment, and relaxation. Physical effects of intoxication include suppressed respiratory functioning, slurred speech, psychomotor retardation, reduced pain sensations, impairment of attention and memory, constricted pupils, and constipation. Tolerance develops rapidly. Due to the comparatively short half-life of heroin (30 minutes versus 2 to 3.5 hours for morphine), administration four times per day is common in addicts. Thus, daily activities revolve around obtaining and administering opiates. Withdrawal is generally very unpleasant and involves nausea, vomiting, diarrhea, muscle aches, tremor, fatigue, insomnia, fever, dysphoric mood, and cravings and can last up to 8 days (Tapert et al., 1998). Administration of street opiates poses a particular risk for overdose because purity levels remain unknown to the user. Because many opiate users inject, additional risks of HIV infection, hepatitis, cellulitis, endocarditis, and tuberculosis are imminent. Death from opiate overdose most commonly results from respiratory depression. No consistent neuropsychological deficits have been identified among tolerant users or detoxified former users (Zacny, 1995).

Cannabinols

Marijuana is the most commonly used illicit drug in the United States. Users ingest THC by smoking marijuana leaves ("pot," "weed"), smoking resin ("hashish"), or eating cannabinoids mixed with food. Intoxicating effects include relaxation, euphoria, altered perception, impaired motor coordination, the sensation of slowed time, impaired judgment, and social withdrawal (APA, 1994). THC has a relatively long half-life of 2 to 7 days. Anxiety, paranoia, attention and memory impairment, panic, and hallucinations may occur acutely. Physical symptoms include increased appetite, dry mouth, bloodshot eyes, and tachycardia (Tapert et al., 1999). Although its use involves fewer physiological changes than most other drugs of abuse, the consequences of chronic use may include amotivational syndrome as well as lung diseases similar to those experienced by tobacco smokers. Males may suffer impaired sperm production, decreased testosterone secretion, and decreased size of prostate and testes. Females can experience blocked ovulation (Cohen, 1981; McGlothlin & West, 1968, Tapert et al., 1998).

Studies of marijuana's influence on cognition have yielded mixed results (Culver & King, 1974;

Wert & Raulin, 1986). Recent studies have demonstrated some mild impairments in attention, problem solving, and verbal learning following at least 1 day of abstinence among chronic, heavy users (Pope & Yurgelun-Todd, 1996), visuospatial memory problems in chronic female users (Pope, Jacobs, Mialet, Yurgelun-Todd, & Gruber, 1997), and complex problem solving (Block, Farinpour, & Braverman, 1992).

Hallucinogens

These drugs produce dramatic alterations in sensation and perception and include lysergic acid diethylamide (LSD), psilocybin (from certain mushrooms), dimethyltryptamine (DMT), mescaline (from the peyote cactus), 2,5-dimethoxy-4-methylamphetamine (DOM or STP), methylene dioxyamphetamine (MDA), methylene dioxymethamphetamine (MDMA, "ecstasy," "E," or "X"), 2C-B ("Nexus"), ibotenic acid, and muscimol.

Hallucinogens are usually taken orally. Users experience intensification of perceptions, visual hallucinations, derealization, euphoria, alertness, and emotional lability. Confusion, paranoia, panic, loss of control, and depression may result. The most imminent risk during intoxication is acting on delusional beliefs (e.g., ability to fly). Physical effects include pupillary dilation, tachycardia, tremors, nausea, and sweating (Tapert et al., 1998). Heavy, long-term LSD use has been inconsistently associated with mild deficits in speeded visuomotor scanning abilities (Culver & King, 1974), and MDMA ("ecstasy") may produce verbal learning and memory impairments (Krystal & Price, 1992). Incorrect chemical synthesis of MDMA and MDA can produce substances that cause severe Parkinsonian symptoms (e.g., MTPT). Hallucinogenic effects tend to be more intense for younger users than for older users. Tolerance can develop with frequent use (Tapert et al., 1999).

Dissociatives

Phencyclidine (PCP, Sernylan[®], "Angel Dust") and related compounds (Ketamine[®], Ketaject[®]) were developed as anesthetics and became street drugs in the 1960s. Users can smoke, snort, orally ingest, or inject them. Because PCP is relatively inexpensive, drug dealers often mix it with other drugs (particularly marijuana) to intensify effects. Intoxicating effects include marked behavioral change, assaultiveness, belligerence, unpredict-

tability, impaired judgment, euphoria, hallucinations, intensified perceptions, and heightened emotions. Some users experience hyperactivity, panic, paranoia, and confusion. Physical effects include numbness and diminished response to pain, psychomotor agitation and discoordination, tachycardia, slurred speech, and sometimes, catatonia, convulsions, respiratory depression, coma, and death (see review by Tapert et al., 1999). PCP has a half-life of approximately 18 hours, and, due to profoundly impaired judgment and reduced fear of pain, users may engage in very violent or destructive behaviors while high. PCP use is associated with long-term impairments in abstraction and motor skills (Carlin, Grant, Adams, & Reed, 1979).

Inhalants

Inhalants of abuse include industrial and household compounds, such as glues, aerosol sprays, gasoline, paints, paint thinners, nail polish remover, correction fluid, certain cleaning solvents, and nitrous oxide (“poppers,” “rush”). Due to availability and low cost, children, adolescents, and youth from economically disadvantaged regions comprise the majority of inhalant users. Euphoria, floating sensations, temporal distortion, and visual hallucinations occur acutely, followed by apathy, confusion, irritability, assaultiveness, and panic. Physical effects include loss of coordination, dizziness, headache, slurred speech, lethargy, psychomotor retardation, tremor, and blurred vision. Inhalant abuse can lead to serious physiological problems, including respiratory damage, eye, nose, and throat damage, as well as kidney, liver, heart, gastrointestinal, and nervous system damage (Morton, 1990). Death can occur from heart arrhythmias or suffocation from breathing out of plastic bags containing the solvent. Inhalant abuse is robustly associated with impaired attention, memory, fine motor, and visuospatial functioning (Allison & Jerrom, 1984).

Assessment

Treatment planning and evaluation of treatment response are accomplished by assessment procedures developed specifically for the field of substance use disorders. Methods for assessing substance use may involve screening for alcohol or drug problems, assessing substance use behaviors,

determining diagnosis, or evaluating outcomes. Measures of substance involvement described in this chapter are exemplars of instruments available to assist treatment providers and researchers in tailoring interventions and evaluating substance use behaviors. Although substances differ in consumption patterns and physiological properties, broad similarities across psychoactive substances guide diagnostic procedures, as evidenced by the adoption of uniform dependence criteria across substances in the DSM-IV (APA, 1994). Thorough assessments should include evaluating alcohol and illicit drug use, given the prevalence and poorer treatment outcomes associated with polysubstance disorders (Kolar, Brown, Weddington, & Ball, 1990; Rounsaville, Dolinsky, Babor, & Meyer, 1987).

Self-Report Assessment Issues and Strategies

The accuracy of self-reported substance use has been questioned due to acute and chronic memory problems associated with substance use, motivation to avoid the negative consequences of use, stigmatization, and minimization of personal problems (Carroll, 1995). However, empirical investigations have found that self-reports of substance use are relatively reliable and valid. Studies have substantiated the reliability and validity of alcohol use self-reports across populations (e.g., adolescents, college students, inpatients, outpatient, and normal drinkers; Babor, Brown, & Del Boca, 1990; Babor, Stephens, & Marlatt, 1987; Brown, Myers, et al., 1998; Maisto, Sobell, Cooper, & Sobell, 1979), as well as the accuracy of self-reported tobacco and other substance use (Brown, Myers, et al., 1998; Ehrman & Robbins, 1994).

Specific strategies enhance the accuracy of substance-related assessments (Babor et al., 1987). A critical first step is to verify that the client is not intoxicated or experiencing withdrawal states that may compromise memory or attention at the time of assessment. Unlike many other clinical symptoms, substance use and associated problems are observable or detectable. Methods of increasing self-report accuracy capitalize on these features by obtaining corroborating information from spouses, relatives, friends, records (e.g., medical and legal), and biological tests (Babor et al., 1987; Maisto, McKay, & Connors, 1990). Informing a client that these resources will be used improves reliability. Assuring both the client and collateral contacts of

confidentiality encourages disclosure without concern for repercussions. In the event of discrepancies among informants, the source indicating that substance use has occurred usually is more accurate (Carroll, 1995). Calendar prompts are helpful (i.e., linking dates to holidays, anniversaries, and important life events).

Computer versions are available for many diagnostic and screening assessment instruments. Individuals may be more comfortable and provide more accurate information on sensitive topics when reporting to a computer, as opposed to a live interviewer. Comparisons of interview, self-report, and computer assessments have typically revealed few differences in the information provided (Davis, Hoffman, Morse, & Luehr, 1992; Skinner & Allen, 1983), and clients may prefer computer assessments to interviews or paper-and-pencil self-reports (Millstein, 1987; Skinner & Allen, 1983) and respond to computer measures more completely (Erdman, Klein, & Greist, 1983).

Screening

Because substance use disorders are highly prevalent but treatment is sought at disproportionately low frequencies, identifying the need for intervention among non-treatment-seeking individuals may be beneficial. For example, alcohol and drug use problems are prevalent in medical patients (Rydon, Redman, Sanson-Fisher, & Reid, 1992), military personnel (Bray, Guess, Marsden, & Herbold, 1989), and college students (Gfroerer, Greenblatt, & Wright, 1997). Screening measures are designed to identify individuals who need intervention or who are at risk of developing substance-related problems in a time-efficient manner (Connors, 1995), and include brief self-report measures, short interviews, and biological markers of substance use.

Widely used self-report instruments developed to screen for alcohol problems include the ten-item Alcohol Use Disorders Identification Test (AUDIT), developed and tested cross-culturally by the World Health Organization (Saunders, Aasland, Babor, De La Fuente, & Grant, 1993), the Michigan Alcoholism Screening Test (MAST; Selzer, 1971), that consists of twenty-five questions, and the four-item Cut down, Annoyed, Guilty, Eye opener (CAGE; Adams, Barry, & Fleming 1996; Mayfield, McLeod, & Hall, 1974), which is widely

used in medical facilities. A comparison of the AUDIT and CAGE showed that the AUDIT performed significantly better in detecting drinking problems among general medical patients (Bradley, Bush, McDonnell, Malone, & Finn, 1998). Even briefer versions of the AUDIT, using only the three questions related to alcohol consumption (frequency, typical quantity, frequency of six or more drinks in a single sitting), performed comparably to the full AUDIT for identifying individuals with current alcohol abuse or dependence. The single item on frequency of binge drinking detected 81% of patients with alcohol abuse or dependence, and only 17% of patients were falsely identified as positive (Bush, Kivlahan, McDonnell, Finn, & Bradley, 1998). Thus, the AUDIT is a preferable alcohol problem screening measure.

The Personal Experience Screening Questionnaire (PESQ; Winters, 1991) is a brief self-report instrument designed to screen for alcohol and drug use problems in adolescents. This forty-item measure takes approximately 10 minutes to complete. Sound psychometric properties have been demonstrated (Winters, 1991, 1992). The PESQ does not provide diagnoses but efficiently assists clinicians and schools in identifying teens who may need substance abuse assessment.

Biological Markers of Substance Use

In addition to self-report screening instruments, biological markers are available for a range of substances including nicotine, alcohol, and both licit and illicit drugs. Biological tests vary in cost, biological specimen (e.g., saliva, breath, urine, and blood), sensitivity, and specificity. Sensitivity refers to the likelihood that a substance will be identified by the test if the substance is present. Specificity refers to the proportion of biological samples that is accurately identified. Generally, tests that are very accurate (both highly sensitive and highly specific) are more costly. Thus, it is advisable to begin biological screening with a very sensitive method and follow positive results using a more expensive test with high specificity (Schuckit, 1995).

The majority of alcohol and other drug testing occurs through urine toxicology due to its relatively low cost. A limitation is that results indicate only the recent presence of the substance, not the quantity or timing of use. Alcohol use is detectable

for approximately 24 hours postconsumption, amphetamines for 48 hours, opiates for 48 hours, cocaine for 3–5 days, barbiturates for 1–7 days, and cannabinoids approximately for 5–7 days. Positive tests may result from regular cannabinol use for up to 3–4 weeks (Schuckit, 1995).

Expired carbon monoxide (CO) and cotinine improve the accuracy of self-reported nicotine use (Hughes, 1993). CO breath samples are less expensive, easily collected, and provide immediate results and reasonable sensitivity to past 24-hour nicotine use (Velicer, Prochaska, Rossi, & Snow, 1992). Cotinine can be tested using saliva, blood, or urine samples and has superior sensitivity and specificity for detecting nicotine use in the past 3–7 days.

Biological markers are also available for detecting prolonged heavy alcohol consumption and corroborating a suspicion of relapse. These include relatively inexpensive liver function tests such as gamma-glutamyltransferase (GGT), aspartate aminotransferase (SGOT), alanine aminotransferase (SGPT), and a red blood cell test for mean corpuscular volume (MCV). Medical problems can cause false positive results. These tests are most useful in combination (Irwin, Baird, Smith, & Schuckit, 1988). A newer test, carbohydrate-deficient transferrin (CDT), is more expensive but is more accurate than GGT or MCV in men under age 40, smokers (Yersin, Nicolet, Decrey, Burnier, van Mele, & Pecoud, 1995), patients with liver disease, and early relapsers (Schmidt et al., 1997).

A less studied biological screening method analyzes hair follicles. Most drugs are carried by the bloodstream to the scalp, where the substance is incorporated into the hair follicles. Because hair grows predictably over time, separate sections of hair samples can provide estimates of the months in which various drugs were used (Strang, Black, March, & Smith, 1993).

Diagnosis

Diagnostic assessment involves following a set of diagnostic criteria to determine if an individual has a clinical disorder. The DSM-IV (APA, 1994) is the most widely used diagnostic system in the United States and has criteria for substance disorders similar to the *International Classification of Diseases and Related Health Problems* (ICD-10;

World Health Organization, 1992) which is used worldwide. In selecting diagnostic measures, considerations include available resources, administrative time, training required, cost of the measure, scoring methods, and client characteristics (e.g., age and culture). Many instruments were originally developed with predominantly Caucasian adult male samples and should be reviewed for reliability and validity for use with adolescents, older adults, women, and non-Caucasians.

Methods for diagnosis include structured and semistructured interviews distinguished by the level of interviewer judgment and flexibility incorporated in the assessment process. The NIMH Diagnostic Interview Schedule (DIS; Spitzer, 1983) and the WHO Composite International Diagnostic Interview—Substance Abuse Module (CIDI-SAM; Cottler et al., 1995) are reliable structured interviews that do not require professional training, but some clinicians report a mechanical quality to this type of interview. Semistructured measures allow more discretion on the part of interviewers to determine when more detailed questioning is needed, but require more professional training. The Psychiatric Research Interview for Substance and Mental Disorders (PRISM; formerly known as the Structured Clinical Interview for DSM-III-R, Alcohol/Drug Version; SCID-A/D) is a widely used semistructured measure with more flexibility, that provides diagnoses for other Axis I and II disorders as well.

Specifiers that indicate severity and other characteristics (e.g., physiological dependence) can be useful in both clinical and research settings. For example, the Alcohol Dependence Scale (Horn, Skinner, Wanberg, & Foster, 1984) provides a reliable quantitative measure of the severity of alcohol dependence based on twenty-five questions covering withdrawal symptoms, impaired control over drinking, compulsion to drink, tolerance, and alcohol-seeking behaviors.

The Addiction Severity Index (ASI; McLellan et al., 1992) is a structured interview that queries personal/family characteristics and provides severity estimates for problems in six life areas frequently impacted by substance abuse (medical, employment/financial support, drug/alcohol use, legal/criminal justice involvement, family/social, and psychological/psychiatric). Separate categories of substances assessed include alcohol, heroin, methadone, other opiates/analgesics, barbiturates,

other sedatives/hypnotics/tranquilizers, cocaine, amphetamines, cannabis, hallucinogens, inhalants, and polysubstance use. The ASI requires 45–60 minutes to administer and 10–15 minutes to score and has been normed on multiple samples that consistently demonstrate strong psychometric characteristics (Friedman & Granick, 1994). The composite score for drugs is a weighted sum of the frequencies of several different types of drug use, and consequently heavy users of a single substance are likely to receive lower scores than less frequent users of multiple drugs (Carroll et al., 1994). Therefore, evaluation of clinical progress may be influenced by the pattern of drug use for a particular client, and this measure may be less sensitive to change for some substance users (Carroll, 1995).

The Customary Drinking and Drug Use Record (CDDR; Brown, Myers, et al., 1998) is a structured interview that assesses recent (prior 3 months) and lifetime characteristics of adolescent alcohol and other drug involvement; it queries separately for marijuana, amphetamines, barbiturates, hallucinogens, cocaine, inhalants, opiates, prescription medications, and other substance not previously identified. Additionally, age of initiation and progression to regular use, negative consequences, withdrawal, and dependence are assessed. Reliability and validity have been demonstrated for community and clinical samples of adolescents and young adults (Brown, Myers et al., 1998).

Detailed Substance Assessments

Detailed assessments provide valuable information on patterns of substance use, including quantity and frequency of use, binge use, high-risk situations, and progress in treatment. Methods for assessing substance use have been classified into two categories: summary (also called aggregate or quantity-frequency) measures and detailed daily assessments (Room, 1990). Clients report the quantity of alcohol that they typically consume, the maximum number of drinks consumed in one sitting, how frequently they drink, and how frequently they use a variety of drugs. The three major types of alcoholic beverages (beer, wine, and hard liquor) are often queried for separately. Drug use is more difficult to quantify due to differences in quantity descriptions and quality of “street” drugs; thus, frequency of drug use is more reliable,

although money spent on heroin or cocaine may estimate the quantity (Ehrman & Robbins, 1994).

Daily instruments such as the Timeline Follow-back (TLFB; Sobell, Kwan, & Sobell, 1995; Sobell, Toneatto, Sobell, 1994) use a calendar to prompt detailed assessment of a client’s substance use over a period of time up to 1 year. Individuals retrospectively estimate daily substance use. Salient event anchors (e.g., incarcerations, hospitalizations, pay days, birthdates, and holidays) aid recall. The TLFB was initially developed for assessing alcohol use, and has been adapted to assess other drug and tobacco use (Brown, Burgess, et al., 1998; Ehrman & Robbins, 1994). Daily techniques permit examining substance use patterns over time. Clients can record substance use on an ongoing basis with self-monitoring diaries and cards.

Other facets of drug involvement are useful in treatment planning, evaluation, and research. For example, self-efficacy (confidence in one’s ability to execute a given behavior) is related to alcohol and drug treatment outcomes (Marlatt, Baer, & Quigley, 1995). The Situational Confidence Questionnaire (Annis & Graham, 1988), Drug-Taking Confidence Questionnaire (Sklar et al., 1997), and Smoking Self-Efficacy Questionnaire (Colletti, Supnick, & Payne, 1985) assess self-efficacy related to alcohol, other drugs, and cigarette use. The Inventory of Drinking Situations (Annis, 1982) and Inventory of Drug-Taking Situations (Annis & Martin, 1985) identify situations in which the client drank or used drugs during the past year, based on eight relapse precipitant categories developed by Marlatt and Gordon (1985). Personal expectancies about the effects of alcohol or drugs have also been associated with use patterns (e.g., Brown et al., 1985; Schafer & Brown, 1991). The Alcohol Expectancy Questionnaire (Brown, Christiansen, & Goldman, 1987) assesses the anticipated effects of alcohol use and has been adapted for adolescent populations (Christiansen, Goldman, & Brown, 1996) and for other substances (e.g., stimulants, marijuana, and nicotine; Schafer & Brown, 1991). Profiles on these scales help identify relapse risks and can focus interventions on situations that require strategies and skills for avoiding future substance use. Summaries of a variety of substance use measures are described in a manual published by the National Institute on Alcohol Abuse and Alcoholism (Allen & Columbus, 1995).

Treatment

In any given month, an estimated 2.3 million adults meet clinical criteria for drug dependence or abuse based on household interviews (Regier et al., 1990). Including criminal justice populations (inmates, probationers, or parolees), homeless people, and pregnant women (bearing a lower threshold for treatment need), an estimated 5.5 million individuals need treatment at any given time (Institute of Medicine, 1990). People transition in and out of these diagnostic labels as a function of biology, conditioning, and social factors. Due to the heterogeneity among individuals with substance use disorders, different forms of treatment are needed (Institute of Medicine, 1990).

In response to this need for treatment, therapeutic strategies developed to treat addictive disorders have evolved over time. Because initial alcohol and drug cessation attempts were most commonly followed by resuming substance use (Hunt, Barnett, & Branch, 1971), the need for a more extensive framework for addressing addictive behaviors became evident. Addiction theory and therapies began to incorporate behavioral principles. Limitations of early behavioral theories that focused on immediate environmental contingencies led to consideration of cognitive and affective factors associated with substance use patterns (e.g., Blane & Leonard, 1987). Behavioral principles, cognitive and affective factors, and behavioral choice theory have been combined to form sophisticated models of addiction. Behavioral choice theory extended the scope of earlier behavior theories, recognizing that behaviors (such as substance use) depend on immediate environmental contingencies and also on the availability of valued alternate activities and environmental constraints (Vuchnich & Tucker, 1996). Contemporary interventions may encompass components of these theoretical contributions.

Thus, the clinician and client have a wide variety of treatment options. Alcohol and drug abuse treatments vary in multiple ways: the format of treatment services (individual, family, group), type of treatment provider (peers, paraprofessionals, professionals), length of treatment (brief interventions to lifelong participation), treatment intensity (inpatient hospitalization, outpatient treatment, or community meetings on an as needed basis), and treatment modality (pharmacological therapy, psychotherapy, therapeutic com-

munities). These multiple facets coexist in various combinations, often with little empirical information to guide optimal treatment choices. In initial therapeutic sessions, interventions specifically developed to enhance motivation and engage the client in the treatment process have proven useful.

Motivational Enhancement Therapy (MET)

Because client motivation is a central concern in addressing addictive behaviors clients are often ambivalent about initiating or continuing treatment. A treatment approach specifically aimed at enhancing motivation was developed by Miller and Rollnick (1991) based on therapeutic elements found effective across interventions. Therapists work in an empathic manner with clients to develop cognitive dissonance between current substance use behaviors and personal goals or values, such as health, self-esteem, or role responsibilities. Therapists avoid confrontation with client statements and instead, "roll with resistance" to explore and resolve ambivalence. Therapists support client self-efficacy to change by examining alternative avenues for achieving desired goals, problem solving to remove barriers to behavior change, and encouraging clients to mobilize personal resources. These MET interview techniques have been empirically supported for treating less severe alcohol and nicotine problems. Although initially considered effective mostly for mildly dependent individuals, recent studies have shown efficacy with a variety of patients, including those who express high levels of anger (Miller & Hester, 1995; Project MATCH Research Group, 1998).

Changing substance abuse behaviors is challenging and complex. The transtheoretical model is a useful heuristic that illustrates the five steps of the change process (DiClemente & Prochaska, 1998): (1) precontemplation (unaware of the problem or unwilling to change), (2) contemplation (considering change), (3) preparation (deciding to change), (4) action (implementing change), and (5) maintenance (behavior change sustained several months and integrated into lifestyle; DiClemente & Prochaska, 1998). Individuals may progress or revert to previous stages. This model is helpful in depicting the complexities and motivational levels involved in behavior change (Miller, 1998a).

For some clients, brief motivational interventions may be adequate to inspire behavior change. Short-term approaches include a variety of low-intensity interventions, collectively known as brief interventions, that have proven beneficial in a range of settings.

Brief Interventions (BI)

BIs are a collection of techniques that generally involve one to three sessions of counseling, psychoeducation, professional advice, and/or bibliotherapy (Miller et al., 1995). Commonly, reducing use or preventing problem use, not necessarily abstinence, is the therapeutic goal. Research findings demonstrate that not all substance users require protracted, intensive therapy for healthy behavior change. Four types of clients have been the primary focus of this type of intervention: (1) hazardous drivers, (2) smokers, (3) mildly to moderately alcohol-dependent individuals, and (4) highly dependent drinkers not reached by other services (Heather, 1995). BI is frequently administered in emergency departments or primary care settings. Providers include primary care physicians, nurses, and social workers. An extension of this cost-effective approach is Guided Self-Change (Sobell & Sobell, 1998), which provides readings, exercises, assessment, and personalized feedback regarding substance use patterns, high-risk situations, and relapse prevention techniques. Positive treatment outcomes have been reported following just two–four sessions for alcohol and tobacco problems (Sobell & Sobell, 1998).

Motivational Enhancement, Brief Interventions, and Guided Self-Change are typically delivered individually in outpatient contexts by professionals or paraprofessionals during brief time frames with flexible treatment goals. These approaches all strive to engage clients in initiating changes in substance use behaviors; at times they use personal and community resources.

Self-Help Groups

Self-help groups, one of the most widely recognized and readily available addiction resources, are composed of peers who face similar difficulties and shared goals for change. The most widely known contemporary self-help group, Alcoholics Anonymous (AA; Alcoholics Anonymous World Services, 1976), has 96,000 weekly

group meetings throughout the United States and 150 countries. Similar groups have been developed for other substance use disorders (e.g., Narcotics Anonymous, Cocaine Anonymous, and Nicotine Anonymous) and other addictive behaviors (e.g., Gamblers Anonymous, Overeaters Anonymous). Twelve-step participants share experiences at meetings, obtain sponsorships by successful members, read literature on the principles and steps, and use a spiritual focus to achieve abstinence and seek life meaning. Recovery is considered a lifelong process, and complete abstinence is the only means of managing addiction. Groups are also available to support friends and families of those with addictions (e.g., Al-anon, Adult Children of Alcoholics).

Although twelve-step groups are dominant in the United States, the majority of individuals referred to them do not follow through with long-term attendance (National Academy of Sciences, 1990). Alternative support groups (e.g., Women for Sobriety, Men for Sobriety, Rational Recovery, Moderation Management, and Self-Management and Recovery Training) have emerged that differ from twelve-step groups by emphasizing self-reliance and secular methods of recovery. The primary drawback of these alternatives is limited availability outside of major metropolitan areas. Detailed descriptions of self-help and alternative support groups are provided by McCrady and Delaney (1995) and Horvath (1997), respectively.

In the event that low-intensity approaches prove ineffective for a particular client, short-term inpatient or outpatient treatment formats may be indicated. Treatment providers are professionals or paraprofessionals, and often combinations of individual and group formats are included. Group modalities offer unique therapeutic features, including observational learning and social support (Yalom, 1985). In addition, group counseling may be cost-efficient (Schuckit, 1995). Short-term inpatient treatment programs typically encourage continuing participation in more extended intervention programs following discharge, including outpatient aftercare, self-help groups, residential treatment facilities, or therapeutic communities.

A range of therapeutic approaches that have proven useful in outpatient and inpatient treatment settings is described next. It should be remembered that the features of these interventions overlap at times and multiple techniques are often provided in combination within a single treatment

setting. Treatments developed by psychologists based on theoretical and empirical foundations will be presented first, followed by a brief presentation of effective pharmacotherapies available in these settings.

Relapse Prevention

Relapse Prevention (RP), developed by Marlatt and Gordon (1985), was based on empirical observations that substance use disordered individuals could cease addictive behaviors briefly but had difficulty maintaining the change over time. RP provides behavioral and cognitive skills training to avoid or minimize relapse. Clients are taught to identify and anticipate situations that increase the risk for relapse and to prepare coping strategies to avoid or manage these high-risk situations. If a relapse occurs, it is viewed as a learning experience for fine-tuning strategies and efforts for the future. Balanced lifestyles are encouraged to reduce the reliance on psychoactive substances for pleasurable experiences.

Coping and Social Skills Training

Coping and Social Skills Training (CSST; Monti et al., 1990; Monti, Gulliver, & Myers, 1994) developed from social cognitive learning theory based on the premise that substance abusing individuals exhibit deficits in coping and social skills necessary for adaptive daily living. CSST interventions develop interpersonal skills, affect regulation, stress management, and coping with substance availability cues (Monti, Rohsenow, Colby, & Abrams, 1995). Treatment begins with assessing client strengths and weaknesses in these domains and specifying risky situations for relapse. Because alcohol and drug use cues are not always avoidable in natural environments, exposure to substance-use cues in the safety of the treatment setting seeks to extinguish craving responses (Niaura, Rohsenow, Binkoff, & Monti, 1988).

Contingency Contracting

Contingency contracting, based on operant behavior principles, involves creating a contract between the patient and treatment provider for reinforcers (or punishers) to eliminate substance use and shape goal-directed behaviors (e.g., attending therapy sessions, working). For example, cocaine

abusers have been paid with vouchers for not using cocaine, and increases in voucher amounts escalate for successive weeks of abstinence (Silverman et al., 1996, 1998). Alternatively, clients may agree to an aversive consequence for relapse, such as having employers notified of their drug use (Anker & Crowley, 1982). Another study used small fines (\$5) to patients for not attending therapy appointments without appropriate prior notification (Boudin et al., 1977). Contingency contracting has proven effective in reducing substance use (Dolan, Black, Penk, Robinowitz, & DeFord, 1985; Silverman et al., 1996, 1998) although effects have been transient in some studies (Magura, Casriel, Goldsmith, Strug, & Lipton, 1988). The success of contingency contracting relies on behavioral principles, and careful design and implementation are required. For example, voucher-reinforcement for smoking cessation demonstrated differing outcomes for fixed versus progressive rate reinforcement schedules (Roll, Higgins, & Badger, 1996).

Interpersonal Psychotherapy (IPT)

Long-term substance abuse is associated with multiple social and interpersonal problems, and relationships often become severely strained. Based on the principle that disturbances in interpersonal functioning are related to depressive disorders, IPT techniques were initially developed to focus on clients' difficulties, improve interpersonal skills, expand social support, and decrease depressive symptoms (Klerman, Weissman, Rounsaville, & Chevron, 1984; Rounsaville, Glazer, Wilber, Weissman, & Kleber, 1983; Rounsaville, Gawin, & Kleber, 1985). IPT is adapted to substance use disorders, and the therapist helps clients identify and change maladaptive interpersonal patterns in relationships and recognize the influence of substance use on interactions. IPT is designed as a time-limited, supportive intervention, and has been applied to eating disorders as well (Fairburn, Jones, Peveler, Connor, & Hope, 1991; Wilfley et al., 1993).

Extending this approach focused on interpersonal relationships, approaches that include couples, family members, and multiple systems (e.g., home, school, and work in multisystemic therapy) have also demonstrated efficacy in addressing addictive behaviors (Henggeler & Borduin, 1995; Stanton & Shadish, 1997; Waldron, 1997).

Couple and Family Therapies

Positive couple and family environments are associated with better treatment outcomes (Moos, Finney, & Cronkite, 1990). Because interpersonal conflict is associated with relapse after treatment (Marlatt & Gordon, 1985), interventions to enhance couple and family functioning hold promise for improving treatment outcomes of substance use disorder. Couple and family treatment interventions motivate the substance abusing family member to enter treatment, support change efforts once initiated, and alter family interactions to provide a more conducive environment for maintaining abstinence. Strategies for reestablishing trust, increasing positive interactions, enhancing communication skills, and increasing problem solving and conflict resolution are established components of empirically validated couple and family therapies (O'Farrell, 1995). An important preliminary step involves evaluating the potential for domestic violence and appropriate provisions for the safety of all involved.

Multidimensional family therapy (MDFT) is a promising family-based therapy for adolescent substance abusers, with intervention strategies for teen, parent, and extrafamilial relationships (Liddle, 1995). Work with parents may include supportive therapy, education about adolescence, training in parental monitoring, family-management skills, and appropriate negotiating skills. The clinician provides support and empathy, problem solving, and assistance to the teen in making changes. Parents and teens are seen together to work on communication facilitation. MDFT interventions have been effective in treating adolescent drug abuse and improving conflictual teen-parent interactions (Diamond & Liddle, 1996; Liddle, 1995).

Multisystemic therapy (MST) has shown favorable results with adolescents who are involved in a variety of antisocial behaviors, including substance abuse (Henggeler, Melton, & Smith, 1992; Henggeler, Schoenwald, & Pickrel, 1995). Interventions are developed in collaboration with family members and delivered in the natural setting (e.g., home and school) to enhance generalization. Emphasis is placed on preserving the family system. Family, school, community, and peer influences on adolescent development and behaviors are addressed. Therapy intensity is adjusted based on client need (Henggeler et al., 1997). Positive outcomes have included improvements in family

cohesion, peer relations, and reductions in future arrests, criminal behaviors, and substance use.

Community Reinforcement

The Community reinforcement approach (CRA) recognizes the powerful influence of environmental contingencies and was developed to incorporate social, recreational, family, and job-related reinforcers into treatment (Smith & Meyers, 1995). Individually tailored skills training to improve these areas, as well as substance-related skills, are important elements of this behavioral treatment approach (e.g., communication skills, problem solving, drink refusal training, job counseling, recreational counseling, marital therapy). A key component of CRA is functional analysis of both substance-related and non-substance-related behaviors. Thoughts, feelings, events, and behaviors preceding and following substance use are assessed, and the function of substance use is explored with the client. This analysis helps to identify "high-risk" situations and develop coping strategies to manage or avoid these situations without resuming substance use. Additionally, a similar analysis is conducted for non-substance-related activities to assist the client in identifying pleasurable experiences other than alcohol or drug use. Strong support has been demonstrated for CRA with alcohol, cocaine, marijuana, and heroin abusers (Azrin, Sisson, Meyers, & Godley, 1982; Higgins et al., 1993; Smith, Meyers, & Delaney, 1998).

Couples, family, multisystemic, and community reinforcement approaches extend the influence of interventions beyond the specialized substance treatment setting to incorporate the client's environment. Generalization of skills learned in therapy settings is likely to be enhanced by including natural environmental contexts, and environmental contingencies can be enlisted to aid in the recovery process. In addition to these psychotherapeutic and environmental interventions, pharmacological interventions to address physiological aspects of substance dependence, it has been shown are effective for some substances of abuse.

Pharmacotherapies

Pharmacotherapies for substance-related addictions work through various mechanisms: relieving withdrawal, reducing craving (replacement), block-

ing the reinforcing effects of drug consumption, or counterconditioning aversive responses. No medication can cure substance use disorders, but some pharmacotherapies reduce substance-related problems, as well as symptoms, associated with concomitant psychiatric disorders.

Short-term interventions for alcohol detoxification and short-term withdrawal include administration of benzodiazepines, slowly tapering the dose during a 5–7 day period (Schuckit, 1996). Long term pharmacotherapies include disulfiram (Antabuse®), which causes a severe adverse reaction to alcohol shortly after consumption and reduces the likelihood of relapses. Naltrexone, an opiate antagonist, has shown promising results in reducing relapse and severity of relapse to alcohol (O'Malley, Jaffe, et al., 1992; Volpicelli, Alterman, Hayashida, & O'Brien, 1992). Variable compliance with disulfiram and naltrexone therapy compromises the efficacy of these treatments. Acamprosate is a medication that increases GABA activity and decreases glutamate action with few side effects. Although not yet available in the United States, acamprosate has shown modest clinical benefits in extending initial abstinence, reducing drinking days, and increasing the proportion of patients who remained abstinent in initial human trials in Europe (Sass, Soyka, Mann, & Zieglansberger, 1996; Whitworth et al., 1996).

Two opiate replacement therapies have significantly improved outcomes for opiate disorders. Methadone is a long-acting (~24 hours), orally administered opiate that shares many pharmacological features with heroin. Due to cross-tolerance and the long half-life of methadone, the risks of illicit injection opiate use (e.g., impurity of "street" drugs, crime, HIV risk) are significantly reduced (Ball & Ross, 1991). L-alpha-Acetylmethadol (LAAM) is even longer acting (48–72 hours) and has also shown evidence that it reduces illicit opiate use, increases the duration of treatment participation, and reduces criminal behaviors (Hubbard, Craddock, Flynn, Anderson, & Etheridge, 1997; Ling, Charuvastra, Kaim, & Klett, 1976). Although improved outcomes have clearly been demonstrated, opiate replacement therapies continue to be stigmatized by some, based on the premise that one addiction is just being replaced by another. Although technically correct, a properly dosed methadone treatment coupled with ancillary services (e.g., self-help groups, psychotherapy, and access to condoms; Calsyn, Meinecke, Saxon, & Stanton, 1992; Calsyn et al., 1994) facili-

tates stable functioning. The long-acting properties of replacement therapies reduce the rapid cycling of euphoria, withdrawal, and drug seeking associated with short-acting, illegally obtained opiates such as heroin (Zweben & Sorensen, 1988). Naltrexone, an opiate antagonist, demonstrated modest reduction in heroin use in clinical trials. However, heroin addicts are more difficult to retain in this type of pharmacotherapy than in opiate replacement therapies (O'Brien, 1996; Tappert et al., 1998).

Nicotine replacement therapies (e.g., nicotine transdermal patch, gum, and nasal sprays) reduce the symptoms of nicotine withdrawal and have been helpful in achieving initial abstinence among smokers (Hughes, 1993). Modest but long-term (6–12 months) improved rates of abstinence have been achieved using these products as adjuncts to cognitive-behavioral relapse prevention approaches (O'Brien, 1996). One study examined the effect of the dose of nicotine patches and found that abstinence rates improved with increased doses (0, 7, 14, 21 mg; Transdermal Nicotine Study Group, 1991). Replacement therapies are the most developed pharmacotherapies for smoking cessation, but antidepressant medications such as bupropion (Wellbutrin®, Zyban®) may reduce nicotine craving (O'Brien & McKay, 1998). Clonidine, an anti-hypertensive agent that reduces alcohol and opiate withdrawal, also reduces tobacco withdrawal and craving, although beneficial effects are short-lived (Covey & Glassman, 1991; Niaura, Brown, Goldstein, Murphy, & Abrams, 1996). The mechanism of action for clonidine is not clear, and some studies suggest that effects may be limited to women (Covey & Glassman, 1991; Hughes, 1993). Mecamylamine, a nicotinic blocking agent that prevents the subjective reinforcing effects of tobacco use, is under investigation but has significant side effects that reduce treatment compliance (Hughes, 1993).

For patients with concomitant mental health disorders, treating persisting psychiatric symptoms improves substance abuse outcome. Negative affective states, frequently experienced by those with comorbid disorders, have been identified as relapse precursors (Marlatt, 1985). Thus, pharmacological interventions to reduce negative mood would also be likely to improve substance use outcomes. As an example, the selective serotonergic re-uptake inhibitor, fluoxetine, is effective in treating major depression, and decreases in both depressive symptoms and alcohol consump-

tion have been demonstrated among depressed individuals with alcohol dependence (Cornelius et al., 1997).

In summary, medications have demonstrated robust effectiveness in ameliorating withdrawal symptoms, modest efficacy in reducing alcohol and nicotine cravings, and significant benefits in replacing illicit opiates. Pharmacotherapies are most useful in a comprehensive treatment program that involves psychological interventions described previously (O'Brien, 1996; Schuckit, 1996). To date, medications have not been identified that are effective in treating other substances of abuse (O'Brien, 1996).

Research has repeatedly demonstrated that initial addictive behavior changes, like other behavioral changes, are difficult to maintain over time. Often, a complete lifestyle change is beneficial. Various residential arrangements designed to promote substance-free living help extend gains achieved through psychosocial interventions and pharmacotherapy. Extended living arrangements following addictions treatment are also needed due to the prevalence of substance use disorders among homeless individuals (e.g., Bassuk, Rubin, & Lauriat, 1984).

Therapeutic Communities and Residential Treatment Facilities

Abstinence-focused residential facilities are known by a variety of names: sober living environments, halfway houses, recovery homes, residential treatment programs, and therapeutic communities, to name a few. They all share a common emphasis on providing substance-free living environments but vary in the methods and services offered. Many short-term inpatient and outpatient substance abuse treatment programs advise clients to reside in this type of environment for at least several months after initial abstinence, based on empirical findings of improved outcomes (Hubbard et al., 1997; Moos, King, & Patterson, 1996).

Community residential facilities provide substance-free environments to assist substance abusers between hospital discharge and subsequent independent living. Typically, continuous staffing is provided and is available for emergencies (Moos et al., 1994). Individual and group counseling, vocational and discharge planning, and connection with community resources such as self-help programs are common components of

these facilities. Contracts for this type of residential program have been provided for 60 days of care and 30-day extensions, if needed, by the Department of Veterans Affairs since 1980 in response to the need for a transitional environment. Research on outcomes has evidenced reduced readmission rates for patients who participated in these residential programs (Moos et al., 1994).

Therapeutic communities (TCs) are based on "family" models; members of the program act as a surrogate family, helping each other to change substance-related behaviors (De Leon, 1989; Sorensen, Acampora, & Iscoff, 1984). TCs emphasize increasing residents' self-esteem, self-reliance, and use of social supports, and provide education, vocational services, and, after several months of abstinence, independent living arrangements. Any substance use usually results in immediate expulsion to preserve the drug-free environment. Length of stay varies, but a year or longer is common to accomplish the complete transition to drug-free living.

Alternatively, if an individual is not considering treatment or is resistant to abstinence-focused interventions, alternative intervention strategies that target reducing the negative or harmful consequences of alcohol and drug use may be beneficial.

Harm Reduction

Harm reduction techniques, which emerged from a public health approach to substance abuse, focus on strategies for reducing the negative consequences of substance use (Marlatt, 1998). Harm reduction interventions operate at both the individual and public policy levels. The approach is pragmatic and nonjudgmental and is designed to engage individuals on their own terms while reducing personal and societal harm due to substance use. An advantage of harm reduction approaches is the potential to engage non-treatment-seeking individuals. Abstinence is viewed as an ideal (no risk for harm), but behavior changes that move the individual along a continuum away from harm are viewed as steps in the right direction. These approaches address risky behaviors that co-occur with substance use, such as unsafe sexual practices, violence, and driving while intoxicated. Harm reduction strategies for illicit drug users include drug replacement interventions (e.g., methadone) and programs to reduce the risks of drug administration (e.g., clean needle exchange pro-

grams and education to reduce the risks of needle use; Tapert et al., 1998). Reviews of studies on needle exchange programs (NEPs) report decreased rates of HIV risk behaviors (e.g., reductions in needle sharing and giving away used needles) and some evidence of reductions in subcutaneous abscesses and hepatitis B and C (Lurie et al., 1993). As another example of harm reduction strategies, a harm reduction intervention with college students was associated with significant reductions in both drinking and harmful consequences, compared to students assigned to a nonintervention group (Marlatt et al., 1998). An excellent, comprehensive presentation on harm reduction principles and strategies is provided by Marlatt (1998).

Project MATCH (Project MATCH Research Group, 1997) compared three different treatments and tested the hypothesis that matching substance abusers to treatments based on personal attributes would result in superior treatment outcomes. Clients were randomly assigned to 12-Step Facilitation (TSF), Cognitive Behavioral Coping Skills Therapy (CBT), or Motivational Enhancement Therapy (MET), and received the manual-driven, individually administered treatment. Extensive baseline assessments of client attributes facilitated evaluation of outcomes as a function of the type of treatment received (see Nathan et al., this volume for details). At 12 months posttreatment, clients had substantially reduced drinking from pretreatment levels in all three treatments. However, few client-treatment matching hypotheses were supported. Generalizations of results are limited by the sample studied, which excluded drug-dependent, homeless, psychiatrically diagnosed, and cognitively impaired individuals, and by delivery of treatment in a format not typical of standard practice. Thus, efficacy, but not effectiveness, of treatments was addressed by Project MATCH. Finally, the absence of a control group prohibits investigating the natural course in this specialized population.

The Drug Abuse Treatment Outcome Study (DATOS; Hubbard et al., 1997) examined substance use and life functioning outcomes of 3000 patients in eleven metropolitan areas during the 12 months following treatment. Four types of treatments were evaluated: long-term residential, outpatient drug-free programs, short-term inpatient, and methadone maintenance. Major reductions in most types of drug use were observed in the year following treatment relative to pretreatment use in

all four treatment formats. In long-term residential programs, weekly heroin and cocaine use dropped by 66%, and marijuana and heavy alcohol use were reduced by more than 50% from the pretreatment to the posttreatment year. The weekly use of alcohol and all drugs was reduced by 50% in outpatient drug-free programs, and weekly use was 33% of pretreatment levels for those treated in short-term inpatient programs. In methadone maintenance programs, weekly heroin use declined by 33%, and weekly cocaine use was reduced by 50% from pretreatment levels, although marijuana and heavy alcohol use did not change after treatment. Rates of suicidal thoughts and attempts declined in all groups except the methadone clients. Predatory criminal activities and risky sexual behaviors were significantly reduced, but physical health limitations and less than full-time employment remained high in all treatment types.

DATOS evaluated the effect of treatment length on outcome. Clients who received 3 months or more of treatment in long-term residential programs and outpatient drug-free programs reported lower rates of drug use at 12-month follow-up than clients who were treated for less than 3 months. Methadone maintenance clients who remained in the programs used significantly less heroin than clients who dropped out. Reduced illegal activity, risky sexual behaviors, and unemployment were also associated with longer treatment duration, but cocaine, marijuana, and alcohol use were not. These findings were generally consistent with previous major drug treatment studies (Drug Abuse Reporting Program [Simpson & Sells, 1982] and Treatment Outcome Prospective Study [Hubbard et al., 1989]). In summary, the DATOS results confirmed that participation in drug treatment is associated with positive changes in substance use and life functioning in the year after treatment and that clients who remain in treatment longer than 3 months receive more benefits. DATOS findings must be considered in the context of two study limitations: data relied solely on self-reports without corroboration from biological tests or collateral interviews, and only 70% of follow-up interviews were completed.

Special Populations

No understanding of substance use is complete without acknowledging the special circumstances

and variations in use, assessment, treatment, and outcome for different populations. Sensitivity to the unique characteristics and issues potentially relevant to individual clients is important in all phases of therapeutic contact. Following are some factors associated with commonly encountered special populations.

Women

Men and women experience many aspects of substance abuse similarly, but some important gender differences affect consequences and treatment for females. The most widely recognized issue for women is the teratogenic effect of substances on fetal development. Fetal alcohol syndrome (FAS) seen in the infants of women who consume large amounts of alcohol during pregnancy involves a cluster of physical (e.g., facial dysmorphism and small stature) and neuropsychological (e.g., mental retardation and attentional impairment) effects that persist throughout the life-span. Less severe fetal alcohol effects (FAE) have been documented at lower levels of alcohol consumption. Alcohol is not uniformly teratogenic, suggesting complex relationships with factors such as drinking patterns, gestational period, nutrition, and genetics.

Cigarette smoking is related to retarded fetal growth, premature birth, and low birth weight, and effects appear related to smoking levels (Collins, 1993). Cocaine use during pregnancy increases the likelihood of slow fetal growth, low birth weight, early labor, spontaneous abortion, and sudden infant death syndrome (Fox, 1994; Miller & Hyatt, 1992; Zuckerman et al., 1989), although other studies demonstrate modest effects of cocaine when drinking, smoking, and nutrition are considered (Lester, LaGasse, Freier, & Brunner, 1996). Infants born to mothers addicted to cocaine are irritable, respond excessively to stimulation, and show impaired motor coordination, and these effects are detectable months later (Cole & Cole, 1993). Mothers addicted to heroin or methadone give birth to babies who are also addicted; treatment is often necessary shortly after birth to avoid potentially life-threatening withdrawal. These infants are more likely to be premature, underweight, and at risk for respiratory illnesses. Mortality is twice as high for neonates of opiate-addicted mothers (Bolton, 1983; Ostrea & Chavez, 1979). Detoxification causes irritability, tremors,

disturbed sleep, and diminished motor control in these infants. Impaired attention and motor control have been documented up to a year later (Jones & Lopez, 1990). Other gynecologic and obstetric problems are more common for women who smoke cigarettes, or abuse alcohol or drugs (Collins, 1993).

A relationship between victimization and trauma (e.g., childhood sexual abuse, domestic violence) and substance abuse has been documented in female populations (Downs, Miller, & Gondoli, 1987; Miller, Downs, & Gondoli, 1989), increasing the need for comprehensive assessment in these domains and treatment to address concomitant posttraumatic stress disorder, if indicated. Although women may face more consequences for substance abuse than men, services may be less available and less utilized by women (Dawson, 1996). Child-care responsibilities, limited financial resources, and societal stigmatization can be greater barriers to treatment for substance-abusing women than for men (Collins, 1993).

Adolescents

Substance use and related disorders are relatively common during adolescence (typically defined as ages 13 to 20) and have implications for adult functioning. Unique risk factors, consequences, diagnostic criteria, assessment approaches, and treatment methods are pertinent to understanding substance abuse and dependence during the teenage years. For youth, substance abuse may be considered a cluster of problem behaviors, rather than an independent diagnosis (Donovan & Jessor, 1985). Problem behavior theory describes adolescent deviance as a single factor of unconventionality in which a variety of problematic behaviors co-occur, such as drug taking, smoking, precocious sexual involvement, gambling, and involvement in other criminal and health-threatening behaviors (Donovan & Jessor, 1985; Newcomb & Bentler, 1989).

Families and peers influence problem behavior and initiation of substance involvement. The influence of peers and the desire to "fit in" with group norms increases throughout child and adolescent development and is the most robust risk factor for early substance use (Bentler, 1992; Costanzo & Shaw, 1966). Peers influence exposure and access to drugs, model use or abstinence, and act as powerful reinforcers regarding substance use de-

isions. Youths select their peer groups and are selected by peers largely on the basis of shared values and interests (Dishion, Patterson, & Reid, 1988). Youths with social networks composed of substance users are likely to assume beliefs and values consistent with a substance-using lifestyle (Tapert et al., 1999). Youths without role models who reinforce healthy coping strategies are more likely to use (Holden et al., 1988; Tucker, 1982) or continue to abuse substances (Myers & Brown, 1990; Richter, Brown, & Mott, 1991). By contrast, positive social supports offset potential substance-related problems that may emerge in youth (Newcomb & Bentler, 1988b).

Negative health consequences for youth have been linked to abuse or dependence on the most commonly used substances. Teen smokers have increased rates of respiratory problems, and teen drinkers and drug users are more likely to experience motor vehicle crashes and other traumatic injuries (Aarons et al., 1999). Modest cognitive deficits have been associated with substance abuse in adolescence (Moss, Kirisci, Gordon, & Tarter, 1994), and withdrawal symptoms have been related to decreased retention of information and poor visuospatial functioning (Tapert & Brown, 1999).

Diagnostic criteria for substance abuse and dependence are based on adult symptom patterns. However, adolescents have characteristic substance use profiles and life consequences. Substance-involved adolescents typically use multiple intoxicating substances (Brown et al., 1994; Stewart & Brown, 1995). Adolescents can experience preoccupation with substances, loss of control over substance use, and reckless behavior while using, but are less likely than adults to report continued use despite medical problems (Martin, Arria, Mezzich, & Bukstein, 1993; Stewart & Brown, 1995). Current diagnostic criteria may not accurately capture all adolescent problematic substance use patterns. For example, abuse criteria lack applicability to adolescent life demands and form a less useful diagnostic construct (Martin, Kaczynski, Maisto, Bukstein, & Moss, 1995; Martin, Langenbucher, Kaczynski, & Chung, 1996).

Optimal assessment tools used with adolescents tailor wording to an appropriate reading level, acknowledge that polysubstance use is the norm for adolescent substance abusers, use computer administration formats when possible (Wright, Aquilino, & Supple, 1998), and consider the previ-

ously mentioned diagnostic challenges. The Personal Experience Inventory (Winters & Henly, 1989) is a self-report measure that assesses the severity of substance use and psychosocial functioning in adolescents. The Problem Severity scales in this well-validated self-report instrument discriminate between clinical and nonclinical adolescent samples (Henly & Winters, 1988). The Adolescent Diagnostic Interview (Winters & Henly, 1993) is a structured interview developed to assess substance use disorders, global functioning, psychosocial stressors, and cognitive functioning. Extensive information beneficial in treatment planning for adolescents is attained with this instrument which has demonstrated sound psychometric characteristics. Similarly, the Teen Addiction Severity Index (Kaminer, Bukstein, & Tarter, 1991), modeled after the adult Addiction Severity Index, collects substance-related information across domains of adolescent life functioning. Adequate psychometric properties have been reported (Kaminer, Wagner, Plummer, & Seifer, 1993).

Avenues to success for youths with substance use disorders, include (1) engaging in treatment programs that incorporate family involvement or (2) participating in activities that are incompatible with substance use (e.g., sports, jobs, active participation in academics, and volunteer activities; Brown et al., 1994). Multidimensional family therapy (Liddle, 1995) is a family-based therapy that focuses on engaging the youth in the treatment process. Multisystemic therapy (Henggeler et al., 1992, 1995) works with teens, parents, school systems, community resources, and peers to decrease problem behaviors (see previous section on Treatments for more detail on these therapies). Incorporating families to the extent possible helps many recovering teens. However, involvement in healthy activities is critical for success for teens whose parents have substance use disorders or other major problems.

Elderly

Substance use and substance-related disorders are less prevalent among the elderly (over age 65) than in younger populations (Graham, 1986). However, characterization of substance use problems in older adults is hampered by assessment challenges. Older drinkers often underreport consumption and problems (Atkinson & Kofoed, 1982; Graham, 1986), and many assessment in-

struments have not been validated with older adults. Diagnostic criteria for role obligations and social functioning are insensitive for seniors with limited responsibilities and social networks and cause substance problems to go unnoticed. Additionally, symptoms of substance use disorders may resemble other age-related illnesses (e.g., dementia, malnutrition, or bone damage) and may complicate the diagnostic picture (Schuckit, 1990). Identifying substance abuse in this population is important, however, because more than 75% of adults over the age of 65 take prescription medications; many of them interact adversely with alcohol, tobacco, and illicit drugs (e.g., Adams, 1995). Due to physiological changes and medical problems associated with aging, the elderly are more sensitive to alcohol and drug effects and the synergistic effects of substances; Morgan et al., 1996; Smith, 1995). The MAST has been adapted specifically to assess problem drinking in older adults (Michigan Alcohol Screening Test—Geriatric Version; Blow et al., 1992).

Suggestions for treating older problem substance users include (1) avoiding confrontation and increasing the supportive nature of therapy; (2) focusing on coping skills related to loneliness, depression, and social isolation rather than occupational or relationship issues; (3) slowing the pace of group-based skills training; (4) addressing medical and transportation needs (Schonfeld & Dupree, 1995); and (5) specifically tailoring printed materials to an older audience (including seniors in photos and graphics, content specific to older age groups, especially the benefits of quitting at any age (Morgan et al., 1996). Older adults have treatment outcomes similar to those of adults in general (Kashner, Rodell, Ogden, Guggenheim, & Karson, 1992; Kofoed, Tolson, Atkinson, Toth, & Turner, 1987).

Psychiatric Comorbidity

Individuals with other mental health disorders have a twofold increase in lifetime risk of alcohol abuse or dependence and a fourfold increase in lifetime risk of drug abuse or dependence. Among individuals with alcohol use disorders, 37% had another psychiatric disorder. Over half of those with drug use disorders have also had histories of psychiatric disorders (Regier et al., 1990). Substance use disorders and concomitant psychiatric comorbidity are often associated with a poor prog-

nosis (e.g., Dickey & Azeni, 1996; Ouimette, Finney, & Moos, 1997; Rounsaville, Kosten, Weissman, & Kleber, 1986). Many clients with severe mental health disorders have difficulty connecting with substance-related self-help organizations for a variety of reasons (Noordsy, Schwab, Fox, & Drake, 1996). Youths with comorbid mood disorders and who start abusing substances at younger ages evidence greater difficulty maintaining problem-free status after treatment (Brown et al., 1994; Tapert et al., 1999).

Substance intoxication, chronic use effects, and withdrawal states can mimic symptoms of other psychiatric disorders, including depression, anxiety, paranoia, delusions, and hallucinations (Boutros & Bowers, 1996; Brown & Schuckit, 1988; Brown, Irwin, & Schuckit, 1991). Many alcohol-dependent individuals report clinical levels of depression when admitted for treatment, but only a small minority remains clinically depressed 4 weeks later (Brown & Schuckit, 1988). Similar findings have been reported for cocaine abusers (Brown, Monti et al., 1998). Correspondingly, many in treatment for alcohol problems report elevated levels of state anxiety at admission, which typically reduce to normal levels following several weeks of abstinence (Brown et al., 1991). Psychotic symptoms induced by substance intoxication or withdrawal (e.g., alcohol, stimulants, and cannabinoids) also tend to remit within days of abstinence. Exceptions include amphetamine-induced psychotic symptoms experienced by some abusers for up to a year or more of abstinence and PCP-induced psychotic symptoms that last for up to 30 days following the most recent use (Bacon, Granholm, & Withers, 1998). Accurate assessment determines whether psychiatric symptoms are substance-induced and likely to remit with abstinence or are indicative of an independent psychiatric disorder that requires specific treatments. Making this evaluation can be difficult, and the following guidelines are suggested:

1. The Timeline Technique (Bacon et al., 1998; Schuckit & Hesselbrock, 1994) involves constructing a lifetime calendar delineating the timing of specific substance dependence symptoms, psychiatric symptoms, and periods of abstinence. The clinician can evaluate whether psychiatric symptoms occurred before or after the onset of substance dependence, as well as whether psychiatric symp-

- toms were experienced during periods of abstinence.
2. Familiarity with the quality and severity of substance-specific intoxication and withdrawal symptoms (Bacon et al., 1998) and the duration of abstinence required for substance-induced symptom remission (e.g., Brown et al., 1991, 1994) will aid clinical evaluation.
 3. A family history of psychiatric disorders with evidence of genetic influence (e.g., schizophrenia, bipolar disorders) may be indicative of independent psychiatric disorders.
 4. Patients with concomitant psychiatric disorders are more likely to require repeated treatment for substance dependence (Rounsaville, Dolinsky, Babor, & Meyer, 1987).

Ethnicity and Culture

Substance use and problem development is influenced by genetic, social, and environmental factors, all of which may interact with culture. The Epidemiological Catchment Area (ECA) Study found prevalence rates of lifetime substance abuse or dependence comparable between African-American and Caucasian adults (Helzer, Burnam, & McEvoy, 1991), but African-Americans experience more social and medical consequences than Caucasians (Caetano & Schafer, 1996). Hispanic men have relatively high rates of alcohol use and abuse, whereas Hispanic women have low rates (Lex, 1987), and drug use rates are lower for Hispanics than Caucasians (Robins & Regier, 1991). Acculturation and U.S. nativity have been reported as risk factors for illicit drug use among Mexican-Americans (Vega, Alderete, Kolody, & Anguila-Gaxiola, 1998). Alcohol abuse and dependence are high among American Indians and Alaskan natives. The age-adjusted death rate due to alcohol dependence is nearly seven times higher than the overall U. S. rate (U. S. Department of Health and Human Services, 1997). Substantial variations are found in substance use patterns in relation to tribal affiliation, and some tribes now report high rates of abstinence.

Asian-Americans have lower rates of alcohol consumption, abuse, and dependence (Klatsky, Siegelau, Landy, & Friedman, 1983), partially due to genetic influences that reduce their ability to metabolize alcohol, resulting in aversive physi-

ological reactions to drinking among some Asian individuals. Jewish samples evidence particularly low rates of alcohol abuse and dependence (Weissman, Myers, & Harding, 1980).

HIV

Substance use continues to be significantly associated with HIV transmission. Methadone maintenance, LAAM, needle exchange programs, and community information programs demonstrate favorable HIV risk reduction for injection drug users (Ling et al., 1976; Magura, Rosenblum, & Rodriguez, 1998). Needle exchange and community outreach programs reach injection drug users who are not in treatment programs (Peterson, Dimeff, Tapert, & Stern, 1998). Risky sexual behaviors are more resistant to change (Haverkos, 1998). Alcohol reduces inhibitions and increases the likelihood of risky sexual activity (Steele & Josephs, 1990). Stimulant intoxication is associated with participation in highly risky sexual behaviors, but substance abuse treatment can result in reduced numbers of sexual partners (Shoptaw, Reback, Frosch, & Rawson, 1998). In summary, interventions decrease HIV risk by reducing the frequency of injection, decreasing needle sharing, and reducing risky sexual behaviors (Iguchi, 1998; Shoptaw et al., 1998).

General Recommendations

Substance use disorders are common mental health problems in our society and bear significant personal and societal consequences. The severity of problems may range from brief experimentation to protracted, life-threatening alcohol or drug involvement. Several models were presented that have been employed to conceptualize why people repeatedly engage in these harmful behaviors. Current models incorporate evidence from studies of genetics, conditioning, social learning, behavioral economics, and cognitive psychology. These theories guide our understanding of the way addiction processes are developed, maintained, and best treated.

Given the documented prevalence of substance use disorders, particularly in mental health settings, it is recommended that brief screening assessments for substance involvement and substance-related problems be conducted routinely. Positive

results on screening assessments indicate the need for more extensive assessment. Detailed substance assessments should incorporate evaluation of comorbid mental health disorders that may influence clinical course and treatment planning decisions. In the event that assessments indicate problem substance use, the client's current motivation to change should be discussed, and motivational enhancement strategies should be initiated based on the motivational level or stage.

Diverse treatment options are available for substance use disorders. Enlisting client participation in the treatment planning process and willingness to "meet the client" toward goal establishment have been empirically supported. Consideration of nonabstinence goals can be discussed openly and nonjudgmentally, weighing the advisability of this alternative goal in view of the client's unique characteristics. Clear professional advice should be provided in support of abstinence when indicated, but research findings indicate that confrontation should be avoided. Situations in which abstinence should clearly be advised include the presence of liver disease, pregnancy, severe dependence, and the use of prescription medications. Studies support the involvement of family members in substance disorder treatments. Increasing availability and access to valued alternative non-drug activities will support the long-term process of behavior change. Pharmacotherapies in conjunction with psychotherapy interventions often enhance substance use outcomes for some substances, including tobacco, alcohol, and opiates.

Although significant progress has been made in understanding and treating substance use disorders in recent decades, significant limitations in our knowledge remain. Findings have not yet provided many clear guidelines to clinicians in attempting to optimally match clients to types of treatments. Some researchers have advised that clinicians maintain a stance of "informed eclecticism, an openness to a variety of approaches that is guided by scientific evidence" (Miller & Hester, 1995). Additionally, little is known regarding the efficacy and effectiveness of group versus individual interventions for substance use disorders.

A third limitation in the substance abuse treatment field is the lack of information on whether comorbid psychiatric disorders are best treated simultaneously or independently and whether treatments should be integrated. Researchers are working to address these questions, and client prefer-

ences may be the best guide for treatment selection at this time. For example, preliminary studies of tobacco cessation interventions conducted concurrently with other substance abuse treatment have suggested some success in outcomes. Researchers have proposed dual-diagnosis treatments for substance abusers with severe mental health disorders such as schizophrenia and bipolar disorders (Drake, 1996; Osher & Kofoed, 1989), and research findings are beginning to support such integrated treatments (e.g., Drake, McHugo, & Noordsy, 1993; Drake, Mueser, Clark, & Wallach, 1996).

Alcohol-Related Disorders: Psychopathology, Diagnosis, Etiology, and Treatment

**Peter E. Nathan, Anne Helene Skinstad,
and Sara Dolan**

Introduction

Alcohol-related disorders in DSM-IV (APA, 1994) include the alcohol use disorders and the alcohol-induced disorders. Alcohol abuse and alcohol dependence comprise the alcohol use disorders. These conditions exact substantial costs from both society and individual abusers; they are the principal focus of this chapter. Alcohol-induced disorders, which include alcohol intoxication delirium, alcohol withdrawal delirium, alcohol-induced persisting dementia, and alcohol-induced persisting amnesic disorder, are serious sequelae of alcohol abuse and dependence; they are a secondary focus of the chapter.

Alcohol Use Disorders

Alcohol abuse comprises “a maladaptive pattern of alcohol use leading to clinically significant impairment or distress” (American Psychiatric Association [APA], 1994, p. 182) that involves

recurrent, significant, social or occupational problems caused by alcohol. These problems include failure to meet major role obligations at home, school, or work; the use of alcohol in physically hazardous situations; recurrent alcohol-related legal problems; and continued use of alcohol despite the substantial problems it has already caused.

Alcohol dependence encompasses “a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues use of alcohol despite significant alcohol-related problems” (APA, 1994, p. 176). Physiological symptoms typically include tolerance and withdrawal symptoms. Other behaviors attest to the loss of control over alcohol consumption, including ingesting more alcohol over a longer period of time than intended; experiencing a persistent desire or having a history of unsuccessful efforts to reduce or control the alcohol use; spending a great deal of time obtaining, ingesting, or recovering from the effects of alcohol; giving up or reducing important activities because of alcohol; and continuing to ingest alcohol despite a physical or psychological problem caused or made worse by the drug.

The latest figures on alcohol use in the United States (Grant, 1997), derived from a large and representative sample of the U.S. population, indicate that 66.0% of Americans over the age of 18 years has consumed alcohol at some time in their lives and that 44.4% of them are currently doing it.

Peter E. Nathan, Anne Helene Skinstad, and Sara Dolan •
University of Iowa, Iowa City, Iowa 52242-1316.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

Grant (1997) also estimated lifetime and current prevalences of DSM-IV alcohol dependence: 13.3% of the population (about 34.5 million Americans) met the criteria for alcohol dependence at some time in their lives and 4.4% (about 11.4 citizens) currently meet those criteria. Given these figures, it is not surprising that alcohol dependence is one of the nation's leading public health problems.

Alcohol-Induced Disorders

Alcohol intoxication delirium is characterized by a disturbance of consciousness (that is, reduced clarity of awareness of the environment) that results in diminished ability to focus, sustain, or shift attention and deterioration in cognition (typically involving memory deficit, disorientation, and/or language disturbance) or the development of perceptual disturbances. All of these symptoms may develop during alcohol intoxication.

Alcohol withdrawal delirium develops during alcohol withdrawal; it is known more commonly as *delirium tremens*. This syndrome, which affects fewer than 5% of alcoholics hospitalized for severe withdrawal, develops within the week following a reduction in or the cessation of heavy drinking. It is characterized by confusion, disorientation, and severe tremulousness ("the shakes"). Alternating periods of agitation and calm may be punctuated by vivid visual and tactile hallucinations, illusions, and autonomic hyperactivity. The disorder is generally of short duration (15% of those who experience it recover within 24 hours), but it has a mortality rate of 10–15%, if it is not recognized and treated.

Alcohol-induced persisting dementia is signaled by the irreversible development of multiple cognitive deficits (including aphasia, apraxia, agnosia, and/or disturbance in executive functioning), as well as impaired memory (impaired ability to learn new information or to recall previously learned information). These symptoms reflect the persisting effects of alcohol on the brain, sometimes long after the patient has stopped abusive drinking.

Alcohol-induced persisting amnesic disorder involves a profound impairment in the ability to learn new information or to recall previously learned information or past events; these symptoms are etiologically related to the persisting effects of alcohol and are marked enough to impair social or occupational functioning. Otherwise known as *Korsakoff's syndrome*, this irreversible condi-

tion results from a long-term deficiency in vitamin B₁ (thiamin) that sometimes accompanies chronic alcohol abuse.

Diagnosis

A Brief Historical Perspective

The first *Diagnostic and Statistical Manual of Mental Disorders* (APA, 1952) clustered alcoholism and drug addiction, sexual deviations (later renamed the paraphilias), and antisocial and dissocial reactions (now termed antisocial personality disorder) as a single diagnostic entity called sociopathic personality disturbances. This phrase was meant to imply that persons who behave in one or more of these ways have chosen to flaunt society's rules. Alcoholism and drug addiction were similarly grouped with personality disorders and sexual deviations in DSM-II (APA, 1968) for the same reason. Both of these initial diagnostic arrangements reflected the distaste that the drafters of the first two *Diagnostic and Statistical Manuals* felt for behaviors that seriously transgressed contemporary social norms.

When a rapidly growing research literature began to point to the roles of genetic and environmental factors in the etiology of many psychopathological disorders, the developers of DSM-III (APA, 1980) and DSM-III-R (APA, 1987) moved away from the psychoanalytic underpinnings of their 1952 and 1968 predecessors toward empirically supported diagnostic and etiologic information. For the same reason, alcohol and drug abuse and dependence were separated in 1980 from the renamed paraphilias and personality disorders when voluminous research began to suggest profound differences in the signs, symptoms, etiology, and courses of these conditions.

The 1980 and 1987 diagnostic manuals, unlike their predecessors, distinguished the behavioral consequences of alcohol and drug abuse and dependence from their central nervous system consequences. They also differentiated the signs and symptoms of alcohol and drug abuse much more clearly from those of dependence. However, whereas DSM-III required the presence of signs of tolerance or withdrawal to confirm the diagnosis of substance dependence, DSM-III-R deemphasized tolerance and withdrawal symptoms in favor of the complex of behaviors associated with loss of control over drinking, which Edwards and Gross

(1976) termed the substance dependence syndrome.

The DSM-IV Substance Use Disorders Work Group attempted to resolve the long-standing diagnostic question how to conceptualize alcohol dependence best, as well as several other important unresolved issues, by undertaking an extensive, multisite field trial (Cottler et al., 1995). Data from the field trial were used to address the following four questions:

Should the new diagnostic criteria reemphasize or deemphasize tolerance and physical withdrawal symptoms for the diagnosis of dependence? Substantial proportions of dependent users of amphetamines, hallucinogens, inhalants, PCP, and sedatives in the field trial failed to experience tolerance or withdrawal symptoms, even though from 86 to 99% of persons dependent on alcohol, cannabis, cocaine, opiates, sedatives, and nicotine did so. Because these conflicting data prevented it from generalizing across substances on this key diagnostic issue, the Work Group decided to request clinicians to specify one of two criteria set qualifiers, "with physiological dependence" or "without physiological dependence," to highlight this issue in anticipation of DSM-V.

Should the new diagnostic criteria deemphasize social consequences and occupational impairment as criteria for dependence? Substantial numbers of all substance users, except those using cocaine, failed to report either social consequences or occupational impairment. As a consequence, the Work Group decided that the social and occupational consequences of alcohol and drug use better described abuse than dependence, so these criteria became the principal cues to substance abuse.

Could DSM-IV offer a shorter list of criteria for dependence, thereby easing the diagnostic task of clinicians and researchers? As just noted, the Work Group moved the diagnostic criteria relating to social and occupational consequences from dependence to abuse. As a result, abuse came to represent substance misuse with adverse social or occupational consequences but without evidence of compulsive use, tolerance, or withdrawal, whereas dependence signaled compulsive use with or without physiological accompaniments. In making these changes, the Work Group substantially clarified the separate conceptual bases for substance abuse and dependence.

Should abuse be made more distinct from dependence (as it was in DSM-III), not just a resid-

ual category (as it became in DSM-III-R)? As noted before, in reconceptualizing substance abuse and dependence, the DSM-IV Work Group provided specific contexts and distinct sets of criteria for the abuse and dependence diagnoses, thereby making both more distinct and more meaningful.

The alcohol dependence syndrome (Edwards & Gross, 1976), which substantially influenced the diagnostic conception of dependence in DSM-III-R (APA, 1987) and, to a lesser extent, DSM-IV, posits that a combination of behavioral conditioning and physiological processes best define the dependence syndrome. The syndrome's most important symptom is impaired control over drinking: "loss of control" drinking. A recent examination of the validity of DSM-IV alcohol dependence and abuse diagnoses in a randomly selected community sample of 936 household residents strongly supported the validity of the alcohol dependence diagnosis but not the validity of the alcohol abuse diagnosis (Hasin et al., 1997). These findings suggest that although clinicians and researchers can have substantial confidence in the validity of DSM-IV diagnoses of alcohol dependence, the validity of the alcohol abuse diagnosis is a good deal more problematic.

The Research Diagnostic Project

The Research Diagnostic Project (RDP) of the Center of Alcohol Studies, Rutgers University, recently explored a range of issues in substance abuse diagnosis by gathering clinical data from patients treated in four public and four private treatment settings, balanced across inpatient and outpatient facilities, that are located in five North-eastern states.

The reliability of lifetime DSM-IV diagnoses of alcohol, cannabis, cocaine, and opiate abuse and dependence was explored in an early RDP study (Langenbucher, Morgenstern, Labouvie, & Nathan, 1994a). The reliability of the new DSM-IV decision rules, it was found, is excellent, and an especially strong relationship was observed between the reliability of a symptom and its centrality to the individual abuse pattern.

Agreement among diagnostic systems was a particular concern of the DSM-IV Task Force, which worked hard to bring DSM-IV and ICD-10 (World Health Organization, 1992) into greater diagnostic concordance so that mental health workers across the world could better communicate diagnostically. Langenbucher, Morgenstern,

Labouvie, and Nathan (1994b) examined diagnostic agreement among DSM-III, DSM-IV and ICD-10 for alcohol, amphetamines, cannabis, cocaine, hallucinogens, opiates, PCP, and sedative/hypnotics. They concluded that ICD-10 is the most sensitive diagnostic system, because it diagnoses a larger number of cases than either of the two versions of the DSM. Generally satisfactory statistical agreement was found between ICD-10 "harmful use" and DSM "abuse." The three diagnostic systems diverged strongly, however, in cases whose symptoms barely reached the diagnostic threshold.

As we noted earlier, the predictive validity of tolerance and withdrawal symptoms remains an important unanswered question (e.g., Blaine, Horton & Towle, 1995; Schuckit, 1996). Although it has been assumed that both signal increased risk of dependence-related medical problems and relapse, two recent studies (Carroll, Rounsaville & Bryant, 1994; Rounsaville & Bryant, 1992) reported that tolerance and withdrawal symptoms did not predict deterioration in physical status or a return to substance misuse. With like aims in mind, Langenbucher and his colleagues (in press) compared the predictive validity of four sets of dependence criteria: the DSM-IV criteria for alcohol dependence with and without physiological dependence, an alternative dichotomous criterion for physiological dependence, and a dimensional measure of physiological dependence specifically designed to predict multiple indexes of medical problems and relapse behavior. As Rounsaville and his colleagues previously reported, DSM-IV physiological alcohol dependence failed to predict either medical problems or relapse. Langenbucher, however, blamed this failure on operational problems in DSM-IV, rather than on a specific lack of predictive validity for physiological dependence: he concluded as a consequence that physiological dependence can serve as a course specifier for alcohol problems. However, to serve this purpose, it must be more sensitively scaled than it is in DSM-IV, either by using alternative criteria for coding physiological dependence or by developing a dimensional measure.

Diagnosticians must differentiate among cases varying within as well as those varying between diagnostic categories. Severity is one of the most important within-category descriptive dimensions that influences patient/treatment matching (McCrary & Langenbucher, 1996), reimbursement for various levels of care (Jencks & Goldman, 1987),

and determination of the length-of-stay (Mezzich & Sharfstein, 1985). Langenbucher, Sulesund, Chung and Morgenstern (1996) compared the relapse prediction efficiency of illness severity (reflected by the DSM-IV symptom count and scores on the Alcohol Dependence Scale and the Addiction Severity Index) and self-efficacy (reflecting patients' estimates of the likelihood of remaining sober). The Alcohol Dependence Scale predicted four of five relapse indicators; self-efficacy did not contribute to this prediction. These findings favor illness severity, particularly, severity of physiological dependence, over self-efficacy as the best predictor of treatment outcome, thereby suggesting that physiological aspects of dependence may be more important than cognitive mechanisms in influencing the likelihood of relapse.

The order of appearance of the symptoms of a given disorder is often predictable, in which case it contributes to valid diagnoses; when the sequencing of symptoms is not predictable, the validity of the diagnosis is lower. A study of the onset and staging of symptoms of alcohol abuse and dependence (Langenbucher & Chung, 1995) identified three successive stages: alcohol abuse, alcohol dependence, and accommodation to the illness. The model survived a rigorous series of tests for goodness-of-fit that support the construct validity of alcohol abuse as a discrete first illness phase and of alcohol dependence as distinct from and succeeding abuse. These findings support the common perception that alcohol abuse is a distinct stop along the road to alcohol dependence for many individuals (Helzer, 1994).

Etiology

Genetic/Biological Factors

Alcoholism runs in families. Does it do so because alcoholic parents transmit a genetic predisposition to alcohol abuse or dependence to their children, because the environment alcoholic parents create produces psychological or behavioral consequences for their children that lead to abuse or dependence, or both, or neither? We review here the data, increasingly substantial over the past 25 years, that point to the heightened risk of alcohol abuse and dependence transmitted genetically from alcoholic parent to child. However, the review does not extend to research on the molecu-

lar genetics of alcoholism, which is still growing and still conflicted. That research now focuses on the function of the DRD2 gene, located on chromosome 11q22-q23. The DRD2 gene encodes the dopamine D2 receptor, which many neuroscientists believe is involved in the genetic transmission of alcoholism (Edenberg et al., 1998).

Concordance Rates for Alcoholism in

Twins. If there is a genetic component in the risk of alcoholism, then identical twins, who possess identical genes, should exhibit similar consumption and abuse histories, and fraternal twins, who share an average of 50% of their genetic material, should differ more in consumption and abuse histories. In fact, researchers using the twin method to study the genetics of alcoholism confirmed these expectations.

In one of the earliest twin studies of the genetics of alcoholism, Kaij (1960) reported concordance rates of 54% for alcohol abuse among Swedish monozygotic twins; it was 28% among dizygotic twins. A number of subsequent twin studies confirmed these initial findings on the genetics of abuse. In a study of 850 pairs of American like-sex twins who were high school juniors at the time, Leohlin (1977) reported that identical twins were also significantly more concordant for heavy drinking than fraternal twins. And, in a recent study of 1030 female-female twin pairs in Virginia, Kendler and his colleagues (1992) found that concordance for alcohol dependence was significantly higher among monozygotic than dizygotic twin pairs; overall, 58% of identical twin pairs and only 29% of fraternal twin pairs were concordant for alcoholism.

Adoption Studies of Children of Alcoholics.

Adoption studies hold environmental influences constant, which twin studies may not, and they permit systematic variation in genetic factors. Many behavioral scientists believe that adoption studies provide the clearest perspective to date on the role of genetic factors in mental disorders.

The first adoption studies of children of alcoholics compared four groups of young adult children of Danish alcoholics (Goodwin, 1976, 1979, 1985). Sons of alcoholics raised by nonalcoholic foster parents, sons of alcoholics raised by their biological parents, and daughters of alcoholics raised, respectively, by nonalcoholic foster parents and by their biological parents were included. Paired with each of these four groups was a control group matched for age, gender, and adoption sta-

tus. All adoptees had been separated from their biological parents during the first few weeks of life and then adopted by nonrelatives. The studies yielded two principal findings: (1) sons of alcoholics were about four times more likely than sons of nonalcoholics to become alcoholics as adults, regardless of whether they were raised by their biological parents or by nonalcoholic adoptive parents; (2) the influence of genetics on the daughters of alcoholics was not as strong as on the sons of alcoholics.

Subsequent adoption research in Sweden (Bohman, Cloninger, von Knorring, & Sigvardsson, 1984) confirmed Goodwin's conclusions about the impact of genetic factors on the sons of alcoholics and showed, as well, that genetic factors also significantly affect daughters of alcoholics. The Swedish research also suggested the existence of two forms of inherited alcoholism. Analyzing data from 2000 Swedish adoptees, Bohman, Sigvardsson, and Cloninger (1981) and Cloninger, Bohman, and Sigvardsson (1981) identified two groups of alcoholics that differed in alcoholism heritability. The more numerous, lower heritability, Type I alcoholics began drinking in their mid-twenties to thirties, although typically they did not develop alcohol problems until middle age; they had a high risk of liver disease and showed little antisocial behavior and relatively few social and occupational problems. Children of Type I alcoholics were twice as likely to develop alcoholism as persons without a family history of alcoholism; sons of Type I alcoholics raised in troubled adoptive homes were at even greater risk of developing alcoholism. In contrast, the higher heritability Type II alcoholics, whose alcoholism began very early, experienced profound social and occupational problems but relatively few medical difficulties. Their biological sons—but not their biological daughters—were nine times more likely to develop alcoholism, regardless of environmental influences.

Although a number of investigators have been unable to validate Cloninger's typology, it has generated a great deal of fruitful research (e.g., Fils-Aime et al., 1996; Hallman, von Knorring, & Orelund, 1996; Howard, Kivlahan, & Walker, 1997).

A Biological/Genetic Basis for Alcohol Abuse and Dependence? Do these data prove that the children of alcoholics are destined to follow in their parents' footsteps? No, they do not. Despite

the enhanced risk of alcoholism that adult children of alcoholics carry, most children of alcoholics do not become substance abusers, and most alcoholics are not the children of alcoholics, affirming the importance of sociocultural, learning-based, and other factors in the development of substance abuse (Prescott et al., 1994; Schuckit, 1994a).

To this end, Sher and his colleagues (1997) recently explored possible relationships among childhood stressors (including disrupted family rituals, embarrassment, abuse and neglect), paternal alcoholism, and alcohol abuse and dependence in the adolescent and early adult children of alcoholic fathers. Sher and his colleagues asked whether exposure to stressors during childhood further increases the substantial risk of developing alcoholism that children of alcoholic fathers already have. Not unexpectedly, the answer was qualified. Paternal alcoholism was associated with every childhood stressor studied, and a number of these stressors (specifically, verbal, emotional, physical, and sexual abuse) were related to alcohol use disorder in adolescence or early adulthood, but self-reported childhood stressors overall were only moderately and inconsistently related to the development of alcohol problems. In other words, environmental stressors like parental abuse in childhood do affect the genetic burden of familial alcoholism, but how and why they do so is not yet well understood.

Sociocultural Influences

Demographic Factors. The racial, religious, national, and ethnic groups to which our parents and we belong, as well as our gender, profession, education, and age, influence who we are, including the likelihood that we will abuse alcohol and drugs (Johnson et al., 1990). This is hardly surprising. Our parents' sociocultural group memberships shaped their child-rearing practices, just as our own membership in these groups influenced our behavior during childhood and impacts it now.

Hispanics and African-Americans are at greater risk than Caucasians of developing alcohol-related problems. This was the conclusion from a recent U.S. adult household survey of alcohol-related problems and social consequences among representative groups of Caucasians, African-Americans, and Hispanics between 1984 and 1992 (Caetano, 1997). Caetano hypothesized that these ethnic differences in risk status reflect inequalities in in-

come distribution, employment, education, and access to adequate health care among these groups.

Age also strongly affects rates of alcohol and drug consumption and risk of abuse. Both men and women drink most heavily between the ages of 18 and 25. Substantially lower rates characterize persons over 45 years of age, especially those over 65 (Grant, 1997; NIAAA, 1997). Wechsler and his colleagues (1994) recently reported some startling data on drinking by college students, who represent a highly visible subgroup of this heavy drinking, young adult cohort. Surveying the drinking practices of 17,592 undergraduates at 140 U.S. colleges and universities, these researchers found that almost half (44%) of their sample met criteria as binge drinkers and almost one-fifth (19%) were frequent binge drinkers. Binge drinking was defined as consumption of five or more drinks (for men) and four or more drinks (for women) on a single occasion during the 2 weeks before the survey; frequent binge drinkers reported three or more binges during the same period. A strong, positive relationship linked frequency of binge drinking and significant alcohol-related health and other problems. Frequent binge drinkers were seven to ten times more likely than nonbinge drinkers to fail to use protection when having sex, to engage in unplanned sexual activity, to get into trouble with campus police, to damage property, or to get hurt or injured. Binge drinking was strongly age-related: students between 17 and 23 years of age had much higher bingeing rates than older students.

Grant's 1997 survey of more than 40,000 Americans, referred to previously, confirmed that gender powerfully affects the risk of alcoholism in this country: Males were much more likely than females to abuse alcohol at every age. An earlier population survey of alcohol abuse and addiction in five sites across the globe in the late 1980s—in St. Louis, Missouri; Edmonton, Canada; San Juan, Puerto Rico; Seoul, South Korea; and Taipei City, Taiwan—came to the same conclusion (Helzer et al., 1990). Marked disparities between men and women in lifetime prevalence of alcohol dependence were observed in all five geographically diverse sites, confirming in every instance that men were at markedly higher risk of alcoholism than women. As an example, the survey found that lifetime prevalence rates for alcoholism in St. Louis were 29% for men and only 4% for women.

Two factors have been weighed most heavily in

efforts to explain these marked differences between men and women in alcohol abuse and dependence. First, because of women's traditional child-care role, our society tolerates alcohol abuse by women much less readily than it does alcohol abuse by men. Second, recent empirical data on differential rates of metabolism of alcohol by men and women (Frezza et al., 1990) suggest that women possess smaller amounts than men of a crucial enzyme that detoxifies alcohol in the stomach and small intestine. This gender-based metabolic difference explains why alcohol consumed in equivalent doses by men and women has greater behavioral and physiological effects on women (Gallant, 1987). Simply put, fewer women than men drink to excess because alcohol produces more aversive behavioral, bodily, and interpersonal consequences for women than for men.

Peer Influences. Heavy drinking and drug use and rebellious and delinquent behavior by peers are significant risk factors in adolescent substance abuse (Newcomb & Bentler, 1986). Conversely, having peers who do not drink abusively, use drugs, or commit rebellious or delinquent acts protects adolescents against substance use and abuse (Jessor & Jessor, 1977).

Gottfredson and Koper (1996) found that adolescent peer drinking, drug use, rebelliousness, and delinquency were more closely linked to initiating substance use in Caucasians than in African-Americans and more in African-American males than in African-American females, a finding which Reifman et al. (1998) subsequently confirmed. Reifman and his colleagues (1998) also reported that peer drinking alone did not predict progression to heavier drinking in Caucasian and African-American adolescents. The degree of parental monitoring of drinking and the extent of parental efforts to control other troubling aspects of the behavior of their adolescents interacted with peer influences to influence the likelihood that heavier drinking by the adolescents would progress.

In a study of 25,411 male and female undergraduates from sixty-one U.S. colleges and universities that replicated and extended the 1994 study by Wechsler and his colleagues reviewed earlier, Cashin, Presley, and Meilman (1998) related alcohol consumption, binge drinking, the consequences of use, and beliefs about drinking to membership in fraternities and sororities. It has long been assumed that fraternities and sororities represent a powerful source of peer influence on

their members. As predicted, students in the Greek system averaged significantly more drinks per week, engaged in heavy drinking significantly more often, and suffered significantly more negative consequences of their drinking than non-Greeks. The officers of fraternities and sororities consumed alcohol, engaged in heavy drinking, and experienced negative consequences at levels at least as high and, in some cases, higher than that of other Greek members. Whether these heavy drinking officers were leading or following their fellow Greeks could not be determined from the design of this study.

Learning-Based Factors

Classical Conditioning. Such common symptoms of alcohol dependence as craving and tolerance have been interpreted as classical conditioning mechanisms. For example, a series of experiments with alcohol (Crowell, Hinson, & Siegel, 1981) and morphine (Siegel, 1978) showed that substance-dependent rats that developed drug tolerance maintained it only when they were tested under the environmental conditions originally associated with the drug or alcohol administration. Tolerance was not observed when the drug was given in a novel environment. These experiments led Siegel and his colleagues to propose the *conditioned compensatory response model*, a classical conditioning model of drug tolerance. According to Siegel (1978), environmental stimuli linked with drug intake become associated with the drug's effects on the body to elicit a conditioned response opposite to the drug's effect, thus creating a compensating response designed to maintain bodily homeostasis. As this conditioned response increases in magnitude with continued drug intake, the drug's effects decrease and tolerance increases.

The *conditioned appetitive motivational model* is a classical conditioning model of craving (Stewart, deWit, & Eikelboom, 1984). It explains the common observation that the conditioned stimuli associated with the positive reinforcing effects of drugs (for example, the smell, sounds, and lighting of the place where alcohol is most often ingested) sometimes become capable themselves of eliciting a positive motivational state similar to that elicited by a preferred alcoholic beverage itself. This state, in turn, creates strong, continuing urges to seek and use alcohol. This model helps explain

the great difficulty that recovering alcoholics have in maintaining abstinence when they must return to the environments in which they originally developed their dependence.

Operant Conditioning. Nathan and O'Brien (1971) described a series of studies of operant conditioning mechanisms in alcohol self-administration by humans. They explored the behavior of alcoholic subjects who lived for up to 33 days in a self-contained experimental environment at Boston City Hospital. The social behavior, mood, and drinking behavior of matched groups of alcoholics and nonalcoholics were compared during this prolonged period. Operant procedures assessed the differential reinforcement value of alcohol and social interaction, both of which are extremely powerful reinforcers for these subjects. All subjects had to press an operant panel's push-button repeatedly, on a high fixed-ratio schedule, to earn points to "purchase" alcohol, time out of their rooms in a social area, or both.

Comparisons of the operant behavior of the alcoholic and nonalcoholic groups revealed the following:

- Alcoholics worked much longer and harder to earn points to purchase alcohol. As a result, though both alcoholics and nonalcoholics reached the same high blood-alcohol levels early in drinking, alcoholics remained at these levels longer and returned to them more frequently. They drank almost twice as much as the nonalcoholics.
- Nonalcoholics worked much longer and harder to earn points that permitted them to leave their rooms and spend time with each other in a social area. By contrast, alcoholics remained social isolates before, during, and after drinking.
- Once drinking began, alcoholics became significantly more depressed and less active and demonstrated significantly more psychopathology (including anxiety, manic behavior, depression, paranoia, and phobic and compulsive behavior) than nonalcoholics.

This research program ultimately led a number of other clinical researchers to explore operant programs designed to reinforce alcoholics to reduce or stop their drinking. Bigelow, Cohen, Liebson, and Faillace (1972) and Bigelow, Liebson, and Griffiths (1974), for example, reported marked reductions in drinking by alcoholics when they were reinforced with money and other rewards for

maintaining limited periods of abstinence in a laboratory setting.

A Biopsychosocial View of Alcoholism Etiology

The past two decades have witnessed great progress in establishing empirically the key factors associated with the etiology of alcohol abuse and dependence. Much more remains to be understood, but we certainly know enough now to advocate a biopsychosocial view of the etiology of alcoholism. We make this claim convinced that genetic/biological, sociocultural, and learning-based factors exert their own distinct influences on the etiology of these conditions. It is also clear that emphasizing one or another of these factors over the others provides a limiting view of etiology, whereas stressing their coordinate power to impact the development of alcohol abuse and dependence most accurately describes our current knowledge about the etiology of these conditions.

Markers of Risk for Alcohol-Related Disorders

Family History

A family history of alcoholism is the strongest single predictor of heightened risk of alcoholism (Cadoret, 1980; Cotton, 1979). Three different research programs conducted during three different recent decades (Cloninger et al., 1981; Goodwin et al., 1974; Kendler et al., 1992) demonstrated that a family history of alcoholism substantially increases the risk of alcoholism in the children of alcoholics. The risk of alcoholism is increased, presumably, because still-unidentified mediators of risk are genetically transmitted.

Schuckit (1997) describes an ongoing prospective study, now in its fifteenth year, of 453 sons of alcoholics and controls originally chosen at random from lists of university students and non-academic staff at the University of California, San Diego. We refer here to data from this study on the level of reaction to an alcohol challenge as a marker of heightened risk of alcoholism. Here, we call readers' attention to a recent article by Schuckit and Smith (1996), which compared the men in their sample who were family history positive (FH+) for paternal alcoholism with a matched family history negative (FH-) comparison group;

in all other relevant respects, the two groups were indistinguishable from one another. At the 8.2 year follow-up mark, when the men were in their early 30s, the prevalence of DSM-III-R alcohol abuse and dependence among the FH+ men was 14.1 and 28.6%, respectively, compared to 6 and 10.8% for the FH- men, thereby affirming the impact of a family history of alcoholism on the rates of alcoholism in the FH+ men in this sample.

Neurophysiological Index

ERP: Auditory and Visual P300. The event-related potential (ERP) is an electroencephalographic (EEG) technique that reflects the electrical events that arise during the processing of information by the brain following an external auditory or visual stimulus. Testing the hypothesis that the visual P300 wave deficit, a distinct ERP waveform, was a genetically determined marker of enhanced risk for alcoholism, Begleiter and his colleagues (1984) compared the ERPs of a group of 12-year-old boys who had alcoholic fathers with those of a matched group without a history of paternal alcoholism. Significant differences in the P300 voltage distinguished the two groups. Moreover, the boys with a paternal history of alcoholism showed a P300 pattern similar to that previously seen in abstinent chronic alcoholics (Porjesz & Begleiter, 1983). Subsequent reports of diminished P300 voltage in groups of boys and girls with family histories of alcoholism (Hill & Steinhauer, 1993; O'Connor, Hesselbrock, & Tasman, 1986; Steinhauer & Hill, 1993) supported the validity of the Begleiter group's initial findings, although other researchers—most recently, Holguin, Corral, and Cadaveira (1998)—failed to do so.

Auditory stimuli have not been associated with P300 amplitude reductions as consistently as visual stimuli. For example, Hill, Steinhauer, and Locke (1995) observed no differences in the amplitude of the P300 component of the ERP to two auditory stimuli among alcoholics from "high-density, multigenerational families," first-degree nonalcoholic relatives from the same families, and nonalcoholic controls from low-density families. This finding contrasts with the same authors' report of reliable visual P300 amplitude differences in high- and low-risk children from the same high- and low-density families (Hill & Steinhauer, 1993; Steinhauer & Hill, 1993).

Ramachandran and his colleagues (1996) hypothesized that reduced P300 amplitudes are signs

of cortical inhibition that interferes with the ability to respond to novel stimuli and reflects a developmental lag in high-risk youth. Ramsey and Finn (1997) propose, instead, that diminished P300 amplitudes may reflect deficits in the motivational-cognitive system of children of alcoholics. They drew this conclusion after comparing visual P300 amplitudes of family-history positive (FH+) and family-history negative (FH-) men under both monetary incentive and no-incentive conditions and found that only the FH- men increased the amplitude of their P300 in the incentive condition.

Level of Reaction to Alcohol. Twenty years ago, Nathan and Lipscomb (1979) and Lipscomb, Carpenter, and Nathan (1979) reported that some nonalcoholic individuals given a challenge dose of alcohol showed little body sway in response to the challenge, whereas others swayed substantially. The degree of body sway in response to the challenge dose of alcohol turned out to be associated with subsequent development of tolerance to alcohol: Subjects who were relatively unresponsive to the challenge dose were more likely to demonstrate substantial tolerance following a period of sustained drinking than those who showed significant body sway following ingestion of the challenge dose. Nathan and his colleagues hypothesized that body sway following an alcohol challenge in nondependent drinkers might be a marker for heightened risk of alcoholism.

Subsequently, Schuckit and his colleagues (Schuckit, 1985; Schuckit, 1994b; Schuckit & Gold, 1988) compared the level of response to alcohol challenge (LR) in the family history positive (FH+) and family history negative (FH-) subjects of their longitudinal study of multiple markers of risk of developing alcoholism. In two of the most recent reports of this research, Schuckit and Smith (1996, 1997) reported that LR at the age of 20 years had turned out to be a marker for increased risk of later alcoholism: FH+ males with low LR scores were significantly more likely than FH- males with low LR scores to develop alcoholism, and FH+ males with low LR scores were significantly more likely than FH+ males with high LR scores to develop later alcoholism. These authors concluded, as had Nathan and his colleagues (1979), that "these data are consistent with the conclusion that LR might be a mediator of the alcoholism risk" (Schuckit & Smith, 1996, p. 202). They posit that young drinkers in whom alcohol consumption induces little effect, especially those with family histories of alcoholism,

might well drink more over time to achieve a stronger effect than those on whom alcohol has a stronger initial effect.

Personality Traits

Despite repeated attempts, efforts to identify a predominant personality style in alcohol- or drug-dependent individuals—the “addictive personality”—have failed to yield a single trait dimension or pattern of dimensions characteristic of many, most, or all such persons (e.g., Nathan, 1988; Sutker & Allain, 1988). However, substantial data have been gathered in recent years which suggest that personality traits are markers of the risk of alcoholism and probably contribute to the development and/or persistence of an addiction.

To this end, Allen, Fertig, and Mattson (1994) identified five discrete personality trait patterns in a group of 400 primary alcoholics; each trait pattern was associated with a different set of motivations to use alcohol and drugs. For example, alcohol-dependent individuals who were dependent on others and hostile toward peers most often used alcohol to dampen dysphoric mood and respond to peer pressure, and alcoholics who admitted to feeling socially isolated used alcohol to alleviate the emotional distress that accompanies social alienation.

Reviewing data on the personality topography of individuals diagnosed with alcohol dependence or antisocial personality disorder (the two are often comorbid), Sher and Trull (1994) identified three broad dimensions of personality common to both disorders. Neuroticism/negative emotionality, impulsivity/disinhibition and, to a lesser extent, extroversion/sociability all contribute to the development and persistence of these conditions. These three personality dimensions have emerged repeatedly in efforts to characterize the personality traits of alcohol and drug abusers. What remains, above all, is to determine whether and how these dimensions of personality differ between substance abusers and persons with antisocial personality disorder.

Alcohol Expectancies

Alcohol expectancies are the attitudes and beliefs that we hold about the effects that alcohol will have on our thoughts, feelings, and behavior. In 1980, Brown and her colleagues (Brown et al.,

1980) developed the first questionnaire to assess alcohol expectancies. Since then, a number of other expectancy questionnaires have been developed to address methodological problems in Brown's Alcohol Expectancy Questionnaire (AEQ; Brown et al., 1980). These instruments include the Effects of Drinking Alcohol (EDA; Leigh, 1987; Leigh & Stacy, 1993), the Comprehensive Effects of Alcohol (CEOA; Fromme, Stroot, & Kaplan, 1993), and the Drinking Expectancy Questionnaire (DEQ; Young & Oei, 1990).

These instruments, along with the AEQ, have successfully predicted a number of variables related to alcohol consumption in both adults (e.g., Brown, Goldman, & Christiansen, 1985) and children (Smith et al., 1995). Alcohol expectancies also differentiate between heavy and light drinkers (see review by Goldman et al., 1991) and, interacting with personality variables (Earlywine, Finn, & Martin, 1990; Leonard & Blane, 1988), moderate relationships between drinking and stress (Cooper et al., 1992) and drinking and anxiety (Kushner et al., 1994).

Alcohol expectancies also influence the risk of alcoholism. In a one-year longitudinal study, Christiansen et al. (1989) found that alcohol expectancies in adolescents who had not yet begun regular drinking, predicted eventual alcohol consumption levels by differentiating between those who ultimately became problem drinkers and those who did not. The same research group (Smith et al., 1995) also examined the divergent paths of adolescents with high and low expectations for alcohol's positive effects. Following their subjects for 2 years, they reported a direct relationship between expectancy endorsement and subsequent drinking: The greater their expectations of alcohol's positive effects on social functioning, the greater their alcohol use. Smith and his colleagues also found that expectancies and drinking influenced each other reciprocally: Greater expectancy endorsements led to higher subsequent drinking which led, in turn, to even greater expectancy levels.

Expectancies have also recently been linked to anterior brain functioning in young men at risk of alcoholism (Deckel, Hesselbrock, & Bauer, 1995). Ninety-one young men without significant drug or alcohol histories completed EEGs, batteries of neuropsychological tests, and AEQs. Regression analysis revealed that four of the neuropsychological tests of anterior brain functioning predicted a number of AEQ scales; moreover, frontal, but not

parietal, EEG scores were also associated with AEQ scales. These findings suggest that alcohol-related expectancies may be biologically determined in part by frontal/prefrontal systems and that inherited dysfunctions in these systems might function as risk factors for alcohol abuse or dependence.

The relationship between alcohol expectancies and memory has been another recent focus of expectancy research. Goldman and his colleagues (e.g., Dunn & Goldman, 1996; Rather & Goldman, 1994; Rather, Goldman, Roehrich, & Brannick, 1992; Roehrich & Goldman, 1995) attempted to model alcohol expectancy memory networks, using theories from cognitive psychology. They posit that expectancies are stored as memories and that these memories may implicitly affect future drinking decisions. In the study by Roehrich and Goldman (1995), the effect of implicit priming of drinking on actual consumption was studied. In a 2×2 factorial design, participants were exposed to clips from TV sitcoms (*Cheers* or *Newhart*) in the videotape prime condition and a Stroop task with either alcohol expectancy or neutral words in the semantic prime condition. Subjects were then asked to participate in an alcohol "taste test" in which they rated three different nonalcoholic beers. The dependent measure was how much alcohol each participant consumed. Participants who viewed a clip from *Cheers*, a program set in a Boston bar, consumed significantly more than those who viewed *Newhart* (a program set in a Vermont inn); those in the expectancy word conditions consumed significantly more than those in the control word conditions. Roehrich and Goldman concluded from these findings that memory processes do influence drinking decisions and that alcohol expectancies, as well as other contents of memory, play roles in these processes.

Psychopathology

Interpersonal Aggression

Alcohol intoxication reliably induces aggression in some individuals (Nathan, 1993). Extensive data also implicate alcohol intoxication, alcohol abuse, and alcohol dependence in criminal behavior and family and sexual abuse (NIAAA, 1997). Summarizing two decades of research, Nathan (1993) concluded that

the relationship linking alcohol and aggression remains firmly established in our culture. This relationship appears to depend on a balance of expectancies and drug effects ... [However], when beverage alcohol consumed in moderate quantities exerts an aggression-inducing effect, it most likely does so because the drinker believes that to be its effect rather than because of any drug-induced effect. (p. 463)

Successful efforts to trace the link of alcohol and aggression have taken place in both laboratory settings and the real world.

Using a laboratory-based aggression analogue, Giancola and Zeichner (1995) examined the impact of aggressive personality traits, the degree of subjective intoxication, and the blood alcohol concentration (BAC) on aggression in young adult males and females. Subjects competed against a nonexistent "opponent" by giving electric shocks to, and receiving them from, the opponent under both provocative and nonprovocative conditions. Provocation was defined by the strength of shocks subjects received. Aggression was defined by the intensity of shocks that subjects gave. For males in the high provocation condition, aggressive personality traits, subjective intoxication, and BAC all predicted physical aggression. However, none of these variables was an effective predictor of aggression in women; this finding replicates prior failures to observe heightened aggressivity following intoxication among females in experimental settings (e.g., Gustafson, 1991). Perhaps heightened aggression could be observed in intoxicated women if a different laboratory analogue, one in which the aggression were not as blatantly physical, were employed.

Chermack and Taylor (1995) used the same experimental paradigm to contrast the two principal competing explanations for alcohol's effects on aggression: its pharmacological actions and its effects on expectancy/disinhibition. Male college students were divided into a group already convinced that alcohol increases aggression and a group convinced that it decreases aggression. Subjects were then randomly assigned to active-placebo or high alcohol dose conditions. Subjects who consumed the high alcohol dose delivered significantly higher levels of shock than those who consumed the active-placebo, regardless of preexisting alcohol expectancies. Intoxicated subjects who believed that alcohol increases aggressive behavior delivered more intense shocks in high but not low provocation conditions. Chermack and Taylor's conclusion: The pharmacological ef-

fects of alcohol on aggression play the primary role in the alcohol–aggression nexus. This represents one of the first times that disinhibitory effects of alcohol on aggression were not emphasized following a laboratory demonstration of the alcohol–aggression connection. Chermack and Taylor’s use of an analogue aggression measure, however, tempers our acceptance of this explanation. Real-world aggression is typically expressed in a more complex manner.

A number of authors recently examined linkages between real-world aggressivity and alcohol intoxication and dependence. Moss and Kirisci (1995), for example, undertook a correlational study of alcohol- and drug-misusing dependent adolescents; they found that aggressivity in the real world and symptoms of conduct disorder, which include overt aggressivity, correlated significantly and positively with alcohol consumption. Mezzich and her colleagues (1997) compared a group of alcohol- and drug-abusing adolescent females with a group of nonabusing controls and confirmed that the severity of alcohol/drug use has significant impact on relationships between personality disorder, mood disorder and family impairment, on the one hand, and suicide and violence on the other. Reviewing the extensive literature on the connection between alcohol and violent crime, Zhang, Wiczorek, and Welte (1997) identified four different roles that alcohol plays in crime and violence; these correspond to four major causes of crime at the individual level.

Cognitive Dysfunction

Chronic alcohol abuse causes cognitive impairment, which may involve visual, spatial, or verbal memory; problem-solving; cognitive efficiency; or visuospatial perception (Beatty et al., 1996; Nixon, Tivis, & Parsons, 1995). From one-third to one-half of all chronic alcohol abusers suffer from demonstrable cognitive deficits (e.g., Fals-Stewart, 1996; Fals-Stewart & Lucente, 1994). Speculations on the etiology of these deficits range from alcoholic neurotoxicity (Freund, 1982), heredity (Hegadus et al., 1984), avitaminosis (Victor, Adams, & Collins, 1971), and physical trauma (Wetzig & Hardin, 1990). Cognitive dysfunctions diminish with continued abstinence; after a few months of sobriety, they may largely or completely disappear, depending on the length and severity of the

alcohol abuse, the length of abstinence, and the age of the abuser (Eckardt et al., 1995). Surprisingly, a family history of alcoholism does not affect the prognosis for recovery from alcohol-induced cognitive impairment (Adams et al., 1998). In older abusers, especially those whose abuse histories have been severe, the cognitive impairments may never completely disappear (Goldman et al., 1983).

Research on the long-term cognitive impact of alcohol use and abuse has recently shifted from an exclusive focus on the severe deficits of older alcohol abusers to the more modest impairments of younger social drinkers that may be premonitory to more severe dysfunction. For example, Nichols and Martin (1996) recorded visual ERPs from young, male, heavy and light social drinkers under an alcohol condition designed to induce mild disorientation or an alcohol placebo. The amplitude of the P300 ERP component was significantly more diminished in heavy than in light social drinkers, suggesting that the heavy social drinkers may already have begun to develop an alcohol-induced deficit in information processing. Given prior findings, reviewed before, that alcoholics typically demonstrate a diminished visual P300, these results suggest that this marker of impairment in information processing may constitute an early sign in heavy social drinkers of the serious impairments in cognitive functioning that afflict many chronic alcoholics.

Scheier and Botvin (1995) found that early adolescent alcohol and drug use are associated with small but significant declines in cognitive and self-management strategies that increase in magnitude in middle adolescence if substance use continues. These substance-induced effects may be more than epiphenomena. Scheier and Botvin hypothesize that “early drug use may impede acquisition of critical thinking skills and hinder the learning of important cognitive strategies required for successful transition to adulthood” (1995, p. 379).

Reviewing the nineteen pertinent studies on cognitive functioning in sober social drinkers published since 1986, Parsons and Nixon (1998) propose “an alcohol-causal-threshold hypothesis” that led them to propose that “persons drinking five or six U.S. standard drinks per day over extended time periods manifest some cognitive inefficiencies; at seven to nine drinks per day, mild cognitive deficits are present; and at 10 or more

drinks per day, moderate cognitive deficits equivalent to those found in diagnosed alcoholics are present” (p. 180).

Impaired Sexual Functioning and Increased Sexual Risk-Taking

Prolonged alcohol abuse, it has long been thought, impairs sexual functioning (Fahrner, 1987; Schiavi, 1990), probably by affecting hormonal mechanisms and testicular function in males (Bannister & Lowosky, 1987; Van Thiel et al., 1980). The impact of a history of alcoholism on sexual functioning, marital adjustment, sleep-related erections, sleep disorders, and hormone levels was recently studied in a small sample of abstinent male alcoholics by Schiavi and his colleagues (1995), with unexpected results. Two months to three years after achieving stable sobriety, the recovering alcoholics were compared to a group of nonalcoholic males; both groups of subjects were from 28–50 years of age. Subjects and their sexual partners all received thorough psychosexual evaluations, as well as a polygraphic assessment of sleep pattern, assessment of nocturnal penile tumescence, and nocturnal sequential blood sampling. Surprisingly, the alcoholic men did not differ from the comparison group along any dimension of sexuality or in the number of sexual problems, even though their sexual partners reported significant marital dissatisfaction. Despite a history of severe alcohol dependence, these men had been able to maintain normal sexual function, even in disturbed marriages. Schiavi and his coauthors observed, however, that their alcoholic subjects were not suffering from hepatic or gonadal disease or taking medication; in prior studies, these factors have been associated with impaired sexual function.

Alcohol use and abuse also increases sexual risk-taking (Kim, Celentano, & Crum, 1998). For example, Gordon and Carey (1996) studied the consequences of alcohol intoxication on condom use in a laboratory-based inquiry. Moderate to heavy drinking, young male nonalcoholic subjects were randomly assigned to either alcohol or alcohol placebo conditions. Those in the alcohol condition drank sufficient vodka and tonic to achieve blood alcohol levels of 0.08%; controls drank only tonic. All subjects then completed a battery of self-report measures of condom and AIDS-related knowledge, motivation to use condoms, and be-

havioral self-efficacy for condom use. Subjects who had consumed alcohol reported more negative attitudes toward condom use and lower self-efficacy about the ability to use condoms than subjects who had consumed only tonic.

Parker, Harford, and Rosenstock (1994) explored real-world relationships between sexual risk-taking and alcohol and drug use in a large group of nonabusing young adults. After controlling for age, education, and family income, they found that the quantity and frequency of alcohol use (and that of marijuana and cocaine) were related significantly to sexual risk-taking, which they defined as the degree to which these men and women failed to take reasonable precautions against unintended pregnancy and sexually transmitted disease. Koopman and her colleagues (1994) observed the same phenomenon when they examined relationships between both lifetime and current alcohol and drug use and sexual risk-taking in several hundred male and female adolescent runaways, predominantly African-American and Hispanic, who lived in four residential centers in New York City. Greater frequency of substance use, which included marijuana and cocaine as well as alcohol, was related significantly to more sexual partners and less frequent condom use.

Comorbidity

Alcohol abusers demonstrate more comorbid psychopathology than persons with any other psychiatric syndrome (Ross, Glaser, & Germanson, 1988; Wilson et al., 1996). According to Schuckit (1994c), however, the frequent co-occurrence of alcohol abuse and common forms of psychopathology like depression and anxiety partly reflects base rates, that is, because the prevalence rates of substance abuse, depression, and anxiety are all very high (Helzer et al., 1988), chance alone helps explain their frequent co-occurrence. It is also the case, Schuckit (1994c) continues, that persons with symptoms of two or more disorders—alcoholism and a mood or anxiety disorder, for example—are more likely to seek treatment than those with only one and, for that reason, to be represented in studies of comorbidity based on treatment populations.

A recent general population survey of the comorbidity of major depression and several sub-

stance use disorders revealed pervasive comorbidity among these conditions (Grant, 1995). The association between alcohol and other drug dependence and major depression was greater among older than younger subjects, consistent with the use of alcohol and other sedatives by older people to self-medicate for depression. This association was also greater for women than for men; Grant explained that this relationship derived at least in part from interaction between women's greater vulnerability to stigmatization for alcohol and drug abuse and the DSM-IV abuse criteria, which emphasize strongly the adverse consequences arising from abuse.

Many of the drugs of abuse, including alcohol, produce symptoms that mimic major psychiatric disorders (Schuckit, 1994c). These behaviors have been studied most extensively as a consequence of central nervous system depressant (alcohol, barbiturates, and benzodiazepines) and stimulant (the amphetamines and cocaine) use:

... intoxication with *brain stimulants* can cause many symptoms of *anxiety*, with intake of larger doses even producing syndromes that can look similar to obsessive-compulsive disorder, panic disorder, and generalized anxiety disorder. Withdrawal from brain stimulants as well as repeated and prolonged intoxication with *brain depressants* can cause sadness that might even produce severe and incapacitating *depression* that resembles a major depressive episode. Withdrawal from brain depressant drugs is likely to produce intense and acute anxiety, with the probability of prolonged, but less severe, anxiety during what might be considered a protracted abstinence syndrome. Repeated stimulant intoxication, especially with amphetamines and cocaine, is likely to produce a syndrome of auditory hallucinations along with paranoid delusions that can temporarily resemble *schizophrenia*. (Schuckit, 1994c, p. 46)

Because alcohol sometimes functions briefly as a CNS stimulant, even though its major effect is as a CNS depressant, it can induce symptoms of both anxiety and depression.

Schizophrenia and Other Psychoses

The Epidemiological Catchment Area (ECA) study (Regier et al., 1990) surveyed the mental health status of a large representative sample of the U.S. population in five cities around the country and found that persons diagnosed with schizophrenia experience an elevated lifetime prevalence of alcohol-related disorder, that more than a quarter of persons with schizophrenia simultaneously experience comorbid alcohol-related disorder, and that persons diagnosed with schizophrenia are much more likely to have histories of

alcohol-related disorder than those without the disorder. All three findings confirm the common co-occurrence of alcohol-related disorder and psychosis, prominently including schizophrenia. These conditions co-occur for several reasons: schizophrenic persons, as well as those suffering from other psychotic disorders, tend to be intemperate (e.g., Barbee et al., 1989; Drake, Osher, & Wallach, 1989); alcohol is commonly self-administered by schizophrenic persons in an effort to dampen psychotic symptoms; and persons with the dual diagnoses of schizophrenia and substance abuse are substantially more likely to come to the attention of mental health professionals than those with only one or the other of these disorders (Schuckit, 1994c).

Attention-Deficit/Hyperactivity Disorder (ADHD)

Symptoms of ADHD in persons with alcohol-related disorders are quite common (e.g., Biederman et al., 1995; Wilens et al., 1994). Because ADHD is often a feature of the childhood of individuals who develop alcohol-related disorders as adults, ADHD has been portrayed, most notably, by Tarter and his colleagues (1977) as a precursor of alcohol abuse and possibly shares a common genotype in some individuals. However, questions remain whether ADHD itself or the mood, anxiety, and conduct disorders that often accompany it is primarily responsible for the co-occurrence of alcohol-related disorders and ADHD.

Personality Disorders

Personality disorders and substance-related disorders very often co-occur (Verheul et al., 1998; Zimmerman & Coryell, 1990). The most prevalent of personality disorders comorbid with substance-related disorders is antisocial personality disorder (ASPD). ASPD is most common among persons who abuse illegal drugs, but it also accompanies high rates of alcohol abuse and dependence (Verheul, van den Brink, & Hartgers, 1995), with which it shares personality trait dimensions.

The co-occurrence of ASPD and depression in alcohol-dependent persons is particularly familiar. Holdcraft, Iacono, and McGue (1998) explored these comorbid conditions in more than 200 alcoholic men recruited from a community-based sample (the Minnesota Twin-Family Study); subjects were further divided into four groups: alcoholics

with ASPD, alcoholics with depression, alcoholics with neither ASPD nor depression, and alcoholics with no other psychiatric comorbidity. Depression was associated with a less severe course of alcoholism, but ASPD and alcoholism co-occurred in persons who reported an earlier age of first alcohol intoxication, a more chronic and severe form of alcoholism, more social consequences of drinking, and higher levels of drug use. These findings, which support Cloninger's two-fold alcoholism typology (Bohman, Sigvardsson, & Cloninger, 1981; Cloninger, Bohman, & Sigvardsson, 1981), emphasize the importance of carefully diagnosing comorbid conditions in alcohol abusers for better treatment planning and more accurate prognoses.

Mood Disorders

The mood disorders that include major depressive disorder, dysthymic disorder, and bipolar disorder are among the conditions most commonly comorbid with alcohol-related disorder.

In a longitudinal study designed to examine the impact of alcohol use on the course of depressive disorder (Mueller et al., 1994), patients with dual diagnoses of major depression and alcoholism, as well as those diagnosed only with major depressive disorder, were followed over a 10-year time span. To determine more precisely the impact of alcohol abuse on the course of depression, three patient subtypes based on alcohol usage were constituted; they included patients who were never alcoholic, those who did not meet criteria for current alcoholism, and those who were currently alcoholic. Patients who had never been alcoholic or were not actively alcoholic were twice as likely to recover from major depressive disorder as actively alcoholic patients; this strongly suggests that active alcoholism has a decidedly malignant effect on recovery from major depressive disorder.

In a study with similar goals, Brown and her colleagues (1995) compared changes in the severity of depressive symptoms among men with alcohol dependence, affective disorder, or both during 4 weeks of inpatient treatment for either alcohol dependence or affective disorder. Symptoms of depression remitted more rapidly in men with primary alcoholism than in those with primary depression. Alcohol dependence in persons suffering from primary affective disorder neither intensified symptoms of depression nor interfered with their treatment. These findings, in apparent conflict

with those from the study by Mueller and his colleagues (1994), may reflect the fact that Mueller and his colleagues, unlike Brown and her co-workers, did not distinguish between primary and secondary depression—which appears to be an important distinction to make. Moreover, the severity of the depressive conditions treated in the two studies may also have differed.

Pettinati et al. (1997) explored gender differences in ninety-three alcohol-dependent outpatients divided into approximately equal groups of males with current or lifetime depressive disorders, females with current or lifetime depressive disorders, females without a history of depressive disorder, and males without a history of depressive disorder. Substantial differences between males and females were found. Depressed males had more serious alcoholism—more drinking, more drinking-related problems, and greater alcoholism severity—than depressed females and never-depressed males, whereas depressed female alcoholics were more severely depressed—reported more intense symptoms of depression—than depressed male alcoholics. The significant interaction between gender and comorbid depression observed in this study reinforces the accepted view that gender has important implications for predicting success in treating comorbid alcoholism and depression.

We conclude that depression, for some individuals, is an antecedent to, and for others, it is a consequence of alcohol use and alcohol abuse. Severe depression exacerbates alcohol problems and makes treating them effectively more difficult. Depression, the comorbid behavioral disorder most intimately linked to alcohol abuse and dependence, is also its most troubling accompaniment. The differing expressions of both depression and alcohol dependence in men and women require considering gender when planning treatment for these frequently comorbid conditions.

Social Anxiety, Tension Reduction, and Anxiety Disorders

The first viable alternative to the psychodynamic theory of alcoholism etiology, which held sway during the decades immediately preceding World War II, was the tension-reduction hypothesis (TRH). Buttressed by anecdotal reports from both social drinkers and alcoholics that alcohol reduces anxiety, the TRH gained additional support from empirical research (e.g., Conger, 1951; Masserman &

Yum, 1946) that documented alcohol's capacity to reduce experimentally induced conflict ("anxiety") in rats and cats. The TRH did not fare so well, however, when it was tested in alcoholics. This research (see reviews by Cappell, 1974, and Langenbucher & Nathan, 1993) revealed that alcoholics do not respond consistently to alcohol. Some experience tension relief, others an increase in tension, and still others show no effect at all.

The importance of attitudes toward the tension-reducing effects of alcohol were underlined in research completed a number of years ago (e.g., Abrams & Wilson, 1979; Polivy, Schueneman, & Carlson, 1976; Wilson & Abrams, 1977). This research suggested that the sedative effects of alcohol at low to moderate doses do tend to reduce tension and anxiety in the short run—unless the drinkers' attitudes toward drinking are so conflicted (as are those of many alcoholics) that they experience anxiety rather than tension-relief when beginning to drink again.

A review of contemporary research on alcohol and anxiety by Schuckit and Hesselbrock (1994) was motivated by the observation that although many alcoholics report symptoms of severe anxiety during periods of abstinence, it is unclear whether the anxiety is primarily associated with independent psychiatric syndromes, with the abstinence syndrome, or with the two in combination. Schuckit and Hesselbrock (1994) conclude that

the available data, while imperfect, do not prove a close relationship between lifelong anxiety disorders and alcohol dependence. Further, prospective studies of children of alcoholics and individuals from the general population do not indicate a high rate of anxiety disorders preceding alcohol dependence. The high rates of comorbidity (of alcohol dependence and anxiety disorder) in some studies likely reflect a mixture of true anxiety disorders among alcoholics at a rate equal to or slightly higher than that for the general population, along with temporary, but at times severe, substance-induced anxiety syndromes. (p. 1723)

These conclusions point to a fairly remote relationship between anxiety and alcohol abuse and contrast with the much closer relationship between alcohol abuse and depression reviewed earlier.

Treatment

The search for effective treatments for alcohol use disorders continues. Despite intense efforts

over many years, available treatments still help only some alcoholic patients some of the time. Many persons who abuse alcohol are motivated to moderate or stop their drinking on their own or in treatment, but substantial numbers eventually return to abusive drinking. That is the nature of the disorder: Alcohol dependence is a chronic recurrent disorder, characterized by periods of drinking that are out of control, periods of more moderate drinking, and periods of abstinence (Schuckit, 1995; Vaillant, 1995). Nonetheless, as this section of the chapter demonstrates, the search for effective treatments for alcoholism continues to attract substantial resources and numerous highly motivated research workers.

Nathan summarized the status of alcoholism treatment in the early part of the 90s in the second edition of this volume (1993). The material that follows surveys subsequent developments.

Reviews of Psychosocial Treatment Outcomes

Most reviews have concluded that outcomes of psychosocial treatments for alcoholism depend primarily on two factors, the treatment provided and the characteristics patients bring to it (especially the length and severity of their substance abuse, but also marital, educational, and employment history; physical health status; and comorbid psychopathology). However, recent reviews suggest that other factors, including therapist characteristics, the duration and amount of treatment, and the setting of treatment, also impact treatment outcomes substantially.

Treatments. In their recent review of the treatment outcome research literature, Finney and Moos (1998) ranked fifteen psychosocial treatments on the basis of results from three or more empirical studies of each, as evaluated by Holder et al. (1991), Miller et al. (1995), and Finney and Monahan (1996). Treatments with the highest effectiveness ratings in these reviews all fell into the cognitive-behavioral domain. All aimed to help patients develop skills to cope more effectively with the environmental stressors often implicated in relapse from abstinence. The top four treatments, all cognitive-behavioral, included social skills training, community reinforcement, brief motivational counseling, and behavioral marital therapy.

Social skills training (e.g., Smith & McCrady,

1991) aims to develop more effective assertive and communicative skills, on the assumption that persons who lack these skills may abuse alcohol because it dampens their feelings of social inadequacy or gives them the illusion that they are socially skilled. *Community reinforcement* (Azrin et al., 1982) initially involved interventions that assisted patients with job-related, legal, and family problems and provided them access to an alcohol-free club. Later, the club was dropped and a buddy-support system, group counseling, and behavioral contracting to encourage maintenance of Antabuse treatment were added. Throughout, the focus was on behavioral efforts to modify patients' drinking and enhance their relationships with their families and employers. *Brief motivation counseling* (Miller & Sanchez, 1993) is intended to enhance patients' motivation to modify their abusive drinking, partly by emphasizing the serious consequences of continued abuse, including the negative effects of alcohol abuse on lifespan. *Behavioral marital therapy* (O'Farrell et al., 1993) simultaneously uses behavioral and Antabuse contracts to address the abusive drinking of the alcoholic spouse; it also includes a variety of behavioral approaches designed to improve the marital relationship.

In sharp contrast to these four underused but empirically supported treatments are the three most widely used alcoholism treatment methods, which turn out to have the least documented effectiveness of all of the fifteen treatments cited by Finney and Moos (1998). Even though they lack proven efficacy, *educational films*, *confrontational interventions*, and *general alcoholism counseling* are at the core of many alcoholism programs nationwide.

Therapist Characteristics. What do we know about therapist characteristics that contribute to successful treatment for alcoholism? A great deal of research on the therapist characteristics that affect therapy outcomes more generally has been reported (Beutler, Machado, & Neufeldt, 1994, review this extensive literature), but only Najavits and Weiss (1994) addressed this issue specifically for outcomes of alcoholism treatment. After reviewing seven studies that found marked differences among different therapists in treatment retention or outcome, these authors conclude that therapist characteristics play a more important role in therapy outcome than techniques. Predictably, therapists who were more skilled interper-

sonally, less confrontational, and more empathic produced better outcomes for their alcoholic patients.

Duration and Amount of Treatment. There is considerable support for the effectiveness of brief interventions for alcohol problems (Miller et al., 1995). Most efforts to compare brief with more extended treatments for alcoholism concluded that briefer treatments are generally as efficacious as more extended ones; some observers even concluded that brief treatments have better outcomes (Bien, Miller, & Tonigan, 1993). Miller and Sanchez (1993) proposed the acronym FRAMES as a reminder of the six ingredients of brief therapy for alcoholism that they believe predict favorable outcomes: *F*eedback of personal risk or impairment, *e*mphasis on personal *R*esponsibility for change, *c*lear *A*dvice to change, a *M*enu of alternative change options, *t*herapeutic *E*mpathy, and *e*nhancement of patients' *S*elf-efficacy or optimism about successful change efforts.

Because most studies of brief interventions for alcohol problems have recruited persons with only mild to moderate problems, it is not clear how effective brief interventions are for more severe alcohol dependence. Finney and Moos (1998) and Monahan and Finney (1996) suggest that more serious substance abuse probably benefits from more intensive, longer lasting treatments.

Length of Stay in Treatment. The data on the impact of length of stay in residential treatment facilities on outcomes of treatment for alcoholism are equivocal. Reviews by Miller and Hester (1986) and Mattick and Jarvis (1994) persuaded their authors that the length of inpatient treatment is unrelated to outcome differences, but Monahan and Finney (1996) reached a different conclusion. Their "quantitative synthesis of patient, research design, and treatment effects" convinced them that amount of treatment across 150 treatment groups in 100 studies bore a significant relationship to abstinence rates. In an attempt to explain their divergent findings, they emphasized the 10:1 difference in the amount of treatment received by high- (148 hours of treatment) versus low-intensity (14 hours) treatment groups; a ratio of this magnitude had not been represented in previous randomized trials of treatment duration.

Finney and Moos (1998) submit that "beneficial effects of longer stays in inpatient/residential treatment apply only to more impaired patients with fewer social resources" (p. 161), a conclusion

supported by Welte, Hynes, and Sokolow (1981), who found a clear relationship between length of stay and outcome for patients who had lower but not higher social stability.

Project MATCH (Matching Alcoholism Treatments to Client Heterogeneity)

Only recently, large-scale randomized clinical trials of alcoholism treatments, the “gold standard” for treatment outcomes, have been undertaken. In 1997, results from two such studies, the National Institute on Alcohol Abuse and Alcoholism’s Project MATCH (Project MATCH Research Group, 1993, 1997a,b) and the Veterans Administration’s cooperative study (Ouimette, Finney, & Moos, 1997), were reported.

Project MATCH was a large national multisite clinical trial designed to evaluate a set of patient–treatment matching hypotheses. A priori hypotheses that linked eleven client attributes to three treatments proposed that certain attributes would be associated with better outcomes (in terms of the percentage of days abstinent and drinks per drinking day) when patients received one of the treatments rather than either of the other two. The basic assumption underlying Project MATCH and its series of matching hypotheses was that substance abusers appropriately matched to treatments will experience better outcomes than those who are unmatched or mismatched. An extensive history of research successfully matching patients to treatments supported the validity of these hypotheses (e.g., Longabaugh et al., 1994; Mattson & Allen, 1991; Mattson et al., 1994; Moos, Finney, & Cronkite, 1990).

Project MATCH’s secondary purpose was to compare outcomes of three different, manual-guided, individually delivered 12-week treatments: *Cognitive-Behavioral Coping Skills Treatment* (CBT), *Motivational Enhancement Therapy* (MET), and *Twelve-Step Facilitation* (TSF). The treatments were described as follows:

CBT was based on social learning theory and viewed drinking behavior as functionally related to major problems in an individual’s life, with emphasis placed on overcoming skills deficits and increasing the ability to cope with situations that commonly precipitate relapse. TST was grounded in the concept of alcoholism as a spiritual and medical disease with stated objectives of fostering acceptance of the disease of alcoholism, developing a commitment to participate in AA and beginning to work through the 12 steps . . . MET was based on principles of

motivational psychology and focused on producing internally-motivated change. This treatment was not designed to guide the client, step by step, through recovery, but instead employed motivational strategies to mobilize the individual’s own resources. (Project MATCH Research Group, 1997a, p. 13)

Detailed treatment manuals were provided to each therapist who participated in the study (Kadden et al., 1992; Miller et al., 1992; Nowinski, Baker, & Carroll, 1992) to ensure to the extent possible that different therapists at different sites would deliver the same treatment in the same way.

Two independent, parallel matching studies were conducted, one with 952 patients (72% male) recruited from outpatient settings, the other with 774 patients (80% male) in aftercare treatment after a period of inpatient treatment. Patients were contacted for follow-up every 3 months for a year after the 12-week treatment period; as noted before, primary outcome measures were the percentage of days abstinent and drinks per drinking day. At the 12-month mark, 92 and 93%, respectively, of patients originally treated were successfully contacted.

Contrary to expectation, only two a priori contrasts produced significant posttreatment attribute by treatment interactions (Project MATCH Research Group, 1997b): (1) Outpatients high in anger treated in MET drank less on follow-up than in CBT; (2) Aftercare patients high in alcohol dependence drank less on follow-up in TSF; aftercare patients low in alcohol dependence drank less in CBT. Commenting on this paucity of anticipated matching effects, the Project MATCH Research Group (1997a) frankly observed that “the power of the present study to detect matching effects, and its careful, rigorous implementation, make the lack of substantial findings particularly notable.” The logical inference: “... little evidence to support widely held views regarding the potential value of matching clients, at least on the basis of nine of the client attributes tested, to any of the treatments offered as individual therapy in this study” (Project MATCH Research Group, 1997a, p. 23).

Of primary importance to us, although a secondary focus of Project MATCH, was that “significant and sustained improvements in drinking outcomes were achieved from baseline to 1-year posttreatment by the clients assigned to each of these well-defined and individually delivered psychosocial treatments. There was little difference in

outcomes by type of treatment” (Project MATCH Research Group, 1997a, p. 7).

What were the “significant and sustained improvements in drinking outcomes” to which the Project MATCH Research Group refers? The aftercare group was abstinent only about 1 in 5 days, and the outpatient group was abstinent only about 1 in 4 days before treatment began, but the aftercare group was abstinent about 95% of the days following treatment, and the outpatient group maintained abstinence a bit more than 80% of posttreatment days. Drinks per drinking day for the aftercare group dropped from fifteen to twenty during the pretreatment period to two to three drinks per drinking day posttreatment; the comparable figures for the outpatient group were eleven to thirteen and three to four drinks. Approximately 35% of the aftercare subjects and 19% of the outpatient subjects reported continued complete abstinence throughout the 12 follow-up months.

When these data are weighed in the light of the study’s design, they permit either a positive or a negative evaluation of the effectiveness of the three Project MATCH treatments, depending on which findings are emphasized. The positive view sees that the findings documented marked reductions in the percentage of days abstinent and drinks per drinking day that reflected the effects of three equally robust treatments, all capable of inducing marked changes in drinking that lasted through a full year of follow-up.

The negative view laments the absence of a control group, which makes it impossible to know whether the changes in drinking were related specifically to the treatments or to other factors. The absence of data beyond the 1-year follow-up mark prevents us from knowing to what extent these gains were sustained. Exclusion criteria which ruled out potential clients who lacked residential stability; showed signs of organic impairment; or met diagnostic criteria for cocaine, sedative/hypnotic, stimulant, or opiate-dependence may have yielded a sample population unrepresentative of clients typically seen at public alcoholism treatment facilities nowadays.

Of concern, as well, is the MATCH authors’ decision not to provide detailed data on the numbers of clients who established and maintained abstinence during the follow-up period. The relatively incomplete data that are provided on abstinence make it difficult to compare Project MATCH

outcomes with those from most other alcoholism treatment outcome studies, including the VA cooperative study. In the absence of detailed data on abstinence, we know only that a substantial majority of Project MATCH clients (65% of the aftercare group and 81% of the outpatient group) consumed alcohol during the follow-up period. These data, although scanty, are telling. Most studies and reviews of recovering alcoholics have concluded that those who continue to drink after treatment, however minimally, are at substantial risk of resuming abusive drinking at some point (Nathan & McCrady, 1987; Nathan & Skinstad, 1987; Schuckit, 1995; Vaillant, 1995).

Veterans Administration Medical Centers Cooperative Study

Ouimette, Finney, and Moos (1997) compared the effectiveness of twelve-step, cognitive-behavioral (C-B), and combined twelve-step-C-B models of substance abuse treatment in a nonrandom clinical trial of 3018 detoxified inpatients in the substance abuse treatment programs of fifteen Department of Veterans Affairs Medical Centers (VAMC). Unlike Project MATCH, the major focus of the VAMC study was a direct comparison of two widely used models for substance abuse treatment. The fifteen sites were selected because they offered twelve-step, cognitive-behavioral, and combined cognitive-behavioral inpatient treatment programs that met the investigators’ criteria for quality and theoretical integrity. The desired length of stay in the programs ranged from 21 to 28 days; all provided both individual and group therapy, and all had multidisciplinary staffing.

Follow-up of treatment extended for a year. Eleven outcome measures were used; five reflected alcohol and drug use, two tapped symptoms of anxiety and depression, and three measured social variables, including arrests, employment, and living situation.

The treatments were described as follows:

Twelve-step programs emphasized treatment activities such as 12-step meetings in the community and hospital, and psychotherapy groups covering topics such as working the steps, the *Big Book*, and writing an autobiography. Treatment targeted the patient’s acceptance of an alcoholic-addict identity, acknowledgment of a loss of control-powerlessness over the abused substance, and adherence to abstinence as a treatment goal. . . . C-B programs required participation in relapse prevention groups, cognitive skills training, behavioral skills

training, abstinence skills training, and small C-B therapy groups. The goals of C-B treatment were to teach more adaptive ways of coping, to enhance the patient's sense of self-efficacy to cope with high-risk relapse-inducing situations, and to modify the patient's expectations of the abused substances' effects such that they were more realistic and appropriate. (Ouimette, Finney, & Moos, 1997, p. 232)

Unlike Project MATCH, which randomized assignment of patients to treatments, the VAMC study used a quasi-experimental design that resulted in significant differences among patients in the three treatment conditions. To this end, C-B programs enrolled significantly higher percentages of non-African Americans; mixed twelve-step-C-B programs inducted patients whose alcohol consumption and heroin use were significantly higher at intake and who were most likely to have had prior outpatient substance abuse treatment; and twelve-step programs treated the highest percentage of African-Americans, the lowest percentage of clients ever to inject heroin, and the lowest percentage of clients with prior detoxification-inpatient substance abuse treatment experience or outpatient treatment experience.

Although twelve-step patients were somewhat more likely to be abstinent and to be employed at the 1-year follow-up mark, patients in all three treatments reduced substance use and improved most other areas of functioning equally at both the end of inpatient treatment and the 1-year follow-up. The finding of equal effectiveness was consistent over several treatment subgroups, including patients who attended the "purest" twelve-step and C-B treatment programs and patients who had received the "full dose" of treatment. Moreover, patients with substance abuse diagnoses alone, those with comorbid psychiatric diagnoses, and those who had not entered treatment of their own volition all showed similar improvement at 1-year follow-up, regardless of the type of treatment received.

At the 1-year mark, however, only 25–30% of the patients were judged to be without a substance abuse problem, only 23–29% were considered to be in remission from their substance use disorder, and only 18–25% had been able to maintain abstinence. These figures represent marked improvements over pretreatment rates, but they are nonetheless disturbing in their prognostic significance. As we noted earlier, a great deal of research suggests that many or most recovering alcoholics who continue to drink even in a controlled fashion

following treatment will ultimately return to abusive drinking.

Pharmacological Interventions

Alcohol-Sensitizing Agents. Antabuse (disulfiram) blocks the chemical breakdown of alcohol; individuals who have ingested Antabuse cannot metabolize alcohol beyond the point at which it has been metabolized in the bloodstream to acetaldehyde. Because acetaldehyde is toxic to the body in very small quantities, when even the smallest amount of alcohol has been consumed by someone who has disulfiram in the bloodstream, an acetaldehyde reaction takes place (Christensen et al., 1991). The alcoholic quickly experiences nausea, vomiting, profuse sweating, and markedly increased respiration and heart rate. Alcoholics who have had an Antabuse reaction say it is an experience that they would do almost anything to avoid.

Alcoholics who take an Antabuse tablet every day are "protected" from the impulse to drink even if they are tempted to do so by alcohol-related cues. Because of the dangers of the acetaldehyde reaction, however, physicians in the United States prescribe disulfiram only to patients who are physically fit, motivated to stop drinking, and fully able to appreciate the consequences if they drink while they are taking the drug.

Some experienced clinicians swear by Antabuse; others find it ineffective. The data on its effectiveness are equivocal (Wright & Moore, 1989), largely because it works well for some patients and not at all for others. Patient differences in sensitivity to the effects of the drug may explain its inconsistent effectiveness. In general, clinicians prescribe Antabuse to give alcoholics a recovery "window" that reduces their risk of succumbing to craving. This grace period permits psychological and behavioral gains that will allow discontinuing Antabuse at some point.

Agents for Managing Withdrawal and Maintaining Sobriety. Two decades ago, clinicians in this country routinely gave alcoholics a benzodiazepine, generally, Librium or Valium, during withdrawal. It was widely assumed that these drugs eased the physical and psychological pains of detoxification and prevented the development of more serious withdrawal phenomena like delirium tremens. Nowadays, however, many clinicians have concluded that relatively few alcoholics experience serious enough withdrawal symptoms to

warrant pharmacological intervention (Wartenburg et al., 1990); as a result, many more patients are routinely detoxified nonpharmacologically.

In years past, antianxiety agents were also given to alcoholics in hopes that the drugs would dampen the anxiety for which many alcoholics self-medicate. Instead, however, many alcohol abusers simply added the abuse of these highly addictive drugs to their abuse of alcohol and other substances. As a result, these drugs are now rarely given to persons dependent on alcohol or other drugs (O'Brien & McKay, 1998).

Anticraving Agents. During the past decade, investigations of several drug classes that act on neurotransmitters in the brain, including serotonin re-uptake inhibitors, dopamine agonists, and opioid antagonists, have led to the development of drugs that have the exciting potential to decrease craving and the reinforcing effects of alcohol. These drugs are promising because they have the potential to prevent, rather than simply treat the effects of, alcohol abuse and dependence.

Serotonin re-uptake inhibitors increase quantities of serotonin in the brain. They have produced modest decreases in alcohol consumption in male heavy drinkers with mild to moderate alcohol dependence (Naranjo et al., 1990); serotonin exerts an anticraving effect. Dopamine agonists also decrease alcohol consumption and self-reported craving because of their effect on concentrations of dopamine in the brain (Dongier et al., 1991); dopamine increases craving. Finally, the opioid antagonist, naltrexone, originally developed to treat opioid dependence by inducing withdrawal and blocking subsequent dependence in opioid addicts, has a substantial impact on alcohol consumption by alcoholics. O'Malley and her colleagues (1992), for example, reported that naltrexone led to a marked decrease in alcohol consumption by outpatient alcoholics because the drug reduces the pleasurable feelings that alcohol induces.

Resolution of Alcohol Problems without Treatment

Although we all know people who have recovered from serious alcohol problems on their own, resolution of alcohol problems without treatment has only recently become a focus of research attention. Watson and Sher (1998) reviewed this literature. Perhaps the most surprising of their conclusions is that natural recovery may be the

major path to recovery from alcohol use disorders; estimates range up to three-quarters of all recovering alcoholics who do so without treatment (Sobell, Cunningham, & Sobell, 1996; Vaillant, 1995).

Unfortunately, methodological problems prevent abundant generalization across empirical studies about self-changers, defined as alcoholics who have recovered without treatment. Watson and Sher (1998) noted that differences across studies in the criteria for judging drinking status pre- and postrecovery, in the time that must pass before a person is considered recovered, and in definitions of what constitutes treatment all make it difficult to generalize across these studies. Lack of sample heterogeneity, a problem of a very different nature, also afflicts this literature. Most reports of alcoholics who recover without treatment are of White, middle-aged males, so there is a paucity of data about self-changers who are non-White, older or younger, and/or female. An additional problem stems from the diverse strategies employed to study natural recovery. Some studies have relied on retrospective assessments either systematically from community samples or unsystematically from volunteers, and others have used prospective designs that assess groups of treatment seekers or nonclinical samples. Although each of these strategies can be justified, they differ sufficiently to further impede efforts to generalize their findings.

Despite these formidable methodological problems, some findings have emerged from this literature with enough consistency to consider them valid generalizations. One of the most intriguing concerns *the processes of self-directed change*, which are the strategies self-changers use to recover and the environmental events that precipitate their recovery. Of the ten processes associated with the well-known change model proposed by Prochaska and his colleagues (Prochaska, DiClemente, & Norcross, 1992), eight frequently mentioned in the self-change literature include consciousness raising, self-reevaluation, environmental evaluation, self-liberation, counterconditioning, stimulus control, reinforcement management, and helping relationships.

The *circumstances that surround the decision to stop drinking on one's own* are also a focus of interest. They include the events that lead to self-recognition of the existence of a drinking problem, concerns about alcohol-related health problems, and role transitions (e.g., marrying, taking a new

job). Researchers have also attempted to study the impact of *individual difference variables on success in self-changing*, including the severity of the alcohol problem, a family history of alcoholism, comorbid psychopathology, antisocial personality disorder, other substance use disorders, and a range of personality traits.

These generalizations are tentative because of the methodological shortcomings in the research to date on self-changers. Nonetheless, they might help clinicians identify persons most likely to self-change, to whom less intensive interventions might be offered to encourage their propensity for self-change. What we learn about self-changers also might help us design more effective treatments for alcoholics who require formal treatment because they are unlikely to change on their own.

Conclusions about Treatment

Despite the results of two large-scale, multisite clinical trials of alcoholism treatments, and several recent comprehensive reviews, we cannot yet point to psychosocial or pharmacological treatments for alcohol abuse and dependence whose efficacy has been proven. Regretfully, significant methodological problems make unequivocal interpretation of the findings from Project MATCH and the VAMC Cooperative Study impossible. Both found that cognitive-behavioral and twelve-step treatments are associated with significant reductions in consumption, and Project MATCH provided additional data attesting to the efficacy of motivational enhancement counseling as well, but the absence of control groups and, in the case of Project MATCH, the form in which the follow-up data were reported make us uncertain whether it was the treatments themselves that brought about the positive changes and what the actual dimensions of those changes were. The fact that substantial numbers of treated patients in both studies were drinking at the conclusion of the follow-up periods convinces us they were at substantial risk of returning to abusive drinking at some point.

At the same time, there is reason for optimism. A start has been made. Project MATCH and the VAMC Cooperative Study have identified three treatments that impact drinking by alcoholics markedly, at least for a time. Nonetheless, controlled research on these treatments that documents their centrality in the change process is necessary, as is research designed to explore effec-

tive treatment variations, including combining promising new medications designed to reduce craving with psychosocial interventions designed to heighten motivation to change, to develop alternatives to the alcoholic lifestyle, and to provide clients with a supportive, alcohol-free social environment.

Cocaine and Opioid Abuse/ Dependence Disorders

**Arthur I. Alterman, Charles P. O'Brien,
A. Thomas McLellan, and James R. McKay**

Introduction

This chapter is concerned primarily with the consequences of cocaine and opioid use, with the psychopathology associated with cocaine and opioid dependence, and with the available treatments to address these disorders. These two disorders are associated, directly or indirectly, with very serious biomedical and psychosocial consequences, particularly because both often involve intravenous drug administration and intercourse with multiple sex partners, the two primary modalities for transmitting the AIDS virus. Significant involvement in criminal behavior may also be associated with drug procurement. These patients generally are very difficult to treat because by the time they are seen for treatment, many of them have multiple biomedical problems, directly or indirectly traceable to their substance dependence, as well as psychosocial problems and psychiatric disorders including polysubstance abuse. Thus, a treatment model that considers that substance dependence disorders are chronic over the lifetime in the same sense as diabetes or hypertension is in-

creasingly being adopted (Majewska, 1996; O'Brien & McLellan, 1996). Although we will consider each of the disorders separately in this chapter, it is important at the outset to appreciate that polydrug abuse/dependence is likely to be more common than abuse/dependence of only one drug in many, perhaps the majority, of patients seen (Bartzokis, Beckson, & Ling, 1996). For example, cocaine, benzodiazepine, and alcohol abuse/dependence are clearly problems in many patients who are opioid-dependent, and concurrent alcohol abuse/dependence is present in the majority of cocaine-dependent patients. Marijuana dependence is also highly prevalent in both opioid and cocaine dependence. The existence of these multiple substance dependence disorders clearly complicates treatment, and the adverse interactive effects between two drugs can be far more serious than the combination of their individual effects. For example, in cocaine use, even limited exposure to amphetamines can have severe neurotoxic consequences (Bartzokis et al., 1996). Finally, the geometric growth of managed care treatment systems that have and are taking place in the United States makes it clear that the nature of treatments for substance abuse/dependence are and will be changing markedly. Although there is yet only limited research knowledge about the effects of managed care practices on substance abuse treatment, it has become increasingly clear that cost considerations are greatly influencing the nature and quantity of the treatment services dispensed.

Cocaine Abuse/Dependence

Medical Consequences of Use

Coca leaves have been chewed by South American Indians for several centuries, and cocaine hydrochloride (HCl) has been used since it was isolated in the middle of the nineteenth century by Niemann (Daras, 1996; O'Brien, 1995). Untoward effects related to chewing the leaves or intranasal insufflation of cocaine HCl had been rare. The introduction in 1983 of the alkaloidal form of cocaine, known as crack (Jekel, Allen, Pollewski, Clarke, Dean-Paterson, & Cartwright, 1986), led to the cocaine epidemic in the United States followed by a corresponding rise in the incidence of medical, neurological, and psychiatric complications. Cocaine toxicity manifests itself at the level of nearly every organ system; the most dramatic changes occur in the cardiovascular system, liver, and the brain (Majewska, 1996). "In the cardiovascular system, tachycardia, hypertension, ruptures of blood vessels, arrhythmias, and arteriosclerotic lesions are typical complications that often precede myocardial ischemia and infarction" (Majewska, 1996, p. 2; also see Karch, 1993). Cocaine is directly toxic to the myocardium (Volkow, Fowler, & Ding, 1996). Cocaine is hepatotoxic in humans (Marks & Chapple, 1967) and in animals (Mehanny & Abdel-Rahman, 1991). This hepatotoxicity is enhanced by other drugs such as barbiturates, alcohol, and cocaine adulterants such as amphetamine (Majewska, 1996). Cocaine also induces pulmonary disorders that are particularly severe in cocaine smokers. These disorders include inflammation of and lung infections, pulmonary congestion, edema, hypertrophy of pulmonary arteries, and pulmonary necrosis (Karch, 1993). Cocaine abuse in humans can lead to seizures (Holand, Marx, Earnest, & Ranninger, 1992), optic neuropathy, cerebral infarction (Sloan & Mattioni, 1992), subarachnoid and intracerebral hemorrhage, multifocal cerebral ischemia, cerebral atrophy, and myocardial infarction that leads to global brain ischemia and edema (Daras, Tuchman, & Marks, 1991; Fredericks, Lefkowitz, Challa, & Troost, 1991). Of note, cocaine abuse is a significant risk factor for cerebrovascular complications in young adults (Kaku & Lowenstein, 1990) in whom traditional risk factors are frequently missing (Levine, Brust, Futrell, et al., 1990). Ethanol intoxication has also been associated with strokes

(Gorelick, 1987). Combining both drugs induces more adverse cardiovascular effects in healthy volunteers than cocaine alone (Perez-Reyes & Jeffcoat, 1992). Seizures are not confined to those who abuse cocaine but have also been observed in recreational users of cocaine (Daras, 1996). Headaches are frequently experienced following cocaine use (Dhopes, Maany, & Herring, 1990; Washton & Gold, 1984). These are not always benign and may herald the onset of an acute cerebrovascular accident (CVA; Daras, 1996). There have also been reports of CVAs in neonates whose mothers were addicted to cocaine (Daras, 1996). Thus, cocaine is truly a medically dangerous drug. Importantly, more than 23 million people in the United States have used cocaine at some time in their lives (O'Brien 1996).

Psychopathology Associated with Cocaine Abuse

Morphological, physiological, and neurochemical neurological abnormalities in chronic drug abusers have been demonstrated by using modern diagnostic techniques such as positron emission tomography (PET), computed axial tomography (CAT), magnetic resonance imaging (MRI), and single photon emission computed tomography (SPECT; Bartzokis et al., 1996; Cascella, Perrison, Wong, Broussole, et al., 1991; Langendorf, Anderson, Tupper, Rottenberg, & Weisman, 1996; Pascual-Leone, Dhuna, & Anderson, 1991). Various degrees of cerebral atrophy and brain lesions, particularly in the frontal cortex and basal ganglia, have been found in cocaine abusers (Bartzokis et al., 1996; Langendorf et al., 1996; Pascual-Leone et al., 1991). Cerebral circulatory deficits have also been noted by other investigators (Kosten, Malison, & Wallace, 1996). Typically, frontal lobe degeneration is accompanied by dementia, neuropsychological deficits, apathy, depression, and social disinhibition. Such brain changes in conjunction with abnormalities in catecholamine receptors and re-uptake carriers induced by chronic cocaine usage may underlie the apathy and depression that are common in cocaine abusers (Kosten et al., 1996). Cognitive impairments in cocaine users were described as long ago as 1908 (Daras, 1996). Buck and colleagues (Buck, Sasaki, Hewitt, & Macrae, 1968) described psychological impairment and poor work performance in South American coca leaf chewers. Subsequent studies demon-

strated subtle deficits in auditory recall, concentration, and reaction time (O'Malley, Adamse, Heaton, & Gawin, 1992b; Weinrieb & O'Brien, 1993) that suggest an underlying problem in information processing (Herning & King, 1996). Theoretically, such deficits should adversely influence the ability to benefit from psychosocial treatment, although there is still surprisingly little evidence that superior cognitive abilities are associated with better treatment response by substance abusers (Alterman, Kushner, & Holahan, 1990).

Just as for other substance abuse/dependent patients, the majority of cocaine-dependent patients have considerable Axis I pathology, including additional substance abuse disorders (Halikas, Crosby, Pearson, Nugent, & Carlson, 1994; Rounsaville, Anton, Carroll, Budde, Prusoff, & Gawin, 1991; Ziedonis, Rayford, Bryant, & Rounsaville, 1994). The more common diagnoses include alcohol dependence, major depression, bipolar disorder, phobias, posttraumatic stress disorder (Cottler, Compton, Mager, Spitznagel, & Janca, 1992), antisocial personality disorder (APD), and a history of childhood attention deficit disorder (ADD). APD is as common a diagnosis in cocaine abuser/dependent patients as in opioid abuser/dependent patients (see later), contrasted with the relatively lower rates found in alcohol abuser/dependent patients. The presence of ADD may reflect the efforts of these patients at self-medication. Phobias, ADD, and APD precede the onset of cocaine addiction, whereas depression and alcoholism frequently follow it. In this regard, a residual mood disorder may be seen after cocaine withdrawal and may in some cases require antidepressant medication (O'Brien, 1996). Paranoia and anhedonia are also often observed in chronic cocaine abusers (Kosten et al., 1996; O'Brien, 1996). Thus, the majority of cocaine patients present with comorbid psychopathology. Unemployment, absence of housing arrangements, and legal and family problems are also barriers to effective treatment that often need to be addressed in the treatment process.

Treatment of Cocaine Abuse/Dependence

Lacking a drug substitution method analogous to methadone maintenance or a specific antagonist similar to naltrexone, the initial response of the treatment community to cocaine dependence was to adopt the abstinence-oriented, staged model of

alcoholism treatment. The data on the effectiveness of psychosocial treatments for cocaine dependence as well as recent intensive efforts to facilitate the initiation of abstinence by pharmacological means will be described.

Withdrawal. Although there is no definitive evidence that cocaine produces a withdrawal syndrome such as seen with alcohol, opiates, or sedatives, there is definitely a period of physical and mental instability following continuous use of cocaine, and this has been termed the "withdrawal" period (Schuckit, 1997). The withdrawal effects of cocaine are irritability, weakness, a marked reduction in energy, hypersomnia, depression, loss of concentration, increased appetite, and paranoid ideation (hallucinations and delusions). If paranoid effects occur, they usually last from 2 to 14 days, but can last longer. Kleber (1995) indicates that the symptomatology following the initial barrage of unpleasant symptoms, commonly called the "crash," differs for outpatients and inpatients. In cocaine inpatients, the crash appears "to be followed by gradual improvement in the cocaine-induced impairment with normalization of sleep, energy, and hedonic response" (p. S97). By contrast, "In outpatients, where cocaine availability and craving remain high, the crash is followed by a few days of apparent normalcy. The next phase is a prolonged period of chronic dysphoria and diminished pleasurable responses to the environment" (Kleber, 1995, p. S97). Because cocaine is typically used intermittently, even heavy users experience periods of withdrawal or "crash" (O'Brien, 1996). As indicated, a residual mood disorder may be seen after cocaine withdrawal in some patients (O'Brien, 1996). Because of limited bed capacities, inpatient detoxification is generally limited to cases in need of immediate psychiatric (drug-induced psychosis) or medical (pregnancy, myocardial damage) attention, as there is no effective existing treatment for the abstinence symptomatology during the withdrawal period.

Whether or not the withdrawal symptomatology following cocaine abstinence qualifies for the formal designation of a withdrawal syndrome, the dysphoric psychological state and the physiological instability associated with cocaine abstinence contribute to the considerable difficulties in retaining cocaine-dependent patients in outpatient treatment (Hoffman, Caudill, Koman, Luckey, Flynn, & Hubbard, 1994). Consequently, there has been an intensive effort to evaluate effective psycho-

social and pharmacological treatments for cocaine abstinence symptomatology. A recent study at our University of Pennsylvania Center indicated that a measure of cocaine withdrawal/abstinence symptomatology, the Cocaine Selective Severity Assessment (CSSA), modeled after measures of the alcohol withdrawal syndrome (AWS), was successful in predicting early dropouts from treatment (Kampman et al., 1998). More effective ways of dealing with this abstinence symptomatology are an important starting point in increasing the effectiveness of treating cocaine dependence.

Psychosocial Treatments

High Attrition Rates. As indicated, one of the more difficult problems for the outpatient treatment of cocaine dependence is the high attrition rates. In this regard, Kang and colleagues (Kang, Kleinman, Woody, et al., 1991) found that a treatment program that provided once weekly psychotherapy, nearly half of the treatment candidates (47%) dropped out before the treatment began and 31% completed fewer than six sessions. In a 12-week study of once weekly psychotherapy and/or pharmacotherapy, Carroll et al. (Carroll, Rounsaville, Gordon, Nich, Jatlow, Bisighini, & Gawin, 1994a) reported that 21% of the patients failed to complete 2 weeks of treatment and that only 49/139 (35.2%) completed the full 12 weeks of treatment. In an earlier comparison of two forms of psychosocial treatment for cocaine dependence, Carroll and colleagues (Carroll, Rounsaville, & Gawin, 1991) reported that 24% of the patients dropped out after 1 week of the projected 12-week, once per week course of treatment. Similarly, Higgins et al. (Higgins, Budney, Bickel, Hughes, Foerg, & Badger, 1993) reported that eight (42%) of the patients attending a 3.5-hour per week twelve-step treatment program failed to attend more than one treatment session. Hoffman et al. (1994) also found drop-out rates of 56% within the first week of treatment that provided 90 minutes of group therapy twice weekly.

Effective Psychosocial Treatments. Notwithstanding the evidence for high attrition rates, there is accumulating evidence that treatment for cocaine dependence can be relatively effective, even for patients with relatively limited social resources.

Higgins and colleagues (Higgins, Delaney, Budney, Bickel, Hughes, Foerg, & Fenwick, 1991;

Higgins, et al., 1993) presented evidence that a behavioral treatment that combined contingency reinforcement for those whose urines are negative for cocaine (not for other drugs) and aspects of Azrin's community reinforcement (CRF) treatment approach—marital, job, and recreational counseling (Azrin & Besalel, 1980; Azrin, Naster, & Jones, 1973)—was effective in bringing about abstinence from cocaine during a 12-week study/treatment period. Subjects were thirteen consecutively admitted outpatients who received the behavioral treatment and fifteen consecutively admitted outpatients offered twelve-step counseling. Thus, the study participants were not randomly assigned. Urines were taken four times weekly for all subjects, and no contingencies were attached for the twelve-step patients. Patients who participated in the behavioral program could earn approximately \$1000 worth of points for abstinence during the course of the twelve treatment weeks which could be exchanged for merchandise or services, and twelve-step patients could earn \$240 for giving forty-eight urines during this period. The CRF component of treatment was implemented in twice weekly 1-hour sessions, and the twelve-step counseling consisted of 2 hours of treatment weekly and encouragement to attend at least one self-help group weekly.

Eleven of thirteen behavioral patients completed treatment, as contrasted with five of fifteen 12-step patients. This treatment completion rate for the behavioral program, in itself, is relatively remarkable. Ten of thirteen behavioral patients achieved 4 weeks of abstinence compared with only 3/15 for the twelve-step treatment, and 3/13 were abstinent for all 12 weeks. None of the twelve-step patients achieved even 8 weeks of abstinence. Ninety percent of 552 urines obtained in the behavioral treatment program and 78% of the 312 from the patients who received twelve-step counseling were free of cocaine.

In a second study (Higgins et al., 1993), thirty-eight patients were randomly assigned to either the behavioral or drug abuse counseling treatment. The behavioral treatment was much like that in the earlier study, and the drug counseling program was similar to the twelve-step program implemented in the earlier program. The counseling consisted of one 2.5-hour group and one 1-hour individual therapy session per week for 12 weeks. Both treatment programs were extended an additional 12 weeks through 24 weeks. During weeks

13–24, counseling was reduced to once weekly for both treatment groups, and three times weekly urine monitoring was reduced to twice weekly. Behavioral subjects could earn approximately \$1000 exchangeable for merchandise/services during the first 12 treatment weeks and they were given a \$1 state lottery ticket for each clean urine during the weeks 13–24 treatment “fading” period. Drug counseling patients continued to receive \$5 for each urine, independent of its status.

The results for this latter study were similar to those obtained for the earlier study. A 58% treatment completion rate was obtained for the behavioral patients for the 24 weeks of treatment versus only 11% for drug counseling patients. Although 68 and 42% of the behavioral patients achieved at least 8 and 16 weeks of continuous cocaine abstinence, respectively, these rates were 11 and 5% for drug abuse counseling patients. There was little evidence of a precipitous decline in functioning for the behavioral patients following the removal of the higher intensity treatment/contingency. A subsequent study has now extended the outcome findings to 1-year posttreatment entry and shows that the gains can be sustained through this period (Higgins, Budney, Bickel, Badger, Foerg, & Ogden, 1995).

A study of cocaine dependence treatment by Alterman and colleagues (1994) compared the effectiveness of 4 weeks of intensive, highly structured day hospital (DH—27 hours weekly) treatment with that of inpatient treatment (INP—48 hours of weekly scheduled treatment) with the same treatment elements. The subjects were primarily inner city, male African-Americans treated at a Veterans Administration Medical Center. Fifty-six patients were randomly assigned to the DH and fifty-five to the INP. Group therapy was the primary treatment, and emphasis was on initiating abstinence, a drug-free lifestyle, and education about substance abuse. Both programs endorsed the self-help philosophy and expected participation in self-help groups. Both cocaine- and alcohol-dependent patients were concurrently treated in both programs. Additional treatments available were individual counseling and case management, pharmacotherapy, medical treatment, and recreational and family therapies.

The INP treatment completion rate of 89% was significantly higher than that of the DH treatment (54%). However, at 7 months posttreatment entry, self-reported outcomes indicated considerable im-

provements in both groups for drug and alcohol use, family/social, legal, employment, and psychiatric problems in a variety of Addiction Severity Index measures. The finding of reduced cocaine use was supported by urine data. Both self-report and urine data indicated 50–60% abstinence for both groups at the follow-up assessment. The costs of the DH were about 40% lower than those of the INP treatment.

Several studies by Carroll and colleagues provide further indication of the effectiveness of outpatient treatment for cocaine dependence. An initial study (Carroll et al., 1991) compared the effectiveness of a once per week, 12-week treatment course of individual relapse prevention therapy (RPT) with that of individual interpersonal therapy (IPT) for forty-two randomly assigned patients. Overall, 31% of the subjects were classified as recovered when treatment ended, and 52% completed treatment.

In a subsequent study, Carroll and her colleagues compared the effectiveness of RPT with that of clinical management (CM—standardized form of basic administrative management and minimal clinical support) in an evaluation of the effectiveness of the medication, desipramine (DMI). In that study of 139 cocaine-dependent patients (Carroll, Power, Bryant, & Rounsaville, 1993; Carroll, et al., 1994a), the investigators found evidence of reduced cocaine use and psychosocial and medical problems over the course of treatment, and these reductions were maintained during a 1-year posttreatment follow-up period. As in their earlier work, there was an indication that RPT was the more effective psychosocial treatment. One interesting aspect of that study was a delayed effect of the RPT treatment. At 6 months posttreatment, there were modest differences between the RPT and CM groups; but at the 12-month point, the differences (favoring RPT) were much greater (Carroll, Rounsaville, Nich, Gordon, Wirtz, & Gawin, 1994b). These findings are similar to those of two studies by Woody and colleagues who compared professional psychotherapy with standard drug counseling for methadone maintained patients (Woody, Luborsky, McLellan, O'Brien, Beck, Blaine, et al., 1983; Woody, McLellan, Luborsky, & O'Brien 1995).

Finally, research by Hoffman et al. (1994) shows the contribution of more intensive treatment to increased treatment retention during a 4-month treatment period. This study compared two levels

of intensity of group treatment: either 90 minutes, twice weekly or 120 minutes, five times weekly. Each group therapy condition was also supplemented by one of three individual therapy conditions varying in intensity: (1) no additional treatment, (2) individual psychotherapy (twice weekly in the first month and weekly thereafter), and (3) individual psychotherapy plus weekly family therapy beginning in the second month. The findings revealed that the highest drop-out rates were for the low-intensity group treatment without supplemental individual treatment. Fifty-six percent of the patients in this group dropped out of treatment within the first week. This contrasts with an average drop-out rate of about 35% for five other groups. Similar findings obtained for predicting retention in treatment for 3 months or more. This was only 14% for the low-intensity treatment and about 30% for the five other treatment conditions. Thus, any increase in intensity of treatment above that provided by the twice weekly group therapy, whether it took the form of additional individual therapy or more intensive group therapy, resulted in notable increases in retention. Adding individual treatments to the intensive group therapy condition failed to increase treatment retention.

Summary of Psychosocial Treatment. It is likely that the inability to treat the symptomatology associated with initial abstinence from cocaine in an outpatient setting is a significant contributor to the high early patient drop-out rates that are found in most outpatient treatment programs for cocaine dependence. As indicated previously, higher scores on the CSSA, a measure of withdrawal/abstinence symptomatology, predicts treatment dropout. In addition, we have found in two separate studies (Alterman, McKay, Mulvaney, & McLellan, 1996a; Alterman, Kampman, Boardman, Rutherford, Cacciola, McKay, & Maany, 1997) that a positive initial cocaine urine toxicology, an indication of the patient's inability to achieve abstinence, as well of the severity of cocaine dependence, is highly predictive of treatment dropout. Thus, a beginning is being made in identifying individuals at "high risk" of dropping out of outpatient treatment. Providing incentives to patients or more intensive treatment can help to mitigate the adverse influences which bring about early treatment dropout. Other forms of psychosocial treatment such as motivational enhancement treatment (MET; Miller, Zweben, DiClemente, & Rychtarik, 1992), derived from the alcoholism

field, are being examined for their effectiveness. Additionally, the stage of change measures (Prochaska & DiClemente, 1984) that have recently been used in the alcoholism treatment field (Project Match Research Group, 1997) are being introduced to the field in another effort to enhance the effectiveness of treatment for cocaine dependence. Pharmacotherapy is an alternative/complementary approach to treating cocaine dependence.

Pharmacotherapy

Primary Medications Studied. The reinforcing effects of cocaine and cocaine analogues correlate best with their effectiveness in blocking the dopamine (DA) transporter. This re-uptake blockage results in excess synaptic DA and thus increased DA stimulation at critical brain sites. Cocaine also blocks both norepinephrine (NE) and serotonin (5HT) re-uptake, and chronic use produces changes in these systems, as measured by reductions in the neurotransmitter metabolites MHPG (3-methoxy-4 hydroxyphenylethylene glycol) and 5-HIAA (5-hydroxyindoleacetic acid). Thus, neurotransmitters other than DA may be involved after a period of heavy cocaine use (O'Brien, 1996). Most efforts to identify medications that would be effective in treating patients with cocaine use disorders have been directed toward finding agents that either correct alterations in neurochemical substrates brought on by chronic cocaine use or block the reinforcing effects of cocaine (Kleber, 1995). Although there have been a number of promising leads, no pharmacological agent has yet generated consistent evidence of effectiveness in reducing cocaine use (Kleber, 1995; O'Brien, 1996; O'Brien & McKay, 1997). Several studies evaluated the effects of tricyclic antidepressants, selective serotonin re-uptake inhibitors (SSRIs), and MAO-Is (monoamine oxidase inhibitors). The findings of Nunes and colleagues (Nunes, McGrath, Quitkin, Ocepek-Welikson, Stewart, Koenig, et al., 1995), for a 12-week placebo-controlled trial of imipramine (150–300 mg/daily) in 113 cocaine abusers, are noteworthy. In this study, there was some indication of higher abstinence rates, defined as three consecutive confirmed urine-negative weeks, in the group on imipramine (IMI; 19 vs. 7%). There was also suggestive evidence that these effects were stronger for depressed users of IMI (26% IMI versus 13% PL). Other drugs that influence the DA system have

also been tried. Amantadine, a drug that stimulates dopaminergic transmission may have short-term efficacy as an aid in detoxification because cocaine urines for twenty-one subjects on amantadine during a 10-day trial were significantly more negative during a 1-month period than those of twenty-one placebo subjects (Alterman, Droba, Cornish, Antello, Sweeney, Parikh, & O'Brien, 1992). This study was conducted in the context of the 27-hour per week DH psychosocial treatment. A second study (Kampman, Volpicelli, Alterman, Cornish, Weinrieb, Epperson, et al., 1996) by investigators at the same Center did not replicate these findings, although unpublished findings from this latter study indicate that patients with high CSSA scores at treatment outset did benefit from amantadine (Kampman, 1999). It should be noted that the psychosocial treatment was much less intensive in this latter study.

Other Medications. The kindling phenomenon has been the target of studies using carbamazepine, an anticonvulsant, but several controlled studies failed to demonstrate any benefit (Cornish, Maany, Fudala, Neal, Poole, Volpicelli, & O'Brien, 1995; O'Brien, 1996). Selective serotonin re-uptake inhibitors were also studied. Fluoxetine reportedly produces a significant reduction of cocaine use in methadone maintenance patients, as measured by lower average urinary levels of the cocaine metabolite benzoylecgonine. It is not clear that the reduced levels of benzoylecgonine represent a clinically significant change in patient outcome (Batki, Manfredi, Jacob, & Jones, 1993). These findings have thus far not been replicated in primary cocaine abuse patients (Grabowski, Rhoades, Elk, Schmitz, Davis, Creson, & Kirby, 1995). An interesting line of research recently described by (Kosten, 1996) involves the use of an N-methyl-D-aspartate (NMDA) regulated neurotransmitter, lamotrigine, to combat neurotoxicity resulting from chronic cocaine use. Initial findings demonstrated the drug's safety during acute cocaine administration, a reduction in cocaine use by the outpatient subjects, and selective improvement in cognitive functioning. Finally, open-label pilot research conducted at our Center showed that the medication propranolol had higher retention rates (80%) during the 7-week drug trial than nefazodone, a combination of phentermine and fenfluramine, or a multivitamin control condition (Kampman, McGinnis, Volpicelli, Ehrman, Robbins, & O'Brien, 1996). A trend for reduced co-

caine use, as measured by urine toxicologies, was also revealed for propranolol. A number of potential mechanisms may underlie the effect of propranolol, including a reduction in noradrenergic activity that may ameliorate cocaine craving and in the anxiety associated with abstinence from the drug. A double-blind study is underway to further evaluate effectiveness.

Summary of Treatment for Cocaine Dependence

Our review of psychosocial treatments for cocaine dependence indicated that intensive outpatient treatments in various forms can be relatively effective. The major problem in outpatient treatment is treatment dropout. However, given the current environment in which treatments are becoming increasingly less, rather than more, intensive, it is quite possible that the effectiveness of treatment will decline in the coming years. With regard to pharmacological treatment, several promising drugs are being evaluated that take advantage of distinctive mechanisms. Further, the National Institute of Drug Abuse is currently funding a number of Centers nationally that are dedicated to evaluating the efficacy of promising medications. Thus, there is the possibility that evidence for one or more effective drugs will be established within the coming 5 to 10 years. However, in the same sense that most opiate-dependent persons choose not to use naltrexone (see later), the question remains whether the majority of patients will be inclined to use this medication(s). Finally, an important consideration in regard to the effectiveness of medications is the psychosocial treatment context within which the medication is administered. Research by Carroll and her colleagues with cocaine-dependent patients (Carroll et al., 1994a,b), by Volpicelli and O'Malley and their colleagues (O'Malley, Jaffe, Chang, Schottenfeld, Meyer, & Rounsaville, 1992a; Volpicelli, Alterman, Haysida, O'Brien, & Muentz, 1992) with alcohol-dependent patients, by Rounsaville and colleagues (Rounsaville, Glazer, Wilber, Weissman, & Kleber, 1983) and Woody and colleagues (Woody et al., 1983) with opiate-dependent patients, and by Glassman and Covey (1995) and Hall and colleagues (Hall, Munoz, Reus, & Sees, 1996) working with nicotine-dependent patients uniformly suggests that psychosocial interventions can be combined with pharmacological interventions in

treating dependence disorders and also that the addition of psychosocial support and services may be necessary to achieve the full potential from even clearly effective medications. Ultimately, there is a need for studies that will specify the optimal mix of medication and psychosocial interventions for these disorders. In addition, there is a need for research designed to identify methods for increasing medication compliance so that the full potential from efficacious medications can be realized in real-world settings.

Opioid Abuse/Dependence

Overview

There is some evidence that opioid dependence is increasing in the United States (Kosten & Stine, 1997), and there is the possibility that opioid dependence will replace cocaine dependence as the latest major epidemic in this country. An influx of new users of heroin is being seen, which is one indicator of an epidemic. This epidemic is attributable to a change in the supply side of heroin; new sources are available from Mexico and South America with a much greater purity and lower cost than was available 5 years ago (Kosten & Stine, 1997; O'Brien & McKay, 1997). Because of higher purity, snorting and smoking of heroin is now possible and is being seen. Thus, recent estimates were that there are currently 2 million heroin abusers in the United States (Woody & McNicholas, 1996), but the prevalence may become substantially higher in the near future.

It is important to point out that opioid dependence has been a serious problem in this country for a considerably longer time than cocaine dependence and also that the nature of the two forms of illicit drugs also differ markedly. Accordingly, research and treatment for opioid dependence do not always follow a course parallel to that for cocaine dependence.

A large body of studies conducted in the 1970s revealed that opioid-dependent patients, just as the cocaine-dependent patients previously described, suffer from other forms of psychopathology (Brooner, King, Kidorf, Schmidt, & Bigelow, 1997). Later in this chapter, we describe the findings of a series of studies that systematically examined psychopathology and the relationship between psychopathology and treatment response in

opioid-dependent patients. Investigations of the relationship between psychopathology and treatment response was not described for cocaine-dependent patients because the investigation of this question for these patients has not been nearly as systematic or thorough.

The medical consequences of opioid dependence are also not discussed in this section, because unlike cocaine use, there are virtually no toxic effects from normal doses of opiates or opioids (Kreek, 1992). The significant medical problems associated with opioid dependence result primarily from drug overdose (Kosten & Stine, 1997) or the use of contaminated injection equipment (HIV/AIDS, hepatitis; Woody & McNicholas, 1996).

Just as for other addicting drugs, opiate addiction is seen as a chronic, relapsing disorder (Cooper, 1989; O'Brien & McLellan, 1996; Woody & McNicholas, 1996). There are four major forms of treatment for this disorder: maintenance drug treatment, antagonist drug treatment, residential/therapeutic community treatment, and outpatient drug-free treatment. Managed care restrictions on funding during the past several years have restricted the availability of therapeutic community treatment (National Academy of Sciences, 1996), but residential treatments still exist for selected patients.

Many addicts who relapse need detoxification. Opioids produce marked physiological dependence and withdrawal symptomatology, in contrast to cocaine (Kleber, 1994; Woody & McNicholas, 1996) which requires medical detoxification. Detoxification is often presented as a treatment (and reimbursed by insurance), but research continues to suggest that it should be considered only a first step in a comprehensive rehabilitation program. The distinctions between rehabilitation and "continuing care" are not clear in the treatment of opiate addiction—at least not as it pertains to agonist or antagonist (e.g., methadone, naltrexone, or other medication) maintenance models of treatment. The term aftercare has been applied to the treatment of opioid dependence, but its meaning differs from that connoted for alcohol/cocaine dependence, that is, aftercare has been used to describe a much reduced schedule of treatment for highly stabilized, methadone maintained addicts which could be of value in opening up resources for a greater number of new patients (Cooper, 1989), rather than an emphasis on a qualitatively

different form of treatment. This stage of treatment is often also called the supportive phase (Woody & McNicholas, 1996). The following section of this chapter will discuss the detoxification process for opioid dependence. This section will be followed by a discussion of pharmacological and psychosocial treatments for opiate dependence.

Detoxification

Opiate detoxification is generally implemented in one of two situations. If a patient has been stabilized on methadone for a number of years, appears to have the ability to be drug-free, and communicates this interest, detoxification can be accomplished by using a tapered methadone schedule for several months, which in limited cases can extend over an even longer period (Woody & McNicholas, 1996). This process can be implemented on an outpatient basis, although hospitalization is sometimes helpful at the end of detoxification when the dose is less than 20 to 25 mg. Clonidine or lofexidine are often helpful in blocking signs and symptoms of withdrawal related to autonomic hyperactivity. However, Cushman (1974) showed more than two decades ago, that only a small proportion of detoxification candidates can remain free of opiates for an extended period of time. As with detoxification alone for alcohol/cocaine dependence, detoxification without additional treatment is not recommended. Detoxification is also properly used as an initial stage of treatment for opiate dependence, usually for heroin addicts who prefer not to participate in methadone maintenance and wish to enter into a drug-free outpatient treatment or narcotic antagonist (naltrexone) treatment or into drug-free therapeutic communities.

Numerous detoxification techniques have been proposed. The most commonly used method involves transferring a patient from a short-acting opiate such as heroin to a long-acting opioid such as methadone which blocks symptoms of withdrawal by cross-tolerance. The dose of methadone can then be gradually reduced according to a predetermined schedule, adjusted as needed if the patient reports discomfort or shows signs of a withdrawal syndrome. Clonidine and lofexidine are two nonopioid medications that can block many of the signs and symptoms of opiate withdrawal. The effectiveness of lofexidine in this

regard is currently undergoing evaluation. These drugs can be quite useful when opioids for detoxification are not available. In all detoxification methods, prompt relapse is likely unless the patient becomes engaged in a long-term aftercare program (O'Brien, 1996; O'Brien & McKay, 1997). A relatively new form of detoxification has received considerable attention during the past several years. Twenty-four hour detoxifications from opiates have been accomplished in offices using a combination of a nonopiate sedative to put patients to sleep, followed by administration of increasing doses of a short-acting opiate antagonist, such as naloxone, to displace all opiates from receptor sites. This process can be accomplished while the patient is asleep and, it has been claimed, produces a drug-free state that is unaccompanied by withdrawal symptoms (benzodiazepines and clonidine are sometimes used to medicate low-level residual withdrawal). This rapid detoxification procedure (Loimer, Lenz, Schmid, Presslich, 1991) has been attractive to many clients because of its speed and the claims that it avoids withdrawal symptoms. However, at this time, this process has not been carefully evaluated for efficacy or safety, and it remains controversial because it requires anesthetization. Research is needed to determine the effectiveness of this technique.

Rehabilitation

Maintenance substitution treatment with methadone, levo-alpha-acetylmethadol (LAAM), or buprenorphine are first discussed followed by consideration of antagonist treatment. This is then followed by consideration of psychosocial treatments for opioid dependence.

Maintenance Treatment. *Methadone.* Some opioid addicts can detoxify and remain drug-free, but the majority relapses, even after intensive psychotherapy (Cushman, 1974; State of Oregon, 1996; Gerstein, Johnson, Harwood, Fountain, Suter, & Malloy, 1994). More important, many heroin addicts will not even consider drug-free treatment. In this regard, it is noteworthy that although the sustained stimulation from cocaine cannot be maintained over long periods, the sedation from heroin leads to sustainable long-term dependence (Kosten & Stine, 1997). Thus, the majority of opioid-dependent patients are treated by a form of substitution therapy. Approximately 120,000 individuals currently receive methadone maintenance

(MM) treatment in the United States. MM, developed in the 1960s, consists of transferring the patient from heroin, a short-acting opiate that must be taken by injection two to four times daily, to methadone, a long-acting opioid that need be taken only once daily by mouth. Methadone substitutes for heroin, reduces drug-seeking behavior, and blocks opiate withdrawal symptoms (O'Brien, 1996). It stabilizes physiological systems because of its long duration of action in contrast to the short action of heroin which produces ups and downs (Kreek, 1992). Typically, patients continue to use some heroin during the first few weeks or months on methadone, but usually in reduced amounts and frequency. Methadone does not block the effects of heroin, but it produces cross-tolerance to heroin and all similar drugs. Thus, the effects of usual doses of heroin are diminished; over time the typical patient decreases heroin use further and may stop using heroin entirely (O'Brien & McKay, 1997; Woody & McNicholas, 1996).

The changes produced by transfer to a long-acting opioid are significant. Several reviews of the opioid dependence literature have concluded that in-treatment performance, measured by decreased use of narcotics and other illicit drugs, decreased criminal activity, and increased social productivity, improves in a direct linear relationship to the length of time spent in treatment (Cooper, 1989; Ball & Ross, 1991; O'Brien, 1996). With respect to length of time in treatment, on average, 40 to 50% of newly admitted patients leave outpatient or residential drug-free treatment within the first 3 months of treatment, compared with an average 14% dropout rate in well-run methadone maintenance programs (Cooper, 1989). Importantly, a large number of studies based on a variety of nonexperimental strategies have produced consistent evidence that MM is associated with lower HIV positive rates (Caplehorn & Ross, 1995; Metzger et al., 1993; Metzger, Navaline, & Woody, 1998; Moss, Vranizan, Gorter, Bachetti, Watters, & Osmond, 1994; Novick, Joseph, Croxon, et al., 1994; Serpelloni, Carriere, Rezza, Morganti, Gomma, & Binkin, 1994). The primary mechanism for this reduction is lower needle injection rates associated with treatment participation (Caplehorn & Ross, 1995; Metzger et al., 1998). Indeed, as Metzger and his colleagues (1998, p. 98) point out, "Given the hidden nature of drug use and its social stigmatization, substance abuse treatment provides a location for the delivery and evaluation

of HIV prevention interventions." In this light, research such as that reported by Zanis and colleagues (Zanis, McLellan, Alterman, & Cnaan, 1996), in which outreach efforts may be successfully employed to return discharged MM patients to treatment, takes on increased importance. Thus, there are reasons related to public health to retain patients in methadone maintenance.

As indicated, considerable evidence has been reported that well-run methadone maintenance (MM) programs, which include structured counseling and other problem-oriented treatment, are effective (Cooper, 1989; Dole, 1989). One of the primary requirements is prescribing a sufficient daily dose of methadone. Dole (1989) described unpublished data by Ball (also see Ball & Ross, 1991) that revealed an inverse relationship between the percentage who used heroin during the past month and the dose of methadone hydrochloride prescribed. Daily doses of 60 mg/day and above were associated with no heroin use. That is, a blood level of methadone at concentrations greater than 150 ng/mL is necessary to stop illicit opiate use. However, it is not as clear that the dose levels described by Dole (1989) are as effective now as they once were. Recently, high purity heroin in the United States has become cheaper (Kosten & Stine, 1997). Thus, the average street heroin addict is likely to have a higher level of physiological dependence. This has necessitated higher doses of methadone to prevent withdrawal and to produce sufficient cross-tolerance to counter the effects of very potent heroin. Although very few treatment outcome studies have been done under these new circumstances, there is anecdotal evidence that methadone treatment may be less effective or at least more difficult in the era of cheap and potent heroin (Bickel & Amass, 1995; O'Brien & McKay, 1997). Thus, a survey by the U.S. General Accounting Office (1995) found that rates of recent illicit drug use ranged from 13 to 63% in a sample of methadone maintenance programs. Data from our Center indicate that approximately 50% of the urine toxicologies for heroin and cocaine are positive for patients in the first 6 months of treatment (Alterman, Rutherford, Cacciola, McKay, & Woody, 1996b). Research by Morral and colleagues (Morral, Iguchi, Belding, & Lamb, 1997) revealed that only about 30% of new patients have relatively few drug-free urines by the end of 4 months of treatment. The increased cocaine abuse that has been seen in the past decade

in opioid-dependent patients is associated with poorer outcomes (Woody & McNicholas, 1996). Additionally, the knowledge that HIV positivity can be substantially reduced by retaining users in treatment weakens the contingency-based treatment contract that has been used in MM programs, whereby continued use of other nonprescribed drugs resulted in gradual detoxification and program discharge and is thereby likely to be associated with higher use rates by patients in treatment.

LAAM. Levo-alpha-acetyl methadol (LAAM) is a slower acting substance whose pharmacological effects are similar to that of methadone. It was studied extensively in clinical trials before its approval by the Food and Drug Administration (FDA) in 1993 (O'Brien & McKay, 1997). Its long half-life and even longer acting metabolites produce opiate effects for about 72 hours after a single daily ingestion. This makes LAAM very convenient because it requires dosing only three times per week and still provides physiological stability (O'Brien, 1996). Studies done to date show that treatment results for those who remain on LAAM compare favorably with those obtained with methadone, although LAAM's slower onset probably contributes to the higher initial dropout rate seen when LAAM is compared with methadone (Woody & O'Brien, 1986).

Buprenorphine. Buprenorphine belongs to another class of medications called partial agonists. It is currently approved for treating pain, and it has shown good efficacy as a maintenance medication in addiction treatment in several clinical trials among heroin addicts (Bickel & Amass, 1995). As a partial opiate agonist, operating primarily at the mu receptor, buprenorphine activates opiate receptors and produces effects similar to heroin and methadone, but there is a "ceiling" above which higher doses produce no greater effect. In studies so far, overdose from buprenorphine has not been seen, and if heroin or other opioids are taken, their effects are attenuated or blocked by the presence of buprenorphine (O'Brien, 1996). At the same time, buprenorphine (like all other opiate agonist medications) will produce euphoria, and there are reports that buprenorphine is diverted and sold on the street. A new preparation for this medication is likely to reduce buprenorphine diversion and illicit use. By combining buprenorphine with naloxone (an opiate antagonist), injection can be prevented, thus reducing one important side effect of the medication. An additional potential benefit

from this medication is that, even after protracted periods of maintenance with this drug, it can be terminated at the will of the patient with no need for dose reduction schedules and very few withdrawal effects—due in large part to its very long half-life (Jasinski, Pevnick, & Griffith, 1978). This medication is expected to receive FDA approval and to join methadone and LAAM as a third option for maintenance in treating heroin addicts. Based on experience from clinical trials, there are some heroin addicts who prefer methadone, others who prefer LAAM, and still others who feel that they are most stable and alert on buprenorphine. As with other classes of medications, it is helpful for the clinician to have a choice of medications.

Antagonist Treatment. The discovery of specific opiate receptor antagonists in the early 1970s gave rise to hopes for the "perfect" medication for treating heroin addiction. Naltrexone seemed to be the answer because it specifically blocks mu opiate receptors and kappa receptors to a lesser extent (Raynor, Kong, Chen, Yasuda, Yu, Bell, & Reisine, 1994), but it has little or no direct or agonistic effects of its own. Naltrexone and its short-acting analogue naloxone have high affinity for opiate receptors and will displace drugs like morphine or methadone, resulting in the sudden onset of withdrawal symptoms when given to people who are opioid-dependent. If the heroin addict is first detoxified so that opiate receptors are gradually evacuated, naltrexone will bind to the receptors and prevent subsequent injections of heroin from having an effect. Numerous clinical trials have shown that naltrexone is effective in blocking opiate receptors and safe; thus, it was approved by the FDA in 1983. Unfortunately, naltrexone is a very underused medication for treating heroin addiction. Unlike methadone, it has no positive psychoactive effects. Few street heroin addicts show any interest in this type of treatment, and few programs encourage patients to try it. Opioid antagonists are more complicated to prescribe than methadone, and most physicians have not been trained in their use. Opioid-dependent health care workers such as physicians, pharmacists and nurses often do well on naltrexone because it enables them to return to work with no risk of relapse, even though they work in areas of high drug availability (Washton, Pottash, & Gold, 1984). It should be noted that naltrexone has been found most effective when additional psychosocial treatment services are also provided (Farren, O'Mal-

ley, & Rounsaville, 1997). There is also preliminary evidence that naltrexone is helpful in preventing relapse in probationers who have conditional releases from prison after drug-related crimes (Cornish et al., 1997). Naltrexone is a viable treatment for highly motivated patients whose continued careers depend on completing successful treatment (Farren et al., 1997).

Psychosocial Treatment. A large body of research, thus far, has shown that methadone maintenance is most successful when coupled with a variety of services, including regular client contact and urine drug monitoring (Cooper, 1989). Particularly, because many opiate-dependent patients need assistance with vocational and legal problems and many come to treatment with additional psychiatric symptomatology (Rounsaville, Weissman, Kleber & Wilbur, 1982; McLellan, 1986), there is a need for drug counseling by a certified drug counselor and sometimes a need for psychotherapy or psychotropic medication to combat coexisting psychopathology (Woody & O'Brien, 1986). Yet, the amount of psychosocial treatment provided in MM programs is typically quite modest compared to that which has been provided to alcohol and other substance-dependent patients in the past. At our own Center, for example, patients are usually seen weekly for several months and then are tapered to less frequent meetings (bi-weekly to monthly), once the patient shows evidence of stabilization. Even this amount of treatment exceeds that provided in most community methadone programs. Assessment of treatment services received even by patients who participated in a research-enhanced program of treatment revealed relatively few treatment services in many problem areas—employment, legal, family/social—despite the stated policies of MM programs to provide such services (McLellan, Arndt, Metzger, Woody, & O'Brien, 1993). Not surprisingly, then, little improvement in functioning is seen for many patients beyond the first 2 months of treatment (Cacciola, Alterman, Rutherford, McKay, & McLellan, 1998; also see Morral et al., 1997).

There is clear evidence that methadone patients respond positively to supplemental psychosocial services, particularly professional services. For example, a study conducted at our Center 15 years ago showed that psychotherapy is highly beneficial to Veterans' Administration MM patients (Woody et al., 1983). A second study extended

these findings to community-based MM programs (Woody et al., 1995). Nonetheless, there is a continuing effort to further reduce the amount of psychosocial treatment provided to MM patients on the justification that more patients could be pharmacologically treated with methadone alone and that there is a public health benefit to having more patients improve somewhat than fewer patients improving more (Cooper, 1989). A recent study by McLellan and colleagues (McLellan et al., 1993) showed that increasing the amount and range of psychosocial treatments produced superior outcomes in methadone patients. An equally important finding is that the majority of methadone patients who received minimal counseling, a level of treatment below that usually provided under standard counseling conditions, did very poorly. Thus, though opioid-dependent patients need a markedly greater amount of treatment, current cost considerations are leading to even greater reductions in the amount of treatment provided. It should be noted, however, that a small subgroup of patients in the McLellan et al. (1993) study was able to function reasonably well under the minimal counseling condition. This finding is supported by data that show that about 20% of treatment candidates can achieve relatively stable functioning when put on a waiting list for methadone treatment (Yancovitz et al., 1991). Thus, the majority of, but possibly not all, patients need and can benefit from psychosocial treatment services within the context of methadone or other treatment.

There is a limited amount of research using behavioral contingency contracting procedures with methadone patients. Several approaches have been employed. One of these specifies that the patient must accomplish certain behaviors within a specified period of time or face suspension from the program (Bigelow, Spitzer, & Liebson, 1984). This approach may extend to reducing the methadone dose in response to problematic behaviors. When this is the case, it is in direct conflict with the medical approach to methadone treatment which strongly opposes a reduction in the medications prescribed for a patient based on the patient's poor compliance with treatment requirements (Kreek, 1986). Accordingly, this is an approach rarely seen in practice. Several recent studies by Iguchi and colleagues (Iguchi, Lamb, Belding, Platt, Husband, & Morral, 1996; Iguchi, Belding, Morral, Lamb, & Husband, 1997), provide another example of the use of behavioral approaches to

enhance MM treatment outcomes. In the first study (Iguchi et al., 1996), take-home medications were used to reinforce either the provision of drug-free urines (UA) or attendance in groups that provide training in interpersonal problem solving (TIPS). During the 24-week intervention period, UA participants showed greater improvement than TIPS participants in rates of abstinence from unauthorized drugs. In the second study (Iguchi et al., 1997), vouchers were used to reinforce either provision of urine samples testing negative for illicit drugs (UA group) or the completion of objective, individually defined, treatment-plan-related tasks (TP group). A third group was assigned to the clinic's standard treatment (STD group). Results of urinalysis indicated that the TP condition was significantly more effective than the other two conditions during the 12-week contingency period and tended to retain this superiority for 12-weeks following termination of the specialized treatments.

Psychopathology and the Relationship of Treatment Response to Psychopathology

Opioids are known to produce changes in mood and feeling. It is likely that repeated opioid use is motivated by a desire to reexperience this sense of euphoria. The complex of euphoria and decreased concern with anticipated problems produced by opioids is often referred to as a "high" (Jaffe, 1992; Woody & McNicholas, 1996). "For some individuals, opioids appear to have the capacity to ameliorate certain varieties of depression, to control anxiety, to reduce anger, and to blunt paranoid feelings and ideation" (Jaffe, 1992, p. 187). In this regard, it has been recognized for some time that substance-dependent patients as a group suffer from considerably more psychiatric pathology (other than substance dependence) than the general population (Rounsaville, Weissman, Kleber, & Wilber, 1982; Rounsaville et al., 1986; Rounsaville, Dolinsky, Babor, et al., 1987), particularly major depression and APD. A recent methodologically rigorous diagnostic study by Brooner and colleagues (Brooner et al., 1997) with 716 MM patients interviewed 1 month after admission confirmed these earlier findings and revealed that 25% of the patients qualified for APD (significantly

more men than women—34 vs. 15%) and nearly 16% for lifetime major depression disorder (significantly more women than men—24 vs. 9%). Overall, nearly half of the patients (47.5%) qualified for a lifetime nonsubstance dependence Axis I or Axis II diagnosis.

A number of studies showed that patients with additional psychopathology such as major depression, another substance dependence disorder, or APD, have a poorer response to treatment than patients without additional psychopathology (Gerstley, McLellan, Alterman & Woody, 1990; Rounsaville et al., 1986, 1987; Woody, McLellan, Luborsky, & O'Brien 1985). A seminal investigation by McLellan and colleagues (McLellan et al., 1983; McLellan, 1986) that has been upheld over the years (Kosten, Rounsaville, & Kleber, 1985; Rounsaville et al., 1986) showed that patients with more psychiatric pathology at baseline, as reflected in the psychiatric interviewer severity rating of the Addiction Severity Index (ASI), strongly predicted negative outcomes in several life areas. Indeed, a study by Rounsaville et al. (1986) showed that this index was a better predictor of negative outcomes than various psychiatric disorders.

As noted, APD is a particularly common disorder in opiate-dependent patients and occurs in as many as 50% of male patients (Gerstley et al., 1990; Brooner et al., 1997). In a study extending their initial study on the effectiveness of psychotherapy, Woody and colleagues (Woody et al., 1985) found that patients with an APD diagnosis plus a lifetime diagnosis of major depression were functioning as well at 6 months posttreatment intake as patients with no additional psychiatric diagnoses (other than substance dependence) or those with lifetime major depression. However, patients with the APD diagnosis without major depression generally responded more poorly than the other patients. The insight of this study was the distinction between APD patients with and without major depression that pointed to a possible subtyping of APD patients. It is noteworthy that no further effort has been made to replicate these findings. In a recent effort to extend the findings to MM patients who receive counseling rather than psychotherapy, Alterman and colleagues (Alterman, Rutherford, Cacciola, McKay, & Woody, 1996b) found no differences in outcomes between APD patients with and without lifetime major depression and little indication that APD is a nega-

tive prognostic indicator in MM patients. Because counseling is an overwhelmingly more common treatment than psychotherapy in the current treatment environment, the findings take on increased import.

As previously indicated, the cocaine epidemic added a dimension to MM treatment that has reduced its effectiveness in treating illicit substance use. Many of the particularly recalcitrant patients who continue to use throughout treatment are those implicated in a cycle of opiate and cocaine use (Woody & McNicholas, 1996). In an effort to address this problem, several investigations were conducted to determine whether treatment with a tricyclic antidepressant such as desipramine was effective in reducing cocaine use (Arndt, Dorozynsky, Woody, McLellan, & O'Brien, 1992; Kosten, Morgan, Falcione, & Schottenfield, 1992). The findings of these investigations have not been very encouraging. For example, although there was modest evidence in one study that desipramine was associated with reduced cocaine use in those who did not drop out of the drug trial, the drop-out rate was markedly higher for desipramine than for placebo (Arndt et al., 1992). Thus, provision of specialized treatments for cocaine abuse within the context of MM treatment is still quite limited, and thus far there is little evidence for an effective treatment. Alcohol abuse, although generally not as common as cocaine abuse in MM patients, still constitutes a considerable problem (Bickel, Marion, & Lowinson, 1987). There is little indication of specialized treatment for this problem, although a recent investigation revealed that an increase in problems related to alcohol in the first 6 months of treatment were highly predictive of violent crime and also significantly predicted nonviolent crime (Alterman, McDermott, Cook, et al., 1998). The typical approach to this problem in MM programs is to make methadone dosing contingent on a clean breath alcohol reading. The extent to which this procedure is effective or even actually implemented in practice is unclear.

Summary of Treatment for Opioid Dependence

MM is the dominant treatment for opioid dependence in the United States. It is believed to be associated with reduced HIV risk, reductions in crime, and some modest improvements in other

areas of life functioning. In the past decade, however, several developments have limited the effectiveness of this treatment for reducing illicit drug use. These include the cocaine epidemic and higher purity of heroin on the street. Additionally, the existence of the AIDS epidemic has resulted in a loosening of the behavioral contract that was originally at the foundation of MM treatment. Thus, although MM is still a useful treatment in many ways, particularly from a public health standpoint, it is not achieving the same levels of improvement in patients that were shown earlier.

Etiology and Management of Eating Disorders

**Donald A. Williamson, Nancy L. Zucker,
Corby K. Martin, and Monique A. M. Smeets**

Introduction

The American Psychiatric Association specifies three eating disorders in the current *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* (American Psychiatric Association, 1994): anorexia nervosa, bulimia nervosa, and eating disorder not otherwise specified (NOS). The public has become increasingly aware of eating disorders such as anorexia nervosa and bulimia nervosa in the past two decades largely from descriptions of these disorders in the mass media. However, anorexia nervosa has been known to the medical community since the 1870s, and the symptom of intentional self-starvation has been reported since medieval Europe (Brumberg, 1989). There is some debate as to whether the early reported episodes of anorexia nervosa in the medical literature (e.g., Gull, 1874; Laségue, 1873; Marcé, 1860; Morton, 1694) are equivalent to the modern manifestation of the disease (Parry-Jones & Parry-Jones, 1994). However, several perspectives hold that, although the function of anorexic symptoms may have changed over time, depending on cultural and

environmental contexts, fear of weight gain has been the underlying motivational factor for most cases of anorexia nervosa since the early 1800s (Habermas, 1996).

Bulimia nervosa has a more recent history; the syndrome was first formally delineated by Russell in 1979. However, the Greek term boulimis, literally “ox hunger,” or ravenous hunger, can be traced back for 2000 years. Symptoms of binge eating may have appeared in reaction to scarce food supplies when individuals would overeat in times of prosperity to prepare for periods when supplies were more scarce (Atkinson & Stern, 1997). Later reports of hyperphagia in the sixteenth through nineteenth centuries described a few extreme cases of gluttony associated with morbid obesity (Parry-Jones & Parry-Jones, 1995). These case descriptions probably reflect the earliest identification of a syndrome now called binge-eating disorder (APA, 1994).

To understand the etiology of eating disorders, one must also understand the etiology of obesity. Obesity is generally defined in terms of excess body fat content (Mayer, 1973). One’s percentage of body fat is determined by the relative amount of adipose tissue to muscle and other tissue. Adiposity is conceptualized in terms of adipose (or fat) cellularity. When one gains weight, adipose cells increase in size; when weight is lost, they decrease in size. Of significance is the fact that dieting shrinks only the size of fat cells. Thus, people with excess adipose cellularity will be

Donald A. Williamson, Nancy L. Zucker, Corby K. Martin, and Monique A. M. Smeets • Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, Louisiana 70803.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

likely to gain weight if their body weights are below a "set-point" weight, a hypothetical biologically determined body weight or body energy level that is maintained by the mechanisms of homeostasis (Keesey, 1995). In many ways, eating disorders are motivated by the individual's desire to override the biological mechanisms that determine body size and shape. Longitudinal studies have reported that having a high body weight as an adolescent may increase the likelihood of developing later eating disorder symptoms (Attie & Brooks-Gunn, 1989; Killen, Hayward, et al., 1994). Persons diagnosed with anorexia nervosa are almost certainly maintaining a body weight below the biological "set point." It is probable that many cases of bulimia nervosa are also at a weight level below the person's "set point." Thus, regulating body weight is an important consideration when trying to understand the etiology of eating disorders.

Obesity is influenced by genetic (Bouchard, 1995), physiological, and behavioral factors (Blundell, 1995; Blundell & Hill, 1993). Despite the complex factors that interact to determine body weight, a gain in body mass is predicted by a simple formula: energy input is greater than energy output (Garrow, 1995). Obesity is not considered a psychiatric disorder, however, and it is not regarded as an eating disorder. Most persons diagnosed with binge-eating disorder and some who have bulimia nervosa are obese. For the purposes of this chapter, we have elected to review the psychopathology of anorexia nervosa, bulimia nervosa, and Eating Disorder-NOS, which includes binge-eating disorder. We will not review the research literature pertaining to obesity.

Anorexia Nervosa

Diagnosis and Clinical Description

The DSM-IV lists four criteria necessary for a diagnosis of anorexia nervosa. New to this fourth edition of the DSM is the delineation of two subtypes of anorexic patients: the restricting subtype and the binge-eating/purging subtype. The diagnostic criteria are summarized in Table 1. The first diagnostic criterion requires that individuals intentionally maintain a body weight below weight levels recommended for health. The low weight level suggested as a guideline is less than 85% of one's expected weight level or a failure to make expected gains if the individual has not yet reached

Table 1. Summary of DSM-IV Diagnostic Criteria for Anorexia Nervosa

-
- A. Refusal to maintain normal body weight (e.g., less than 85% of that expected).
 - B. Fear of gaining weight, even though below normal weight.
 - C. The presence of body weight or shape disturbance, self-evaluation being overly influenced by body weight or shape, or refusal of the significance of low body weight.
 - D. The presence of amenorrhea in postmenarcheal females (i.e., the absence of at least three consecutive menstrual cycles).

Restricting Type: The person has not regularly engaged in binge-eating or purgative behaviors. Purgative behaviors include self-induced vomiting and the misuse of laxatives, diuretics, and enemas.

Binge-Eating/Purging Type: The person has regularly engaged in binge-eating or purging behavior.

biological maturity. Walsh and Garner (1997) recommend a flexible interpretation of this guideline. For example, if individuals meet all of the diagnostic criteria for anorexia nervosa but their current weight levels are 90% below that expected, the diagnosis of anorexia nervosa is still warranted (Walsh & Garner, 1997). Factors such as the length of time during which weight loss has occurred (less time is more diagnostic) and the degree of weight loss (more weight loss is more diagnostic) can aid in this decision. In addition, this criterion requires that individuals "refuse" to keep their weight levels in a healthy range. Thus, this criterion excludes those individuals whose biological set-point weight is naturally low and who are continually trying to gain weight or do not experience distress if possible weight gain should occur.

The second diagnostic criterion specifies that the individuals exhibit intense fear of becoming fat or of gaining weight despite their current low weight status. This fear of fatness can be distinguished from the "normative" fear of weight gain present among a majority of adult females in Western society by its intensity, by its irrationality, and by its degree of interference in daily activities and social relationships (Striegel-Moore, Silberstein, & Rodin, 1986). The fear of gaining weight associated with anorexia nervosa is notably inconsistent with their current emaciated weight status (Walsh & Garner, 1997). These individuals

will often eat the same foods and conduct their daily routines in exactly the same way for fear that any minor deviation will cause weight gain. In addition, such individuals will often avoid social activities if such activities will bring them into possible contact with food or will interfere with their ability to engage in restrictive eating or excessive exercise habits.

The third criterion specifies that the individuals experience a disturbance in body image. For example, the individuals may overvalue weight as a determinant of personal worth, may deny the seriousness of their current weight level, or may have an impression of their physical appearance that does not correspond to objective evidence. This criterion describes a disturbance in the way in which one's body size and shape is experienced. This disturbance can be manifested in several ways. There has been much debate as to whether the body-image disturbance seen among patients with anorexia nervosa is perceptual, affective, or a combination of both of these components (Heinberg, 1996). Recent conceptualizations have hypothesized that individuals with anorexia nervosa perceive themselves accurately but are mistaken in the selective interpretation of their bodily experiences (Williamson, 1996). In addition, weight level may have multiple meanings for the anorexic patient. Rather than being an indicator of body mass, the ability to control one's weight represents extreme self-control and feelings of accomplishment for the anorexic patient, whereas weight gain is associated with feelings of self-hatred, personal failure, and intense anxiety (Garner, Vitousek, & Pike, 1997).

The final criterion specifies that normal menstrual functioning is disrupted, such that the individual fails to menstruate for three consecutive menstrual cycles. The clinical significance of the presence of amenorrhea is debated because this symptom is considered an effect of the physical consequences of starvation and not a diagnostic indicator of specific psychological symptoms (Beaumont, Garner, & Touyz, 1994). Historically, this criterion has been used as an indicator of the severity of the individual's current physical status. This criterion specifies that the onset of the symptoms of anorexia nervosa among girls who have attained biological maturity interferes with healthy physiological functioning that results in losing the menstrual cycle. Adolescents may experience primary amenorrhea, the failure to have ever experienced a healthy menstrual cycle. Individuals who

can menstruate only when ovarian steroids are prescribed are also considered to have amenorrhea.

Once a diagnosis of anorexia nervosa has been established, the clinician must classify the individual into one of two subtypes: *the restricting type* (the lack of binge-eating or purgative behavior) or *the binge-eating/purging type* (the person has regularly engaged in binge-eating or purging behavior: self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This distinction is based on recent research evidence that documents a difference in clinical presentation between these two subtypes (e.g., Vitousek & Manke, 1994). Research has demonstrated that anorexics with the binge-eating/purging subtype are more similar to bulimia nervosa patients in their clinical presentation and often demonstrate impulsive behavior patterns and affective instability, whereas restrictor anorexic patients are more likely to exhibit rigid and obsessional personality styles (Vitousek & Manke, 1994; Wonderlich, 1995).

Prevalence

In a recent study, Lucas, Beard, O'Fallon, and Kurland (1988) estimated the incidence of anorexia nervosa during a 45-year period (1935–1979) in the population of Rochester, Minnesota at 7.3 per 100,000 person-years, and the point-prevalence rate was 113.1 per 100,000 person-years in January of 1980. Screened data from the General Practice Research Database in Britain from 1988–1994 for newly diagnosed cases of anorexia nervosa revealed incidence rates of 4.2 per 100,000 (Turnbull et al., 1996). In a population-based sample of 2163 female Caucasian twins, the prevalence of anorexia nervosa was 0.51% (Walters & Kendler, 1995). A recent review that aggregated the data from twelve retrospective cohort incidence studies across cultures that spanned the period from 1950–1992. The study reported that the incidence of anorexia in the female cohort aged 13–19 years was five times greater than the incidence among other age groups and that a nearly threefold increase reported in the past 40 years among women in their 20s and 30s resulted in an incidence rate of 17.7 per 100,000 person-years (Pawluck & Gorey, 1998). Thus, the accumulation of evidence from these studies and other studies that examined prevalence rates for anorexia nervosa indicate that the point prevalence ranges from 0.1–1% of the population and may be higher among certain subgroups of the population,

particularly among adolescent girls in later early adulthood.

Etiology

Cognitive-Behavioral Perspectives. Cognitive-behavioral perspectives of anorexia nervosa emphasize the interaction between environmental pressures for thinness, social modeling of dieting, cognitive bias for body-related information, and principles of reinforcement. Current Western cultural values unduly emphasize that attaining a thin physique is vital to attain rewards such as social acceptance, financial prosperity, and happiness (Rothblum, 1994). Researchers have documented that the ideal body type depicted in the media has become progressively thinner (Garner, Garfinkel, Schwartz, & Thompson, 1980) and within the last two decades, progressively more toned (Brownell, 1991). The effect of this cultural emphasis has been more pronounced in women, and various political, social, and developmental perspectives have been offered to explain this trend (Fallon, Katzman, & Wooley, 1994). However, the sociocultural idealization of a lean and toned physique may also be promoting extreme levels of body dissatisfaction among growing segments of the male population who subsequently "feel too small" and engage in extreme weight gain behaviors such as the abuse of steroids to achieve weight gain. This phenomenon has been referred to as "reverse anorexia" or "muscle dysmorphia" (Pope, Katz, & Hudson, 1983).

Individuals who are vulnerable to such sociocultural influences due to the combination of personality variables, affective instability, and/or biological precursors, it is thought, adopt these cultural messages and subsequently develop a fear of fatness and/or a drive for thinness. According to cognitive-behavioral theories, fear of gaining weight, it is thought, is the primary motivational factor driving extreme food restriction, excessive exercise, and/or purgative behavior. These behaviors are negatively reinforced in that engaging in restrictive eating, excessive exercise, and/or purgative behavior reduces the anxiety associated with a fear of gaining weight. Principles of negative reinforcement may also be operative in helping the individual avoid stressful situations that involve expectations of high performance and family conflicts (Garner, Vitousek, & Pike, 1997).

Among the subset of individuals with anorexia

nervosa who engage in binge eating, it is believed that the extreme biological deprivation caused by fasting leads to episodes of binge eating. The anxiety associated with the consumption of a large amount of food promotes purgative behaviors such as self-induced vomiting, the abuse of laxatives, or the abuse of diuretics to decrease anxiety. Thus, the use of purgative methods is negatively reinforced because it decreases the anxiety associated with excessive food consumption. Fasting can be viewed as the avoidance of eating, which is also motivated by the fear of weight gain (Garner, Vitousek, & Pike, 1997). Thus, cognitive-behavioral theory conceives that dietary restriction, purgative habits, and binge eating are motivated either directly or indirectly by fear of weight gain.

Cognitive schemata are viewed as knowledge structures that direct attention, perception, and the processing of information. In individuals with eating disorders, schemata are related to the "self" and, it is hypothesized, contain stereotyped, affectively-loaded, and overvalued information concerning weight and shape (Williamson, Muller, Reas, & Thaw, in press). Because of the anxiety associated with possible weight gain, the person with an eating disorder becomes vigilant to stimuli that may be interpreted as weight-related. Due to the salience of such stimuli, the individual's attention may be biased to attend to weight-related stimuli and to block other information from awareness (Fairburn, Cooper, Cooper, McKenna, & Anastasiades, 1991). Such processing occurs beyond the level of conscious awareness; thus, this biased interpretation may be given an air of reality (Williamson et al., in press).

There are also significant positive consequences associated with anorexic behaviors. Behaviors resulting in weight loss are positively reinforced by feelings of achievement and self-control. Individuals with anorexia may derive satisfaction from their ability to deny strong biological urges and may engage in behaviors that emphasize these "abilities" such as preparing rich foods for others while refusing to eat.

Biological Perspectives. Recent investigations of biological theories of eating disorders have examined the association between premorbid temperament, patterns of comorbid diagnoses, and persistent personality characteristics following weight restoration. Such investigations have raised the possibility that these traits may contribute to the pathogenesis of the disorder. For example, the

rigidity, obsessionality, and behavioral inhibition consistently seen in patients with anorexia nervosa, it has been found, exist retrospectively before eating disorder symptom onset and persist following weight maintenance (Kaye, 1995, 1997). Bulik, Sullivan, Fear, and Joyce (1997) investigated the differential age of onset for anorexia nervosa, bulimia nervosa, and comorbid anxiety disorders and compared incidence rates with women with major depression or no diagnosis. Results indicated that in 90% of anorexic subjects, 94% of bulimic subjects, and 71% of depressed subjects, anxiety disorders preceded the onset of these other disorders. Subjects diagnosed with anorexia were most likely to have received a prior diagnosis of obsessive compulsive disorder or overanxious disorders, and patients diagnosed with bulimia nervosa were most likely to have received a prior diagnosis of social phobia or overanxious disorder (Bulik et al., 1997). The authors concluded that certain anxiety disorders may serve as nonspecific risk factors for the later development of affective and eating disorders.

Serotonergic systems have often been investigated as a cause of anorexia nervosa due to their influence in modulating appetite, mood, and personality variables such as impulsiveness and aggressiveness (Kaye, 1997). Elevated cerebral spinal fluid (CSF) 5-HIAA levels, the major metabolite of brain serotonin, were found in long-term weight-restored anorexic patients (Kaye, Gwirtsman, George, & Ebert, 1991). Such findings are of interest because low levels of CSF 5-HIAA are associated with impulsive, suicidal, and aggressive behavior—behaviors not traditionally associated with restrictor anorexics.

Further support of potential serotonergic influences on symptom development has been provided by the examination of familial symptom prevalence and inheritance patterns (Kaye, 1997). Family and twin studies, and more recently, behavioral genetic studies have found a high incidence of eating disorders among relatives of anorexics (e.g. Allison & Faith, 1997; Strober, Lampert, Morrell, & Burroughs, 1990). Twin studies have documented a possible genetic basis for anorexia nervosa. A population-based examination of 2163 Caucasian female twin pairs reported that the twin of a person with anorexia nervosa was at risk for anorexia nervosa relative to control subjects (Walters & Kendler, 1995). However, due to the low prevalence of anorexia nervosa in the general pop-

ulation, the number of concordant twins in this study was small. In this study, the dizygotic probandwise concordance rates were larger than the monozygotic rates. The authors concluded that the variance of this sample could not be effectively partitioned into genetic and environmental influences (Walters & Kendler, 1995). Previous reviews of concordance for anorexia among twin pairs relied on treatment samples, but this study may reflect a more accurate estimate of genetic influence on the development of anorexia nervosa. Future research using adoptive and half-sibling studies will be necessary to establish the contribution of genetics to this disorder. It is possible that other characteristics (e.g., obsessiveness) may be transmitted that predispose individuals reared in a certain sociocultural environment to develop anorexia (Strober et al., 1990). However, the difficulty of separating environmental and genetic influences complicates the conclusions drawn from such studies (Hayes, 1998).

Psychodynamic Perspectives. Psychodynamic perspectives encompass a variety of conceptualizations regarding the etiology of anorexia nervosa. For example, Bruch (1973) described antecedent feelings of ineffectiveness and helplessness and deficits in interoceptive awareness that are etiologically related to the development of anorexia nervosa. Persons with anorexia nervosa, it is hypothesized, use extreme discipline over biological urges to compensate for their perceived lack of identity and concomitant sense of loss of control (Bruch, 1973).

Proponents of self-psychology suggest that undeveloped psychic structures result in feelings of dysphoria, tension, numbness, and emptiness (Goodsitt, 1997). Symptoms are viewed as a way to restore a sense of wholeness and often serve to “drown out” the aversive self-states of devitalization (Goodsitt, 1997). For example, principles of self-psychology espouse that the constant activity of an individual with anorexia is an attempt to escape from painful internal conditions of boredom, emptiness, and aimlessness (Goodsitt, 1997).

In other psychodynamic perspectives, anorexia nervosa is conceptualized as a phobic avoidance disorder in which the feared object is adult weight and body shape and concomitantly, adult sexuality (Crisp, 1997). The anorexic is able to avoid these fears by maintaining body weight at a subpubertal level and thus prevents the onset of the menstrual cycle and sexual maturity. Strong drives to ingest

food and grow cause the individual to lose more weight as "insurance" against possible weight gain. Avoidance of eating enables the individual to manage fears of maturation. Over time, the initial motivational drives to achieve an emaciated state may be forgotten while only the drive to lose weight remains.

The initial fears that promoted this deprivation can take many forms, including fears of aging and death, denial of sexuality, or fear of succeeding as an adult (Crisp, 1997). Thus, the individual successfully regresses to a prior state of functioning through physiological and biological deprivation and avoids the challenges of adulthood.

Family-systems theories emphasize that the successful negotiation of developmental stages is essential for healthy adult maturation. Anorexic symptomatology is viewed as a symbolic representation of the individual's failure to negotiate the separation/individuation stage. Anorexic symptoms serve as an attempt to achieve power, autonomy, and independence while at the same time retreating from the developmental challenge of adolescence (Casper, 1982). Family characteristics such as parental overcontrol, discouragement of self-sufficiency, and enmeshment have been described in families of anorexic patients (Johnson & Conners, 1987) and may contribute to this conflict. The development of anorexia, it is thought, provides an individual with a secure self-identity that was not achieved as a result of negotiating development stages.

Comorbidity

Investigators have examined patterns of comorbidity among persons diagnosed with anorexia nervosa to inform treatment planning and to determine possible etiological mechanisms. Affective disorders, anxiety disorders, and personality disorders have received the greatest amount of attention from researchers.

Affective Disorders. The most widely reported comorbid feature of anorexia nervosa is depression; prevalence rates range from 21–91% of individuals who exhibit symptoms of depression during the acute phase of anorexia nervosa (Hudson, Pope, Jonas, & Yergelun-Todd, 1983; Rothenberg, 1990; Wonderlich, 1995). Such high prevalence rates have raised speculation about a common diathesis between the two disorders. However, the physical and behavioral concomitants of the star-

vation process (Keys, Brozek, Henschel, Mickelsen, & Taylor, 1950) often resemble depressive symptoms and may inflate reported prevalence levels. In addition, critical reviews of the research, including patterns of family transmission, response to anti-depressant medication, and time of disorder onset, fail to support a common diathesis for these disorders (Rothenberg, 1990). Rather, Rothenberg (1990) hypothesized that the depression seen in anorexia nervosa may be secondary to a more intrinsic relationship with obsessive-compulsive symptoms.

Anxiety Disorders. Given the obsessive concern with body size and shape among anorexics, much research has been devoted to investigating obsessive symptoms in this population. In a review of the comorbidity literature, Rothenberg (1990) reported that between 11 and 83% of patients displayed obsessive symptoms during the acute phase of anorexia nervosa or after weight restoration. In addition, Rothenberg (1990) concluded that if strict diagnostic criteria for depression were used, then obsessive-compulsive disorders are more prevalent among anorexic patients in the majority of studies. Lifetime prevalence rates of any anxiety disorder in anorectic individuals has ranged from 20–65%, and the most prevalent anxiety diagnoses found among anorexic patients are obsessive-compulsive disorder and social phobia (Herzog, Keller, Sacks, Yeh, & Lavori, 1992; Wonderlich & Mitchell, 1997).

Personality Disorders. The personality characteristics of anorexia nervosa have generated a great deal of interest among researchers and clinicians (Vitousek & Manke, 1994). However, delineation of the personality features of anorexic patients is seriously confounded by the effects of the starvation process on personality features and the lack of reliability in diagnosing personality disorders (Keys et al., 1950; Vitousek & Manke, 1994). Given these limitations, research has suggested that restrictor anorexics are most likely to exhibit personality diagnoses from the anxious-fearful cluster and bulimic anorexics are most likely to exhibit personality diagnoses from the dramatic-erratic cluster (Dennis & Sansone, 1997; Herzog et al., 1992; Wonderlich, 1995).

Long-Term Course of Anorexia Nervosa

Strober, Freeman, and Morrell (1997) assessed the long-term course of recovery and relapse in

eighty-five female and ten male anorexic patients annually for a period of 10–15 years following the index admission. Results indicated that approximately 30% of patients experienced a relapse in anorexic symptoms before recovery and nearly 76% of the sample met criteria for full recovery. However, the length of time to recovery was protracted and ranged from 57 to 79 months (Strober, Freeman, & Morrell, 1997). Steinhausen (1995) reviewed the treatment outcome literature for anorexia nervosa from the 1950s to the 1980s, but methodological shortcomings precluded definitive conclusions regarding treatment outcome. Despite these reservations, means across studies indicate that approximately 40% of anorexic patients recover, one-third improve, and 20% exhibit a chronic course (Steinhausen, 1995).

Bulimia Nervosa

Diagnosis and Clinical Description

Bulimia nervosa is an eating disorder characterized by episodes of binge eating followed by the use of inappropriate compensatory behaviors to prevent weight gain. The most common methods for controlling weight are self-induced vomiting, laxative and diuretic abuse, excessive exercise, and restrictive eating. These behaviors, it is thought, are motivated by an intense fear of weight gain and body-image disturbances, similar to those described for anorexia nervosa. Unlike persons diagnosed with anorexia nervosa, persons diagnosed with bulimia nervosa are usually within the normal weight range, as a result of binge eating and less restrictive eating.

The diagnostic criteria for bulimia nervosa have changed considerably over the years. Russell (1979) first described a variant of anorexia nervosa he called *bulimia nervosa*, and in 1980 the term *bulimia* was included in the DSM-III (APA, 1980). The DSM-III described a syndrome marked by binge eating, followed by negative mood. Purging was not required for the diagnosis; therefore, persons who binge ate, but did not purge, could be diagnosed with bulimia (Williamson, Kelley, Cavell, & Prather, 1987). In the revision of the DSM-III, the DSM-III-R (APA, 1987), the name of the disorder was changed to *bulimia nervosa* and required the presence of purgative behavior and lack of control over eating during binge-eating episodes.

Table 2. Summary of DSM-IV Diagnostic Criteria for Bulimia Nervosa

-
- A. Recurrent episodes of binge eating. Binge eating episodes are marked by both:
 - 1) eating an amount of food that is larger than others would eat in a similar time period and under similar circumstances;
 - 2) a sense of lack of control over eating during the episode.
 - B. Recurrent use of inappropriate compensatory behaviors including fasting, excessive exercise, self-induced vomiting, and the misuse of laxatives, diuretics, or enemas.
 - C. Binge eating and inappropriate compensatory behaviors must occur at least twice a week for 3 months, on average.
 - D. Body weight and shape must influence self-evaluation.
 - E. The disturbance does not occur during Anorexia Nervosa.

Purging Type: The person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas in order to prevent weight gain.

Nonpurging Type: The person has used fasting or excessive exercise, but not self-induced vomiting or the misuse of laxatives, diuretics, or enemas in order to prevent weight gain.

With the publication of the DSM-IV (APA, 1994), the diagnostic criteria for bulimia nervosa, summarized in Table 2, underwent additional changes. The diagnosis of bulimia nervosa requires recurrent episodes of binge eating that are marked by (1) eating an amount of food that is larger than others would eat in a similar time period under similar circumstances and (2) a sense of loss of control over eating during the episode. Some binge-eating episodes involve consuming measurably large amounts of food (e.g., one gallon of ice cream). However, other binges are subjective and may include a piece of candy or eating small amounts of a “forbidden food.” Because of these variations, there is considerable controversy about the most appropriate definition of “binge eating.” For example, Schlundt and Johnson (1990) suggested defining binge eating as eating any food or quantity of food that violates one’s idea of dieting and creates anxiety about gaining weight. However, Garfinkel (1995) recommends that the most appropriate way to define a binge-eating

episode is by comparing the amount of food consumed to what others might eat, taking into consideration the time and social circumstances of the individual's last meal.

The second criterion required for diagnosing bulimia nervosa is recurrent use of inappropriate compensatory behaviors to prevent weight gain such as self-induced vomiting, excessive exercise, or misusing laxatives, diuretics, enemas, and other medications (APA, 1994). The DSM-IV also indicates that both binge eating and inappropriate compensatory behaviors must occur, on average, at least twice per week for three months. This criterion has been often criticized. It may be desirable to set a minimum frequency for binge eating and purging to eliminate those who occasionally engage in bulimic behavior but who do not meet the full syndrome, setting the frequency at two episodes per week, on average, is arbitrary and lacks empirical support (Garfinkel, 1995).

A diagnosis of bulimia nervosa requires that body shape and weight unduly influence the individual's self-evaluation. Concerns about weight and shape appear to be an important factor in developing and maintaining bulimia nervosa (Walsh & Kahn, 1997). Many women who do not have eating disorders also express considerable concern about body size and shape (Hadigan & Walsh, 1991). Therefore, as noted in the discussion of anorexia nervosa, it is important to assess the intensity of concerns about weight and shape before concluding that this criterion has been met.

Finally, the disturbance of bulimia nervosa may not occur exclusively during episodes of anorexia nervosa. This criterion allows the diagnosis of anorexia nervosa to "override," so to speak, the diagnosis of bulimia nervosa. Thus, only one eating disorder may be diagnosed, and priority is given to the diagnosis of anorexia nervosa and the seriousness of the low body weight associated with its diagnosis (Walsh & Garner, 1997).

Following the diagnosis of bulimia nervosa, one of two subtypes, *purging* or *nonpurging*, is required by the DSM-IV. The purging type is diagnosed when the person uses self-induced vomiting or misuses laxatives, diuretics, or enemas to control body weight. The nonpurging type indicates that the person has used fasting, excessive exercise, or other inappropriate compensatory behaviors but has not regularly engaged in self-induced vomiting or misused laxatives, diuretics, or enemas. This system of subtyping has been sup-

ported empirically (Hay, Fairburn, & Doll, 1996) and accommodates findings which demonstrate that persons who have the purging subtype demonstrate greater levels of body-image disturbance and increased levels of anxiety about eating, compared to those who have the nonpurging subtype (Garfinkel, 1995). However, other authors have failed to find differences in measures of eating disturbance and psychopathology between those who purge or do not purge (Hay & Fairburn, 1998).

Prevalence

The prevalence rate of bulimia nervosa varies widely from study to study, depending on the definition of bulimia nervosa and the method of diagnosis. Findings based solely on questionnaires produce higher prevalence rates compared to studies that have used interviews to diagnose bulimia nervosa. Using strict diagnostic criteria, the point-prevalence rate of bulimia nervosa among young females is about 1.0% (Hoek, 1995). This finding is in keeping with the DSM-IV (APA, 1994) reported prevalence rate of approximately 1–3% among adolescent females. The prevalence rate of bulimia nervosa in males is roughly one-tenth that of females (APA, 1994). However, recent findings suggest that male homosexuality may be a specific risk factor for the development of eating disorders (Heffernan, 1994).

Minority populations reportedly have lower prevalence rates of bulimia nervosa than Caucasian populations; however, the estimates of bulimia nervosa in minority populations are likely to be misleading (Smith, 1995). Studies using strict methodology may provide prevalence-rate estimates in minority samples that are higher than once believed, yet are still below those of Caucasian samples (Smith, 1995). This hypothesis is supported by evidence indicating that Caucasian and ethnic minority participants scored similarly on measures of both eating disorder and general psychopathology (le Grange, Telch, & Agras, 1997). Additional evidence suggests that an ethnic subculture does not protect adolescent females from sociocultural factors that influence body dissatisfaction (French et al., 1996).

Etiology

Cognitive-Behavioral Theories. Cognitive-behavioral theories of bulimia nervosa take into

consideration the concept of dietary restraint and anxiety about weight gain. From this perspective, sociocultural pressure for thinness contributes to dissatisfaction with body size among young females (Williamson, Davis, Duchmann, McKenzie, & Watkins, 1990). Young women develop rigid rules about dieting and attempt to restrict caloric intake to avoid the negative connotations of weight gain. If restrictive eating cannot be maintained, dietary restriction may be broken and may lead to binge eating (Polivy & Herman, 1985). Following binge eating, there is an increase in anxiety and feelings of fullness (Rosen & Leitenberg, 1982) that is alleviated following compensatory behavior (Johnson, Jarrell, Chupurdia, & Williamson, 1994). Compensatory behavior subsequently depletes energy stores, increasing the likelihood of future binge-eating episodes (Jarrell, Johnson, & Williamson, 1986). Therefore, dietary restraint is important in initiating binge eating, and fear of weight gain motivates compensatory behavior that reduces anxiety caused by binge eating.

It is clear that dietary restraint is associated with initiating binge eating in bulimia nervosa; however, recent evidence suggests that the role of restraint may be complex. Findings indicate that restraint is a risk factor for bulimia nervosa rather than a necessary precursor (Mussell, Mitchell, Fenna, et al., 1997). From this perspective, predisposing factors such as depression qualitatively alter the experience of restraint or dieting (Lowe, Gleaves, & Murphy-Eberenz, 1998). Therefore, restraint may combine with other factors to contribute to the development of bulimia nervosa (Wilson, 1993). For instance, stressful major life events may combine with restraint to develop bulimia nervosa (Troop & Treasure, 1997). Bulimia nervosa patients, it has been found, experience significantly more stressful life events compared to controls in the year before the onset of their eating disorder (Troop & Treasure, 1997). Evidence also suggests that restraint may combine with excessive exercise or physical activity to contribute to the development of bulimia nervosa (Davis et al., 1997).

Other research has questioned the association of dietary restraint and binge eating. Stice (1998) found that dietary restraint did not predict future bulimic behavior, as the restraint model of bulimia nervosa would predict, but that bulimic behavior predicted future restraint. From this perspective, dietary restraint may be conceptualized as a conse-

quence of binge eating. Ongoing research is needed to explicate the role of restraint in the etiology of bulimia nervosa and to examine other potential factors.

Heatherton and Baumeister (1991) proposed an alternative model of binge eating. They hypothesized that binge eating is motivated by an "escape from self-awareness." Heatherton and Baumeister (1991) hypothesized that binge eaters subject themselves to high standards and when these standards are not met, an aversive emotional state ensues. To escape from this aversive state, cognitive narrowing takes place, and greater attention is given to the environment, contributing to disinhibition of eating.

Biological Theories. Biological evidence suggests that bulimia nervosa may be related to substance use disorders and that both are mediated by endogenous opioids (Hardy & Waller, 1988). Support for this theory comes from findings that altered endogenous opioid activity is related to food cravings and intake (Mercer & Holder, 1997). Patients with bulimia and anorexia nervosa have significantly higher levels of endogenous opioid alkaloids (codeine and morphine) than noneating disorder controls (Marrazzi, Luby, Kinzie, Munjal, & Specker, 1997). Thus, an "auto-addiction opioid model" has been proposed which hypothesizes that endogenous opioids are released when dieting is initiated and this reinforces a state of starvation (Marrazzi et al., 1997). Additionally, the opiate antagonist, naltrexone, it has been found, significantly reduces binge-eating frequency (Marrazzi, Markham, Kinzie, & Luby, 1995), and naloxone, it has been found, reduces the consumption of sweet and high fat foods in persons who binge eat (Drewnowski, Krahn, Demitrack, Nairn, & Gosnell, 1995).

Other biological theories have examined the role of neurotransmitters, particularly serotonin. Serotonin has been linked to the regulation of hunger and satiety, and decreased serotonin in the central nervous system, it is hypothesized, is a predisposing factor in the development of bulimia nervosa (Pike, 1995). Diminished serotonin activity may contribute to, or even precipitate, binge eating. Thus, binge eating may be viewed as a form of self-medication used to alter the negative consequences of decreased serotonin in the brain.

Behavioral genetics can be defined as the study of the way genetics and the environment determine behavioral characteristics (Hewitt, 1997).

Behavioral genetics relies on twin, family, or adoption designs to determine the genetic and environmental contributions to behaviors and disorders. Behavioral genetics has investigated bulimia nervosa and found that there may be a substantial heritable component to bulimia nervosa (Hewitt, 1997). For example, Kendler et al. (1991) found that DSM-III-R bulimia nervosa is more common in monozygotic than in dizygotic twins and that the development of bulimia nervosa is substantially influenced by genetic factors.

Psychoanalytic Theories. Early psychoanalytic theories explained eating disorders as a fear of oral impregnation and a rejection of femininity (Bruch, 1973). Later theories emphasized early mother-child interactions (Lerner, 1983). Lerner (1983) conceptualized a bulimic patient as overreliant on external structure as a consequence of the failure to develop an adequate "self." This failure of ego development leaves the person with a false sense of self. Food becomes a symbol of the failed mother-daughter relationship, and binge eating and purging represent the conflict between a desperate need for the mother and the desire to reject her. Support for psychoanalytic theory is limited; tests of the theory relied on measures of autonomy and found that developing autonomy was not problematic for bulimic patients (Teusch, 1988).

Comorbidity

Affective Disorders. Depressive disorders are consistently associated with bulimia nervosa (Cooper, 1995). Comorbidity studies have found that a majority of cases can be diagnosed with a comorbid affective disorder (Hinz & Williamson, 1987).

Anxiety Disorders. Generalized anxiety and obsessional worry frequently coexist with bulimia nervosa. Pope, Hudson, and Yurgelun-Todd (1984) reported that 50% of the bulimic patients in their sample received an anxiety disorder diagnosis. Obsessive-compulsive disorder commonly accompanies bulimia nervosa. For example, 65% of bulimia nervosa patients in Hudson, Pope, Yurgelun-Todd, Jonas, and Frankenberg's (1987) sample could have been diagnosed with obsessive-compulsive disorder at some point in their lives. Obsessive-compulsive disorder, it is hypothesized, is premorbid to the development of the eating disorder (Thornton & Russell, 1997), and Cooper (1995) reports that OCD may be secondary

to depressed mood in bulimia nervosa patients, as depression and obsessiveness appear to be associated. Additionally, OCD may be a consequence of energy deprivation, or it may be related to the eating disorder itself.

Personality Disorders. Estimates of the prevalence rates of comorbid personality disorders associated with bulimia nervosa patients vary widely. Wonderlich (1995) reports that 21–77% of bulimia nervosa patients suffer from comorbid personality disorders, particularly Cluster B personality disorders. Estimates of borderline personality disorder range from 2–47% in bulimia nervosa samples (Wonderlich, 1995). Dennis and Sansone (1997) report that the average prevalence rate is about 34%. Investigators have hypothesized that bulimia nervosa may mimic borderline personality disorder and may contribute to diagnostic confusion and misdiagnosis (Wonderlich, 1995); however, this hypothesis has not been investigated thoroughly. The presence of comorbid personality disorders in bulimia nervosa patients has been known to interfere with eating disorder treatment and to contribute to poor outcome.

Substance Use Disorders. Substance use disorders are common among bulimia nervosa patients; approximately 23% suffer from alcohol abuse or dependence (Holderness, Brookes-Gunn, & Warren, 1994). Bulimia nervosa patients with comorbid substance use disorders may demonstrate greater levels of impulsivity compared to those without such secondary psychopathology (Wonderlich & Mitchell, 1997).

Eating Disorder Not Otherwise Specified

Diagnosis and Clinical Description

Recently, there has been an increased emphasis in the eating disorder literature on the prevalence and subsequent severity of eating disorder symptoms in the general population. There has been increased attention and recognition that the segment of the population that exhibits eating disorder symptoms at a "subclinical level" constitutes a significant proportion of clinic patients (Beaumont et al., 1994; Shisslak, Crago, & Estes, 1995; Walsh & Garner, 1997; Williamson, Gleaves, & Savin, 1992). These disorders have been called by various names, including atypical eating dis-

orders, subclinical eating disorders, and Eating Disorder-NOS.

Epidemiology

The DSM-IV (APA, 1994) provided greater specificity in the designation of Eating Disorder-NOS diagnoses (Williamson et al., 1992). According to Walsh and Garner (1997), the Eating Disorder-NOS diagnosis represents the presence of clinically significant eating disorder symptoms that do not meet the DSM-IV diagnostic criteria for anorexia nervosa or bulimia nervosa. For example, subclinical bulimia nervosa is defined by a constellation of symptoms, including binge-eating or purgative behavior that occur at a lower frequency or for a shorter duration than that required for the formal diagnosis of bulimia nervosa (Walsh & Garner, 1997). Of additional significance is that a long-term follow-up study reported that 40% of partial eating disorder syndrome patients met the full criteria for a "typical" eating disorder at follow-up (Herzog, Hopkins, & Burns, 1993).

Prevalence

Studies of the prevalence rates of partial syndrome eating disorders indicate that they may occur at a prevalence rate equal to or greater than the diagnoses of bulimia nervosa (1–3%) or anorexia nervosa (0.5%) (Fairburn & Beglin, 1990; Kendler et al., 1991; Patton, 1992). For example, Kendler et al. (1991) documented a prevalence rate of 3% for partial syndrome eating disorders in an epidemiological investigation of eating disorder prevalence among 2163 twins from a population-based register. In a community-based investigation of 8116 subjects, the prevalence of bulimia nervosa was 1.1% and the presence of partial syndrome eating disorder was 1.4% for female participants (Garfinkel et al., 1995). Button and Whitehouse (1995) reported a prevalence rate of 5% for partial syndrome eating disorders among a population of London schoolgirls, and Patton, Johnson-Sabine, Wood, Mann, and Wakeling (1990) reported that 10% of the population had a partial syndrome eating disorder. These disorders also constitute a substantial proportion (40–46%) of adult clients who sought treatment for eating disorder symptoms in the United States (Herzog et al., 1993; Williamson et al., 1992). Prevalence rates for adolescent females referred for eating disorder treat-

ment are similar and range from 35–50% (Bunnell, Cooper, Hertz, & Shenker, 1992).

Comorbidity

Two community studies examined the prevalence rates of comorbid psychiatric diagnoses with subclinical bulimia nervosa (Garfinkel et al., 1995; Kendler et al., 1991). Community-based studies, it is thought, provide more reliable prevalence estimates than clinical samples due to sampling biases of clinical samples (Pedhazzer & Schmelkin, 1991; Wonderlich & Mitchell, 1997). These studies found no significant differences between prevalence rates of comorbid diagnoses of persons with bulimia nervosa or subclinical bulimia nervosa (Garfinkel et al., 1995; Kendler et al., 1991). Reported lifetime prevalence rates of comorbid diagnoses that occur with subclinical bulimia nervosa in these studies are as follows: alcohol dependence: 15.5–30.9%, generalized anxiety disorder: 9.1–11.4%, and major depressive disorder: 36.4–51%.

Etiology

Given the similarity of these disorders to the formal diagnosis of anorexia or bulimia nervosa, the etiologies of the subclinical forms of these disorders are presumed to be the same as those for the full syndromes of anorexia nervosa and bulimia nervosa.

Binge-Eating Disorder

Diagnosis and Clinical Description

Research on eating disorders has occasionally described cases of "nonpurging bulimia" or "obese binge eaters" throughout the years, following Stunkard's (1959) initial case description of an obese binge-eater in 1959. However, it was not until the early 1990s that a formal definition was developed to classify individuals who engage in binge eating, but who do not regularly engage in the compensatory behaviors indicative of bulimia nervosa (Marcus, 1993). This syndrome became known as "binge-eating disorder" (BED) and was included in the DSM-IV (APA, 1994) as a diagnostic category in need of further study. The development of a definition for BED stimulated research in the area and contributed to an accumulating

database on the subject. Much of the earlier research relied on samples that met the binge-eating disorder criteria proposed by Spitzer et al. (1992, 1993); however, recent studies relied on the DSM-IV definition of BED. This chapter will not differentiate between the two because the two sets of criteria varied only minimally.

Persons diagnosed with binge-eating disorder exhibit chaotic eating patterns and consume more calories at normal meals and during binge-eating episodes, compared to weight matched non-binge-eating persons (Yanovski et al., 1992). Most of these individuals are obese and seek weight loss treatment primarily, not eating disorder treatment (Marcus, 1997). The finding that binge-eating disorder most often occurs in obese individuals helps differentiate it from bulimia nervosa, which occurs mostly in individuals of normal weight (Marcus, 1997). However, the key distinction between bulimia nervosa and BED is the absence of inappropriate compensatory behavior in BED.

The research criteria for binge-eating disorder, summarized in Table 3, require recurrent episodes of binge eating, as defined in the diagnostic crite-

Table 3. Summary of DSM-IV Research Criteria for Binge-Eating Disorder

-
- A. Recurrent episodes of binge eating. Binge eating episodes are marked by both:
- 1) eating an amount of food that is larger than others would eat in a similar time period and under similar circumstances;
 - 2) a sense of lack of control over eating during the episode.
- B. The binge-eating episodes are associated with at least three of the following:
- 1) eating faster than normal
 - 2) eating until feeling uncomfortably full
 - 3) eating when not feeling hungry
 - 4) eating alone due to embarrassment of the amount of food one is eating
 - 5) feeling disgusted, depressed, or guilty after over-eating
- C. The presence of distress concerning binge eating.
- D. Binge eating occurs at least 2 days a week for 6 months, on average.
- E. The binge eating is not associated with the regular use of inappropriate compensatory behaviors and Anorexia Nervosa or Bulimia Nervosa are not present.
-

ria for bulimia nervosa. Specifically, the amount of food eaten must be greater than others would eat in a similar circumstance, and a sense of loss of control over eating must be present. The problems discussed earlier in defining a binge-eating episode in bulimia nervosa are also present in BED's criteria. Similarly, it is concluded that the most appropriate way to define a binge-eating episode is by comparing the amount of food consumed to that which others might eat, taking into consideration the time and social circumstances of the individual's last meal (Garfinkel, 1995).

The second criterion for binge-eating disorder requires the presence of three or more of the following characteristics associated with binge-eating episodes: (1) eating more rapidly than normal; (2) eating until feeling uncomfortably full; (3) eating large amounts of food when not feeling hungry; (4) eating alone due to embarrassment over the amount one is eating; or (5) feeling disgusted, depressed, or guilty after overeating.

The diagnostic criteria for bulimia nervosa require that binge eating (and inappropriate compensatory behaviors) occurs, on average, at least twice a week for 3 months. However, the diagnostic criteria for binge-eating disorder require that the binge eating occurs at least 2 days a week for 6 months. Therefore, in binge-eating disorder, the focus is not on the *number of binge-eating episodes*, but rather the *number of days on which binge eating occurred*. This definition is advantageous because obese binge eaters frequently report binge-eating episodes that last throughout the day, making it difficult to determine the "number" of episodes (Marcus, Smith, Santelli, & Kaye, 1992). Nonetheless, the diagnostic validity of the frequency criterion has been questioned by findings that individuals who meet all of the BED criteria except the frequency criterion are indistinguishable in a number of psychological and behavioral variables from individuals diagnosed with binge-eating disorder (Striegel-Moore, Wilson, Wilfley, Elder, & Brownell, 1998).

The diagnosis of binge-eating disorder requires distress concerning binge eating, and the binge eating may not be associated with the regular use of inappropriate compensatory behaviors. This criterion is problematic due to the difficulty in defining "regular use" of inappropriate compensatory behaviors which dictates the differential diagnosis between binge-eating disorder and non-purging bulimia nervosa. Finally, the binge eating

may not occur exclusively during the course of anorexia or bulimia nervosa.

Examination of the diagnostic criteria for binge-eating disorder illustrates the importance of refining the criteria. This may entail eliminating, modifying, or adding criteria. For example, Eldredge and Agras (1996) found that overconcern with weight and shape should be investigated as a diagnostic feature of binge-eating disorder and that emotional eating is associated with binge-eating disorder, not obesity *per se*.

Prevalence

Studies that examined the prevalence of binge-eating disorder have yielded inconsistent findings. Earlier studies reported prevalence rates of 30% in persons who sought weight loss treatment and 2% in community samples (Spitzer, et al., 1992, 1993). These studies relied on self-report instruments; however, other studies relied on interviews to assess binge-eating disorder. For example, Varnado et al. (1997) used the Interview for the Diagnosis of Eating Disorders, Fourth Revision (IDED-IV; Kutlesic, Williamson, Gleaves, Barbin, & Murphey-Eberenz, 1998) to define binge-eating disorder and found prevalence rates of 1.3% in adults who sought weight loss treatment. Studies investigating the efficacy of interviews and questionnaires in defining BED indicate that questionnaires are less reliable than interviews (Greeno, Marcus, & Wing, 1995).

Binge-eating disorder is more common in females than in males (Spitzer, et al., 1992). A recent study that relied on two obese samples found that 77% of those diagnosed with BED were female (Varnado et al., 1997). However, other authors argue that more males are afflicted with BED than have been reported (Fairburn & Walsh, 1995).

Ethnic differences associated with binge-eating disorder are not pronounced (Smith, 1995). In obese samples, Caucasians and African-Americans demonstrated similar prevalence rates of binge-eating disorder (Spitzer et al., 1993).

Etiology

Cognitive-Behavioral Theories. The dietary restraint model of binge eating has been the primary behavioral theory of BED. The dietary restraint model suggests that individuals restrict caloric intake which leads to energy deprivation and

increased internal cues to consume food. Thus, the individual is more susceptible to disinhibition of eating and subsequently binge eats (Polivy & Herman, 1985). Although this theory provides a parsimonious explanation of binge eating in binge-eating disorder, recent research indicates otherwise.

First, evidence suggests that persons diagnosed with BED often do not report restrictive eating (Castonguay, Eldredge, & Agras, 1995). Second, binge eating reportedly occurs before dieting or attempts to restrict caloric consumption (Mussell et al., 1995). These findings argue against the dietary restraint model. Instead, disinhibition appears to be important in mediating binge eating in BED (Mussell, Mitchell, de Zwaan, et al., 1996); however, research is needed to clarify its role.

An alternative theory to the restraint model involves depression and negative mood. Depression, it is hypothesized, is a risk factor for the development of binge-eating disorder (Marcus, 1995), and negative mood is an immediate trigger to initiate binge eating (Castonguay, Eldredge, & Agras, 1995). The manner in which negative mood triggers binge eating may be explained by the "trade-off" hypothesis (Kenardy, Arnow, & Agras, 1996). This hypothesis states that in persons diagnosed with BED, the prebinge emotions (e.g., anger) are experienced as more aversive than the postbinge emotions (e.g., guilt). Therefore, binge eating is perpetuated by the "trade-off" of the less aversive postbinge emotions for the more aversive prebinge emotions.

A final alternative theory to the dietary restraint model is Heatherton and Baumeister's (1991) theory involving an "escape from self-awareness" which was discussed earlier in this chapter. Heatherton and Baumeister (1991) hypothesized that binge eaters subject themselves to high standards, and when these standards are not met, an aversive emotional state ensues. Cognitive narrowing takes place to escape from this aversive state, and greater attention is given to the environment, which leads to disinhibition of eating. This was a broad theory of binge eating proposed before the development of the criteria for binge-eating disorder, but it holds promise in enhancing our understanding of the disinhibition process and the relationship of negative emotional states and binge eating.

Biological Theories. Undoubtedly, the physiological mechanisms involved in regulating food

intake are associated with binge-eating disorder. Evidence suggests that a psychobiological mechanism is involved in binge-eating disorder where a physiological event triggers binge eating (Drewnowski, 1995). Therefore, binge eating is seen as an expression of obesity and is more likely to occur in those individuals susceptible to genetically influenced obesity (Drewnowski, 1995). This model can accommodate the findings that binge eating increases with increasing adiposity (Telch, Agras, & Rossiter, 1988) and that binge-eating disorder is overrepresented in the obese population (Spitzer et al., 1992, 1993).

Binge-eating disorder, it has been hypothesized, shares a common biological determinant with affective disorders. However, evidence indicates that binge eating precedes the first major depressive episode (Mussell et al., 1995) and that binge-eating disorder is not a variant of an affective disorder (Cooper, 1995).

Comorbidity

Binge-eating disorder is associated with depression, anxiety, substance abuse, personality disorders, and eating- and weight-related disturbances. Psychopathology is associated with binge eating and is not an expression of obesity alone (Telch & Agras, 1994).

Affective Disorders. Major depression is one of the most common forms of psychopathology associated with binge-eating disorder. In samples of persons diagnosed with binge-eating disorder, 37–51% of individuals also have major depression compared to 14–26% for non-binge-eating persons (Mussell, Peterson, et al., 1996; Specker, de Zwaan, Raymond, & Mitchell, 1994; Yanovski, Nelson, Dubbert, & Spitzer, 1993).

Anxiety Disorders. Evidence suggests that binge-eating disorder is associated with elevated trait anxiety (Antony, Johnson, Carr-Nangle, & Abel, 1994) and with high rates of anxiety disorders (Marcus, 1995).

Personality Disorders. Personality disorders are more common in persons diagnosed with BED, compared to non-binge-eating controls or the general population. A study that used questionnaires to assess personality disorders obtained prevalence rates of 56% in persons diagnosed with BED and 23% in non-binge-eating controls (Specker et al., 1994). However, interviews obtained personality disorder prevalence rates of 35% in persons with binge-eating disorder compared to

16% in controls (Yanovski, Nelson, Dubbert, & Spitzer, 1993). The types of personality disorders that are more common in persons diagnosed with binge-eating disorder include histrionic, borderline, and avoidant personality disorders (Specker et al., 1994).

Eating- and Weight-Related Psychopathology. Binge-eating disorder is associated with significant eating- and weight-related psychopathology. Persons with binge-eating disorder score significantly higher than non-binge-eating persons on measures of disinhibited eating, drive for thinness (de Zwaan et al., 1994), and body dissatisfaction (Mussell, Peterson et al., 1996), and they have difficulty interpreting hunger and satiety signals (Kuehnel & Wadden, 1994). Additionally, these individuals exhibit greater concern for weight and shape and are more likely to eat in response to negative emotions, compared to non-binge-eating persons (Eldredge & Agras, 1996). Weight cycling may be associated with binge eating (Yanovski & Sebring, 1994), although others have failed to find that association (Kuehnel & Wadden, 1994).

Substance Abuse. Substance abuse or dependence is significantly more common in persons with BED, compared to non-binge-eating persons (Eldredge & Agras, 1996; Mussell, Mitchell, et al., 1996). Researchers have found that 31% of persons diagnosed with BED have histories of alcohol abuse, compared to 9% of non-binge-eating controls (Eldredge & Agras, 1996).

Dimensional Models of Eating Disorders

The existence of these subclinical eating disorders, the ambiguity with which some eating disorder diagnostic criteria are defined, and the prevalence of subclinical eating disorders have led to criticism of the diagnostic nomenclature of eating disorders, namely, whether eating disorders would be better encapsulated by a dimensional as opposed to a categorical approach (Shisslak et al., 1995). Proponents of the latter viewpoint argue that many eating disorder patients are not consistent in their symptomatology but rather alternate between various eating disorder diagnoses, depending on their current weight levels, the presence of binge eating, and the presence of purgative behavior (Beaumont et al., 1994). Other researchers cite that the lack of a clear distinction between clinical versus subclinical levels of pathology precludes a categorical approach (Kendler et al.,

1991). These researchers endorse defining patients on relevant symptom continua rather than applying a blanket categorical label. Critics of these criteria describe the frequency criteria for binge eating, purging, and the absence of menstrual cycles as arbitrary and the criterion of body-image disturbance as ambiguous. The end result is that a substantial segment of the population that seeks treatment does not “fit” the definitions of anorexia nervosa or bulimia nervosa and, therefore, must be classified as Eating Disorder-NOS.

Assessment

Psychological assessment of anorexia nervosa, bulimia nervosa, and Eating Disorder-NOS can be very useful when establishing a case formulation and planning treatment. However, assessing the eating disorder patient is often complicated by the ego-syntonic nature of the symptoms (Garner et al., 1997). Because the eating disorder patients value their thinness and may desire to maintain their current body weights and eating habits, establishing rapport is essential to obtain accurate information and to initiate effective treatment processes (Vitousek, Daly, & Heiser, 1991). In contrast, the bulimic patient may not disclose information about current symptomatology due to shame or embarrassment (Vitousek et al., 1991). The assessment process will proceed most effectively if the interviewer empathizes with the patient’s current ambivalence about engaging in the treatment process.

Assessment is best conceptualized as an ongoing process of information gathering in which hypotheses of etiology and symptom maintenance are formulated and revised as new information is gathered during the course of treatment. There are several important domains that require thorough investigation. First, a detailed weight history should be obtained that includes the individuals highest and lowest weights, the relationship between interpersonal stressors and weight fluctuations, early childhood weight and incidents of teasing, and the client’s ideal weight. Additional areas of assessment include the presence of body-image disturbance, dysfunctional eating behaviors, and comorbid psychopathology. Finally, a thorough assessment involves using multiple methods of data collection, including structured interviews, self-report measures, behavioral observations, and collateral interviews.

Structured Interviews

Structured interviews offer the benefit of a systematized collection of information that may minimize investigator bias. However, such interviews can interfere with the establishment of rapport due to their structured format. Despite this limitation, the structured interview is a useful tool for collecting assessment data.

The patient and family members are often interviewed separately to help establish the validity of the patient’s reports and to begin formulating hypotheses about the relationships among family variables and eating disorder symptom development. A functional analysis of disordered eating behavior is important for effective treatment planning because it can elicit variables that may have contributed to the initiation of disordered eating. Additionally, foods that are avoided because of a belief that they will lead to rapid weight gain (i.e., “forbidden” foods) should be identified for use in exposure therapy to reduce irrational fears associated with such foods.

Several structured interview formats for diagnosing eating disorders have been developed. The Eating Disorder Examination, 12th ed. is the most extensively researched of the structured interviews (Fairburn & Cooper, 1993). The EDE has four subscales that assess different dimensions of pathology associated with disordered eating (restraint, eating concern, shape concern, and weight concern) as well as a global measure of overall severity. The EDE provides operationally defined eating disorder diagnoses and is sensitive to the effects of treatment (Fairburn, Jones, Peveler, Hope, & O’Connor, 1993). Acceptable psychometric properties have been reported (Fairburn & Cooper, 1993).

The Interview for Diagnosis of Eating Disorders, 4th ed. (IDED-IV) was designed specifically for the differential diagnosis of anorexia nervosa, bulimia nervosa, and eating disorder, not otherwise specified, based on the DSM-IV criteria (Kutlesic, Williamson, Gleaves, Barbin, & Murphy-Eberenz, 1998). Satisfactory reliability and validity have been reported (Kutlesic et al., 1998).

Self-Report Inventories

The Eating Attitudes Test (EAT) is a forty-item self-report measure developed to assess anorexic attitudes, beliefs, and behaviors (Garner & Garfinkel, 1979). A factor analysis of the original

measure produced a twenty-six-item measure that is widely utilized in research as a screening tool (Garner, 1997). The EAT discriminates eating disorder patients from nonclinical controls and differentiates binge eaters from individuals diagnosed with bulimia nervosa (Williamson, Prather, McKenzie, & Blouin, 1990). However, the EAT does not discriminate patients diagnosed with anorexia nervosa from patients diagnosed with bulimia nervosa (Williamson, 1990). Psychometric properties of the EAT are reportedly satisfactory (Gross, Rosen, Leitenberg, & Willmuth, 1986).

The Eating Disorder Inventory Revised (EDI-2) was developed to assess the cognitive and behavioral characteristics of anorexia and bulimia nervosa (Garner, 1991). The EDI-2 has eleven subscales: (1) drive for thinness, (2) bulimia, (3) body dissatisfaction, (4) ineffectiveness, (5) perfectionism, (6) interpersonal distrust, (7) interoceptive awareness, (8) maturity fears, (9) asceticism, (10) impulse regulation, and (11) social insecurity. Internal consistency for each of the eleven subscales except asceticism was above .65, and the criterion validity for each subscale is satisfactory. Extensive norms have been established for this measure.

The Bulimia Test-Revised (BULIT-R; Thelen, Farmer, Wonderlich, & Smith, 1991) was developed to assess the symptoms of bulimia nervosa according to the DSM-III-R (APA, 1987). Satisfactory psychometric data have been reported, and the BULIT-R, it was found, discriminates subjects with bulimia nervosa, binge-eating disorder, obesity, and nonclinical subjects (Williamson et al., 1990).

The Binge Eating Scale (BES; Gormally, Black, Daston, & Rardin, 1982) and the Questionnaire on Eating and Weight Patterns (QEWP; Spitzer et al., 1992) have been used to assess BED. However, research has found that the BES and QEWP agree poorly in classifying binge eaters (Gladis, Wadden, Foster, Vogt, & Wingate, 1998). Both scales overestimate the presence of BED, compared to the results of structured interviews for diagnosing BED (Varnado et al., 1997).

Test Meals

Direct observation of eating can be used to assess behavioral avoidance of anxiety-producing foods. This procedure usually consists of informing the patient that purging will be prohibited, measuring the amounts and types of food con-

sumed, and obtaining ratings of fear, anxiety, and the urge to engage in self-induced vomiting or other purgative behavior (Williamson, 1990).

Self-Monitoring

Self-monitoring data can assist behavioral analysis, diagnosis, and evaluation of treatment outcome. This procedure requires that the individual record the amounts and types of food eaten, as well as the behavioral, cognitive, and emotional antecedents and consequences of eating (Schlundt & Johnson, 1990; Williamson et al., 1990). Analysis of these data allows an evaluation of the variations in eating behavior as a function of environmental events. Fairburn and colleagues have used this methodology as an important component of their efficacious and specific treatment protocol for treating bulimia nervosa and more recently, for binge eating disorder (Chambliss & Hollon, 1998; Fairburn et al., 1991; Wilfrey et al., 1993). Williamson (1990) developed a self-monitoring procedure that has been validated for eating disorders (Williamson et al., 1990). Using this method, the person records the type and amount of food intake, the mood before and after eating, hunger before and after eating, and the environmental circumstances before and during eating. For bulimic and purging anorexics, a section allowing reports of the occurrence of purging and associated moods and hunger is included. Self-monitoring for two weeks before entering therapy is recommended to aid in diagnosis and case formulation (Williamson, Prather, Goreczny, Davis, & McKenzie, 1989) and to provide baseline data.

Body Composition

A central diagnostic feature of anorexia nervosa is low body weight. Estimates of body fat percentage are useful for determining the extent of emaciation. Methods employed to determine body fat percentage include neutron activation analysis, underwater weighing, electrical resistance techniques, radioactive potassium studies, and sum of skinfolds. Except for skinfold measurements, however, these techniques are costly and impractical for most clinicians. Quetelet's Body Mass Index (BMI) is a valid and economical means of estimating body mass. BMI is obtained by dividing weight in kilograms by the square of height in meters. It has been suggested that a BMI of 17.5 to

18 or lower is generally used as the criterion for low weight level in anorexia nervosa (WHO, 1992). This measure is highly correlated with body density, total body water, and total potassium estimates of body fat (Webster, Hesp, & Garrow, 1984). Skinfold measurement is another economical and convenient method for determining body fat. Body fat estimates derived from BMI and skinfold measurement may be compared using the norms compiled by Durnin and Womersley (1974).

Body Image

One of the core features of anorexia nervosa and bulimia nervosa is a disturbance of body image. Researchers have often conceptualized that body image consists of two components: perceptual components, which focus on size perception accuracy of body image; and subjective indexes, which assess the attitudinal or cognitive aspect of body-image disturbance (Thompson, 1990).

Numerous questionnaires have been developed to assess attitudes toward the degree of satisfaction with body size. These measures include the EDI-2 subscale that assesses body dissatisfaction (Garner, 1991); the Body Shape Questionnaire (Cooper, Taylor, Cooper, & Fairburn, 1987), which assesses the frequency of thoughts or feelings that express body dissatisfaction; and the Body-Self Relations Questionnaire (Butters & Cash, 1987), which measures attitudes toward appearance, physical fitness, and health.

Perceptual methods for assessing body-image distortion require the person to estimate body size, and the degree of error made in this estimation is determined. A body-distortion index can be computed by dividing the estimated size by actual size, yielding a ratio of over- or underestimation of body size. Numerous methods for estimating body size have been developed during the past 20 years, including (1) manipulation of light beams (Thompson, 1990; Thompson & Spana, 1988); (2) image marking procedures (Bowden, Touyz, Rodriguez, Henley, & Beaumont, 1989); and (3) distorting mirrors, photographs, lenses, or video (Touyz, Beaumont, Collins, McCabe, & Jupp, 1984).

A simple procedure to assess body-image disturbances has been developed by Williamson, Davis, Goreczny, Bennett, and Gleaves (1989). This procedure requires that the individual compare perception of body size to ideal body size.

Female figures that vary from extremely thin to obese are represented on nine cards, from which the subject is instructed to choose the card closest to actual body size and then ideal body size. Body size distortion, body size dissatisfaction, and preference for thinness may be ascertained from this procedure by using normative data. The procedure was found to be reliable and valid in a series of studies (Williamson et al., 1989).

Treatment Planning for Anorexia Nervosa and Bulimia Nervosa

Due to the serious medical consequences and potential mortality of eating disorder symptoms, the initial stage of treatment planning must determine the appropriate level of care for the patient's current medical status. Potential levels of care include inpatient hospitalization, partial day hospitalization, intensive outpatient treatment, and outpatient treatment. Factors to be taken into account when determining the level of care are given in Table 4.

Inpatient Treatment

Before initiating an inpatient hospital stay, a treatment contract is usually formulated with the patient to delineate the goals to be achieved during the inpatient stay and the progress that must be achieved before a less intense level of care can be considered. These goals usually focus on medical stabilization, establishing regular patterns of eating, identifying issues that contribute to current disturbances with eating, identifying and beginning to resolve major cognitive distortions regarding body weight and body image, and relapse prevention plans and readmission criteria (Anderson, Bowers, & Evans, 1997).

Alterations in eating habits, improvement in nutritional status, and a decrease of purgative behavior are usually accomplished by using behavioral approaches (Williamson, Duchmann, Barker, & Bruno, 1998). A primary goal of inpatient hospitalization for anorexic patients is to create a positive energy balance through increased caloric intake and decreased energy expenditure (Anderson et al., 1997). A primary goal of inpatient hospitalization for bulimia nervosa patients is establishing regular eating patterns and eliminating purgative behavior. Behavior is altered by meal planning,

Table 4. Criteria to Determine Level of Care**Inpatient**

1. Extreme emaciation (e.g., body weight is 15% or more below normal).
2. Severe medical complications (e.g., end stage renal disease, diabetes mellitus, extreme dehydration or malnutrition).
3. Repeated failure of less intense levels of treatment.
4. Psychiatric crises (e.g., suicidal attempt or intent).
5. Extreme exacerbation in frequency of purgative behavior.

Partial day hospital

1. Moderate level of emaciation (e.g., body weight is 5% to 15% below normal).
2. Rapid weight loss (e.g., patient is losing 2 lbs. per week over the past 4 weeks).
3. Repeated failure of outpatient treatment.

Intensive outpatient treatment

1. Moderate level of emaciation (e.g., body weight is 5% to 15% below normal).
2. Failure to fully comply with meal plan on an outpatient basis.
3. Repeated failure of outpatient treatment alone.

Outpatient

1. Normal body weight status.
2. Good family/social support system.

behavioral contracting, and education regarding myths about nutrition that patients may have endorsed. Meal planning is initially conducted by a registered dietician who is the "expert" on questions of nutrition and prescribes a plan of eating in the format of a medication regimen emphasizing that for the eating disorder patient, food is medicine.

Reinforcement of behavior change is accomplished by increasing patient privileges and by increasing staff social reinforcement (Williamson et al., 1998; Touyz & Beaumont, 1997). Because one of the primary motivating constructs of anorexic behavior is a fear of weight gain, food is viewed as a feared object. Thus, according to the principles of exposure with response prevention, each meal consumed in the hospital involves exposing the patient to a feared stimulus (food) and preventing the patient from engaging in behaviors that may have previously reduced anxiety (i.e., exercise, purgative behavior). Through the pro-

cess of extinction, anxiety is reduced during the hospital stay. Repeated exposure to feared situations in which the feared negative consequences do not ensue is intended to help to modify dysfunctional beliefs about eating and weight gain.

Partial Day Hospitalization

Once the individual is medically stabilized, the patient may be transitioned to a reduced level of care, referred to as partial day hospitalization. This treatment program usually requires the patient to attend hospital treatment groups during the day, to be supervised for the majority of meals, and to spend evenings at home. In this manner, the patient is gradually reintroduced to the stressors of the family and social environment while still receiving an intensive level of care and medical supervision.

Intensive Outpatient Therapy

Intensive outpatient requires the individual to attend a prescribed number of treatment groups per week, along with a limited number of meals. This level of care is a further transition to outpatient treatment because the patient usually has contact with the eating disorder treatment program for several afternoons during the week. Targets for this level of treatment include maintaining a healthy weight level and increasing patient responsibility for meal planning outside of the hospital.

Outpatient Therapy

Given the limitations imposed on the length of inpatient hospital stays due to current health care policies, the preponderance of treatment for eating disorders occurs on an outpatient basis. Outpatient therapy focuses on the issues identified during the inpatient hospital stay; helps the patient to identify and modify dysfunctional thoughts, schemas, and thinking patterns associated with body image and interpersonal difficulties; and continues to address dysfunctional eating behaviors. Cognitive restructuring is often an important component of outpatient treatment as patients are taught to reevaluate their previous overvaluation of body size and shape as a determination of self-worth. Relapse prevention planning is often a component of outpatient treatment; patients are often provided with

behavioral expectations that must be maintained to avoid readmission to the hospital.

Components of Treatment

Body-Image Therapy. As weight gain occurs, body size distortion and dissatisfaction are likely to worsen. Cognitive behavioral techniques, such as challenging pertinent irrational beliefs and body-image desensitization, can be incorporated into treatment to address these body-image disturbances (Rosen, 1997). Once these beliefs are identified and monitored, patients are taught to challenge irrational thoughts and to generate more rational thinking. Recently published self-help manuals for treating body-image disturbance can be useful adjuncts to an intensive body-image program (Cash, 1997).

Family Therapy. Family therapy has been increasingly recognized as an important component in the effective treatment of anorexia nervosa and is strongly recommended for young anorexic patients. Evidence of the effectiveness of family therapy for treating bulimia nervosa has been less conclusive. However, recent successful interventions have demonstrated the potential utility of this mode of therapy for bulimia nervosa (Russell, Szmukler, Dare, & Eisler, 1987). Family therapy encompasses a variety of theoretical orientations that may focus on the nature of alliances between family members, the function of the eating disorder within the family system, and the communication styles of the family members (Dare & Eisler, 1997). Often the eating disorder has come to serve specific functions within the interacting family system that need to be identified and replaced with more adaptive behaviors, if treatment is to be effective. Family therapy often begins with education about eating disorders and gradually progresses to investigating the family's communication styles and skill deficits through the examples of family interactions that occur during the therapeutic session (Williamson et al., 1998). Recently, Robin and colleagues empirically validated their behavioral family systems treatment protocol for treating adolescent anorexic patients (Robin, Bedway, Siegel, & Gilroy, 1996). In addition, Dare, Eisler, Russell, and Smucker (1990) reported robust findings that adolescents with symptoms of short duration respond well to family therapy.

Treatment of Secondary Psychopathology. As noted in earlier sections, a substantial propor-

tion of patients with eating disorders may have been diagnosed with comorbid psychiatric disorders. The presence of comorbid diagnoses often complicates the treatment of an eating disorder, and the potential interference of secondary psychopathology on treatment adherence must be considered in treatment planning. For example, it may be more difficult to treat the food rituals often seen among anorexic patients when a patient has also been diagnosed with obsessive-compulsive disorder. Effective treatment planning must take into account how these individual diagnostic variables can affect such factors as the therapeutic alliance, the client's motivation for treatment, and the treatment outcome.

Pharmacological Treatment. Advances in using pharmacological agents for treating mental disorders has stimulated research into using such agents for treating eating disorders. The use of antidepressant medications, it has been shown, is efficacious in treating bulimia nervosa (Agras, 1997). In a review of the treatment of bulimia nervosa with antidepressants, the overall effectiveness of these pharmacological agents in reducing the frequency of binge eating and purging was 70% (Agras, 1997). Agras (1997) reported that approximately one-third of patients have full-recovery. However, several factors have been found that affect treatment effectiveness. For example, treatment of short duration with antidepressants, that is, 12–16 weeks, leads to relapse when the medication is withdrawn (Agras et al., 1992). Agras (1997) recommends a treatment trial of antidepressant medication of at least 6 months. In addition, in a study in which sequential antidepressant medication was given, medication was as effective as cognitive-behavior therapy plus placebo (Agras, 1997). Thus, more sophisticated drug regimens may have increased effectiveness. Other classes of drugs such as anxiolytics, opiate antagonists, and mood stabilizers had limited effectiveness in treating bulimia nervosa (Garfinkel & Walsh, 1997).

Despite significant advances in the pharmacological treatment of bulimia nervosa, the core psychopathology of anorexia nervosa remains relatively refractory to pharmacological treatment (Garfinkel & Walsh, 1997). Several types of psychotropic medications have been used to treat anorexia nervosa without significant success. These included antipsychotic medications (Dally & Sargent, 1966), antidepressants (Kaye, Weltzin, Hsu,

& Bulik, 1991), anxiolytics (Garfinkel et al., 1997), appetite-enhancing agents (Vaccarino, Kennedy, Ralevski, & Black, 1994), and prokinetic agents (Szmukler, Young, Miller, Lichtenstein, & Binns, 1995). Further, the significant side effects often associated with using these medications in a patient population with substantial medical complications further precludes their use.

A recent investigation examined the effectiveness of administering fluoxetine, a selective serotonergic re-uptake inhibitor, to the standard outpatient treatment protocol for a group of anorexic patients that had previously received intensive inpatient treatment (Strober, Freeman, DeAntonio, Lampert, & Diamond, 1997). Patients were followed for 24 months postinpatient hospitalization. Results indicated that fluoxetine failed to have a significant effect on maintaining target weight during the follow-up period, on risk of sustained weight loss, or on other clinical measures of outcome (Strober et al., 1997). Anxiolytics have been used by some clinicians to reduce the significant anxiety experienced by patients before a meal, when the patient fails to respond to supportive measures (Anderson, 1987). However, it is recommended that the use of minor tranquilizers be time-limited (Garfinkel & Walsh, 1997). Finally, prokinetic agents, medications that promote gastric emptying, have been investigated (Szmukler et al., 1995). Although such agents do not significantly improve the rate of weight gain, prokinetic agents may improve patient compliance for those individuals who experience significant distress from food consumption (Szmukler et al., 1995).

Treatment Planning for Binge-Eating Disorder

Treatment planning for persons diagnosed with binge-eating disorder is unique because most individuals present for weight loss treatment, not treatment for an eating disorder (Marcus, 1997). Therefore, treatment planning must incorporate problems related to obesity, as well as to comorbid psychopathology. The most popular treatment modality for binge-eating disorder is outpatient cognitive-behavioral therapy (CBT) which was adapted from Fairburn's (1985) treatment for bulimia nervosa (Fairburn, Marcus, & Wilson, 1993). In CBT for binge-eating disorder, overall moderation of food intake and decreasing binge-eating

episodes are targeted as primary treatment goals, and special attention is given to obesity education (Marcus, 1997). The normalization of eating uses the same techniques as CBT for bulimia nervosa, and cognitive restructuring is used to change maladaptive thoughts, beliefs, and values related to eating (Marcus, 1997). Exercise is important in the treatment due to its effects in stress management and increasing energy expenditure, and calorie counting may be used to help define "normal eating" and promote a healthy, balanced diet (Marcus, 1997).

Research has supported the efficacy of CBT for treating binge-eating disorder (Smith, Marcus, & Kaye, 1992). CBT, it has been found, significantly reduces binge-eating frequency and maladaptive attitudes about shape, weight, and eating (Smith, Marcus, & Kaye, 1992). Follow-up studies indicate that CBT maintained significant reductions in binge eating at 1 year follow-up (Wilfrey et al., 1993).

Interpersonal psychotherapy (IPT) asserts that binge eating results from negative affect induced by interpersonal difficulties such as social isolation. Therefore, IPT is not focused on the symptoms of binge eating but on alleviating interpersonal distress and problems. Evidence suggests that IPT is effective in significantly reducing binge eating, and these reductions remain at 1 year follow-up (Wilfrey et al., 1993).

Pharmacotherapy

Medications that have been effective for bulimia nervosa and for depression have been examined in obese persons who binge. Tricyclic antidepressants reduce binge eating compared to placebo in persons diagnosed with nonpurging bulimia (McCann & Agras, 1990). The selective serotonin re-uptake inhibiting antidepressants fluoxetine and fluvoxamine (SSRI) also reduce binge-eating frequency in persons diagnosed with binge-eating disorder (Greeno & Wing, 1996; Hudson, Carter, & Pope, 1996). Opiate antagonists reduce binge-eating frequency in persons diagnosed with binge-eating disorder (Marrazzi, Markham, Kinzie, & Luby, 1995); however, others have failed to replicate these findings (Alger et al., 1991).

Despite the effectiveness of pharmacological interventions, binge-eating frequency and weight often return to baseline levels when the use of medication stops. The use of behavioral interven-

tions, relapse prevention, longer medication trials, and combinations of pharmacotherapy and psychotherapy are advocated to increase the effectiveness of BED treatment (Agras, 1997).

Future Research Directions

Cognitive Bias

When this volume was last published, research into cognitive biases associated with eating disorders was just beginning (Williamson, Barker, & Norris, 1993). During the intervening years, considerable progress has been made. Two recent reviews have summarized these research findings (Williamson, 1996; Williamson, Muller, Reas, & Thaw, in press). Three types of information-processing biases have been reported: (1) selective attentional bias, (2) selective recall (from memory) bias, and (3) selective interpretation bias. For each type of cognitive bias, research has found that information-processing errors are specific to information related to body size/shape and/or eating "fattening" foods. Cognitive biases have also been observed in women of normal weight who are preoccupied with body size/shape (Baker, Williamson, & Sylve, 1995; Jackmann, Williamson, Netemeyer, & Anderson, 1995). These findings suggest that cognitive bias may be a central feature of the eating disorders and may play an important role in maintaining eating disorders (Williamson, Muller, Reas, & Thaw, in press). Williamson (1996) hypothesized that body-image disturbances associated with eating disorders may be conceptualized as a type of cognitive bias. Several longitudinal investigations have identified body concerns and body-image disturbances (Killen, Taylor, et al., 1994, 1996; Thompson, Coovert, Richards, Johnson, & Cattarin, 1995) as an important precursor to the development of a clinical eating disorder syndrome. Given these findings, it would be of considerable interest to assess the relationships among body concerns, cognitive biases related to body and eating, and eating disorder symptoms in developmental studies of girls that span the age ranges before and after puberty, the developmental period of greatest risk for developing eating disorders. Developmental psychopathology studies of cognitive bias could answer questions about the role of body concerns and cognitive bias related to body size/shape as causative versus maintenance

factors for eating disorders. For example, if body concerns consistently precede cognitive biases and the development of eating disorder symptoms, this pattern of findings would argue that the obsession with body size/shape is the earliest indicator of an eating disorder. However, if the presence of cognitive bias for body size/shape is the strongest predictor of eating disorder symptoms, this pattern of findings would argue that information-processing errors may be causative. On the other hand, if cognitive biases covary only with eating disorder symptoms, this pattern of results would argue that cognitive biases are likely to play a maintenance role in eating disorders.

Another approach to answering this question would be to evaluate changes in cognitive bias as a function of treatment. If cognitive biases for body size/shape improve with a reduction of eating disorder symptoms and worsen before relapse, this pattern of findings would suggest a causative role for cognitive bias. Whereas, if cognitive biases covary only with eating disorder symptoms, this pattern of results would argue for a maintenance role for cognitive bias. For persons who respond positively to treatment, it would be of interest to assess the effect of activating weight concerns on the presence of cognitive biases. It is possible that cognitive biases are present only when weight concerns are very active. Research on body image (Baker et al., 1995; McKenzie, Williamson, & Cubic, 1993) has found that body-image disturbances are most pronounced when weight concerns and/or negative affect is elicited. If body-image disturbances are a type of cognitive bias (Williamson, 1996), these findings can be regarded as preliminary evidence to support this hypothesis. This line of research would help clarify whether body concerns and/or cognitive biases for body size/shape are central features of eating disorders. If these body shape concerns are central, then they must be primary targets for treatment and prevention programs for eating disorders or secondary factors that improve with behavioral symptoms, for example, restrictive eating, binge eating, and purging.

Cost-Effective Treatment

Treatment of eating disorders, and especially treatment of anorexia nervosa, is often lengthy and costly (Williamson, Duchmann, et al., 1998). During the past 5 years, managed care (in the United

States) has provided a strong challenge to traditional inpatient treatment programs for eating disorders, because they are very expensive. Because of the limitations of health care insurance benefits for managed care, there is a need to evaluate treatment options that are less intensive and less expensive than inpatient treatment. It will be important to evaluate the treatment outcome of these programs, so that both cost and effectiveness can be determined. As noted earlier, modern treatment programs for eating disorders (e.g., Williamson, Duchmann, et al., 1998) have introduced multiple levels of care: inpatient; day hospital, intensive outpatient, and outpatient levels. This approach to treatment allows reserving the most expensive treatment, inpatient, for patients who are very ill, and it allows limiting intensive treatment to the most critical stages of treatment. This approach also makes it possible to treat less severely ill patients at a less expensive level of care, day hospital or intensive outpatient therapy. At this time, very few reports have described the relative costs and outcomes of different levels of treatment. Williamson, Bruno, Thaw, and Muller (1998) reported that cases of severe eating disorder that were treated in a partial hospital program had outcomes equivalent to those of patients initially treated in an inpatient program. The costs of treatment for patients treated in a partial day hospital program were approximately two-thirds of the costs of inpatient treatment. This type of clinical research is needed if health professionals are to discover effective but less costly approaches to treatment.

Prevention of Eating Disorders

Given the cost and difficulty of effectively treating eating disorders in tertiary care settings, there has been considerable interest in developing prevention programs for eating disorders. Most prevention programs have targeted preadolescent or adolescent girls in school-based prevention programs (e.g., Killen, Hayward et al., 1994; Shisslak et al., 1990). These programs can be conceptualized as primary prevention. When these programs have been evaluated for efficacy, they have generally reported some changes in knowledge about eating disorders, nutrition, and/or dieting, but very limited changes in attitudes about body or eating or in actual behaviors, such as dieting, binge eating, or the use of extreme weight control

behaviors. There has been some discussion of targeting persons who are "at risk" of developing eating disorders (Taylor & Altman, 1997), but very few studies have actually evaluated the impact of the prevention program on "at-risk" cases (Varnado, Zucker, Williamson, Reas, & Thaw, 1998). There is also very little research on the merits of early intervention for eating disorders that can be viewed as secondary prevention for eating disorders. Research on early intervention for anorexia nervosa has yielded mixed results (Schoemaker, 1997), and only a few studies provide evidence that early treatment is more effective, compared to treatment after the eating disorder has become chronic. A recent study on long-term outcome for bulimia nervosa (Reas, Williamson, Martin & Zucker, in press) found that outpatient treatment during the first few years of the onset of bulimia resulted in an 80% recovery rate. Further research on secondary prevention and prevention interventions for "at-risk" children and adolescents is needed.

Risk Factors for Eating Disorders

As noted in the previous sections, there has been much discussion of identifying persons who are "at risk" for eating disorders and there has been considerable interest in identifying *risk factors* for eating disorders. Risk factors have traditionally been viewed as psychosocial or biological variables that are highly correlated with eating disorder symptoms. In recent years, the concept of risk has been the source of considerable debate, and much of the research which was initially described as risk factor studies is now viewed as having identified *correlates* of eating disorder symptoms (Kraemer, Kazdin, Offord, Kessler, Jensen, & Kupfer, 1997). As we discuss following, these correlational studies offer very little insight into risk factors for eating disorders.

To understand this modern literature, it is necessary to define the terms "risk" and "risk factors." In general, the term "risk" refers to the probability of an outcome, for example, development of eating disorder symptoms, within a sample of subjects. The term "risk factor" indicates a measurable characterization of each subject that precedes the outcome of interest and can be used to divide the population into two groups: the high-risk and low-risk population that comprise the whole population (Mrazek & Haggerty, 1994). The term char-

acteristic may refer to a feature of the individual as well as to its context. To demonstrate that a characterization is a risk factor, first, it must be measured in a sample of subjects who are free of the outcome of interest. Second, those who do have the outcome, for example, development of eating disorder symptoms, must be distinguished from those who do not subsequently have the outcome of interest. A statistically significant association between the risk factor and the outcome must be established, which can be used to define a risk factor's *potency*. Kraemer, Kazdin et al. (1997) conceptualize potency as the maximal discrepancy achievable by using a risk factor to dichotomize the population into high- and low-risk groups (e.g., odds ratio).

In view of these considerations, there are two primary problems with most of the earlier risk factor studies. The first problem is that most studies of risk factors for eating disorders have used cross-sectional research designs that simply compared one or more characteristics of an eating disorder group to those of a control group. Other studies simply reported the correlation between a purported risk factor and some measure of eating disorder symptoms. In all of these cross-sectional studies, the precedence of the risk factor to the onset of eating disorder symptoms was not established. Thus, these studies cannot determine whether the purported risk factor is an antecedent or consequence of the eating disorder. For a variable to be a risk factor, it must precede the onset of eating disorder symptoms. The second problem with most of this literature is that few studies indicated the potency of the risk factor. The implication of these considerations is that only longitudinal studies can be viewed as true risk factor research. Unfortunately, there have been only a few longitudinal studies of eating disorders, and they have yielded quite varied results. Of the variables that have been studied in these longitudinal studies, concerns about body weight and shape have been most significantly predictive of the onset of eating disorder symptoms several years later. For example, several studies of girls in the seventh through tenth grades have reported that concern with body size was the strongest predictor of eating disorder symptoms 2 to 4 years later (Attie & Brooks-Gunn, 1989; Killen, Taylor, et al., 1994, 1996; Thompson, Coovert, et al., 1995). Other studies reported that self-esteem (Button, Sonuga-Barke, Davies, & Thompson, 1996) and body mass index

and early pubertal development (Keel, Fulkerson, & Leon, 1997) were significant predictors of eating disorder symptoms in young girls followed for several years.

A few recommendations can be made for future studies on risk factors. In many studies, the best predictor of disordered eating at Time 2 was disordered eating at Time 1 (Leon, Keel, Klump, & Fulkerson, 1997). In these studies, a subset of subjects already experienced some eating-related problems at the first period of assessment. The implication of this observation is that it is important for risk factor studies of eating disorders to begin the studies with children at ages before puberty, the most common period for developing concerns about body size (Lask & Bryant-Waugh, 1997). Self-report questionnaires such as the EAT are frequently used to measure problematic eating behavior. It is most convenient to use questionnaires for this purpose, but most researchers believe that structured interviews such as the EDE (Fairburn & Cooper, 1993) or the IDED-IV (Kutlesic et al., 1998) are the most valid method for assessing symptoms of an eating disorder. The field of risk factor research could benefit from greater use of structured interviews. We also found a general absence of reports of potency in most risk factor studies, though two recent reports (Killen, Taylor, et al., 1994, 1996) reported on the potency of weight concerns as a risk factor for eating disorders.

Summary

Research into the psychopathology of eating disorders has expanded rapidly during the past 10 years. Most authorities on this topic agree that overconcern with body size, fear of fatness, drive for thinness, and disturbances of body image are central cognitive and emotional features of anorexia and bulimia nervosa. The behavioral features of anorexia and bulimia nervosa, for example, restrictive eating, binge eating, and purging, are generally viewed as being motivated by these cognitive and emotional factors. Binge-eating disorder is a new and controversial syndrome. The authors of the DSM-IV (APA, 1994) concluded that more research is needed before BED is sanctioned as a new form of eating disorder. There are important questions about the psychopathology of BED: What are the essential characteristics of this

disorder? What is the prevalence of BED? How does it differ from simple obesity and bulimia nervosa, nonpurging type? Treatment methods for anorexia and bulimia nervosa are advancing, and efforts to improve effectiveness and control the costs of treatment are being made. Treatment for BED is still in its infancy. Prevention programs for eating disorders have been developed, but true tests of the effectiveness of these programs for preventing the onset of an eating disorder have not been conducted. It is now clear that primary and secondary prevention of eating disorders is the direction that is needed for this field of research, and we anticipate that research in this area will become increasingly more sophisticated in the next 10 years.

Sleep Disorders

**Richard R. Bootzin, Rachel Manber,
Derek H. Loewy, Tracy F. Kuo, and Peter L. Franzen**

Introduction

During the past 15 years there has been an explosion of research on sleep and sleep disorders. Much has been learned about the causes and treatment of sleep disorders, including insomnia, sleep apnea, and narcolepsy. In addition, alterations in sleep patterns are so commonly associated with some disorders, such as affective disorders, post-traumatic stress disorder, and fibromyalgia, that they are used as diagnostic criteria for those disorders. More generally, we are all affected by the amount and quality of the sleep we obtain. Sleep has broad, systemic effects on mood, performance, and physical functioning. Thus, understanding sleep is essential to complete understanding of normal and abnormal behavior.

The current chapter is a revision of the chapter by Bootzin, Manber, Perlis, Salvio, and Wyatt (1993). References to research that appeared since the last chapter was written have been added; some sections have been substantially rewritten, new sections have been added, and some sections have been deleted. This chapter must, by necessity, be selective. Sources for additional information are the *International Classification of Sleep*

Disorders, Revised: Diagnostic and Coding Manual (American Sleep Disorders Association, ASDA, 1997) and *Principles and Practice of Sleep Medicine*, 3rd ed. (Kryger, Roth, & Dement, 2000).

Basic Sleep Information

Sleep must be understood within the context of the 24-hour day. Now, there is substantial evidence that sleep-wake behavior has an endogenous rhythm, that is, a rhythm that persists in the absence of environmental cues. Core body temperature is used to measure the underlying sleep-wake circadian rhythm. Within the normal range, higher core body temperatures are associated with alertness, and lower temperatures are associated with sleep and sleepiness.

The presence of an endogenous sleep-wake rhythm of 24.2 to 25.1, rather than 24, hours has been observed under free-running conditions in which participants were kept in isolation from cues of the time of day (Czeisler et al., 1999). Under normal circumstances, environmental influences, such as sunlight, meals, and social activity, entrain the endogenous rhythm to a 24-hour cycle. The combination of bright light during wake and total darkness during sleep is a particularly strong entraining influence and can facilitate adjustment to changes in sleep schedules (Czeisler et al., 1989).

The fact that the endogenous sleep circadian rhythm is longer than 24 hours may help explain some findings regarding jet lag. It has been ob-

served that it takes twice as long to adjust to time changes produced by eastward than westward travel (Moore-Ede, Sulzman, & Fuller, 1982). When traveling east, one is shortening the day, thereby increasing the difference between the endogenous sleep-wake rhythm and the new time zone.

Electrophysiology of Sleep

It is possible to distinguish sleep from wakefulness based solely on behavioral criteria. Stereotypical postures are associated with sleep periods, reductions in responsiveness to the environment, and reductions in activity. These distinctions between sleep and wake can be seen throughout the phylogenetic scale from insects through mammals (Amlaner & Ball, 1994; Hartse, 1994; Zepelin, 1994). In birds and mammals, there are also detectable changes in brain activity associated with sleep.

Sleep recording in humans, called polysomnography, is scored using information from the electroencephalogram (EEG), eye movements (EOG), and muscle activity from the chin (EMG) following the Rechtschaffen and Kales (1968) scoring manual. When an individual is awake, the EEG is characterized by a low-voltage, fast-frequency signal. This signal is dominated by beta (14–20 Hz) and alpha (8–12 Hz) EEG frequencies. As one becomes drowsy, the EEG pattern slows down to a slightly higher amplitude theta rhythm (3–7.5 Hz). If more than 50% of an EEG epoch of 20 or 30 seconds consists of theta, the individual is considered to be in stage 1 sleep. Stage 1, a transitional stage, may also contain slow, rolling, eye movements. Although the first epoch of stage 1 sleep is often used to define sleep onset operationally, individuals aroused from stage 1 usually report that they were about to fall asleep. A more conservative criterion for sleep onset is the appearance of stage 2 sleep.

Stage 2 sleep occurs when certain phasic events, sleep spindles and K-complexes, appear in the EEG. Sleep spindles, named for their sewing-spindle appearance, are short bursts of 12–14 Hz activity and, it is thought, are due to inhibitory neuronal activity during sleep. K-complexes are slow, high-amplitude voltage bursts that consist of a large negative deflection followed by a large positive deflection and, it is thought, are brain responses to external or internal stimuli. The appearance of high-amplitude, slow delta waves

(0.5–2.5 Hz) marks the presence of stages 3 and 4, also called slow-wave sleep. Stage 3 contains 20 to 50% delta waves in an epoch, and stage 4 has more than 50%. The progression from stage 1 to stage 4 sleep is characterized by decreases in frequency and increases in amplitude of the EEG. Arousal thresholds to external stimuli increase with increases in sleep stage.

Rapid-eye-movement (REM) sleep is an activated stage of sleep that occurs cyclically, about every 90 minutes throughout the night and is associated with dreaming. Reports of cognition obtained from REM sleep are longer, more visual, more story-like, and more bizarre than reports from stages 1 through 4 (NREM sleep) that are similar to reports of waking cognition. REM sleep is also quite different physiologically from NREM sleep. In addition to rapid eye movements, postural muscle atonia, irregular respiration, increased heart rate, disrupted temperature regulation, and penile erections occur during REM sleep.

As seen in Figure 1, most slow-wave sleep occurs during the first half of the night. As night progresses, REM sleep periods are longer. Thus, more REM sleep occurs during the last half, than the first half, of the sleep period.

Sleep Deprivation

The short-term effects of one or two days of sleep deprivation are increased irritability, deficits in sustained attention, and sleepiness, particularly at night. With longer periods of sleep deprivation, there is an increase in sleepiness, a loss in fine motor control, and the appearance of mild flu-like symptoms. Extended periods of partial sleep deprivation can also lead to decrements in vigilance and objective, as well as subjective, measures of sleepiness (Dinges et al., 1997). Recovery sleep following three or four nights of sleep deprivation consists mostly of slow-wave and REM sleep. Most of the lost slow-wave sleep and about half of the lost REM sleep are made-up during recovery nights (Horne, 1988).

Circadian sleep-wake and temperature cycles persist even during sleep deprivation. Thus, sleep-deprived individuals are more alert during the hours they would normally be awake and more sleepy when they would normally be asleep. Many industrial accidents such as Three-Mile-Island and Chernobyl occurred during the night shift when individuals would be sleepest.

Figure 1. A typical night for a child, young adult, and elderly person. REM sleep reoccurs throughout the night; the differences that are most noticeable as individuals age are the decrease in stage 4 sleep and the increase in the frequency of awakenings. Reprinted by permission of the *New England Journal of Medicine* from Kales, A., & Kales, J. D. (1974), "Sleep disorders: Recent findings in the diagnosis and treatment of disturbed sleep," *New England Journal of Medicine*, 290, P. 487.

Developmental Changes in Sleep

Sleep, its duration, architecture, and diurnal distribution, changes across the human life-span. These developmental changes in sleep parameters are accompanied by corresponding changes in the types and prevalence rates of sleep disorders. Childhood sleep problems are usually transient, but when they persist, they may influence the child's daytime functioning and impact other family members.

A neonate's sleep is comprised of active and quiet phases, similar but not identical to REM and NREM sleep seen in older children and adults. During the first 6 months of life, slow waves

become more continuous, sleep spindles and K-complexes emerge, and the four stages that characterize adult NREM sleep become distinguishable (Williams et al., 1974). During the same period, there are changes in the distribution and duration of sleep stages. The percentage of time spent in REM sleep decreases from 50 to 30%, and the latency to REM sleep, which is zero minutes at birth, gradually increases and starts to exhibit circadian rhythmicity (Schulz et al., 1983). The percentage of REM sleep gradually decreases during childhood and reaches the adult level of 20 to 25% at adolescence. The number of sleep cycles decreases from a childhood level of seven cycles to

four or five cycles during adolescence (Karacan et al., 1975); this reflects a lengthening of the sleep cycle and a shortening of total sleep duration.

The amount of slow-wave sleep increases in the first 3 years of life, stays constant until the teens, and then gradually declines. Beginning in the teens, the amplitude of slow waves declines with age (Smith et al., 1977). These changes in slow-wave sleep, as individuals age, are associated with lightening in the depth of sleep, as measured by arousal thresholds and the frequency of brief arousals from sleep.

Infants and Toddlers. The total duration of sleep declines sharply during the first year of life from about 17 hours at birth to about 13 hours by the end of the first year and continues to decline gradually to about 11 hours at age 2. By the fourth month of life, the circadian sleep-wake cycle becomes more prominent and more synchronized with the light-dark cycle (Harper et al., 1981). The changes in sleep duration are accompanied by changes in the distribution of sleep throughout the day. By 6 months, most infants have one extended period of sleep at night and two naps.

The most common parental concerns about their children's sleep during infancy and toddlerhood are difficulties in settling to sleep and waking up at night. Treatments are commonly based on stimulus control principles. Parents are informed about the importance of a consistent and relaxing bedtime routine and on the importance of teaching their children to fall asleep on their own, so that the parent's presence will not become a distinguishing stimulus for sleep onset. Often, treatment involves extinguishing old habits and establishing a new and consistent bedtime routine. Extinction of parental presence in the room at bedtime can be accomplished abruptly or by successive approximations in which parents gradually decrease the interval of contact time with their children at bedtime (Ferber, 1985). Estimates of the efficacy of this approach are very high (Adair et al., 1992; Durand & Mindell, 1990; Richman et al., 1985; Sadeh, 1994), and its benefits often generalize beyond the sleep problem (Minde, Faucon, & Faulkner, 1994). When an infant's or toddler's sleep difficulties are a manifestation of separation anxiety, an alternative and effective approach is for a parent to sleep in the child's bedroom for about a week and avoid interactions with the child during the night (Sadeh, 1994). Some form of co-sleeping with infants (sharing the same room or sharing the same bed) is customary in the majority of the

world's cultures. The impact on the mother's sleep indicates a small reduction in slow-wave sleep and an increase in arousal frequency (Mosko, Richard, & McKenna, 1997) that allows increased monitoring of the infant.

Preschool and Early Childhood. Sleep problems common in this age group are those of initiating and maintaining sleep and parasomnias. The results of prospective investigations suggest that childhood complaints about sleep onset and sleep maintenance difficulties are transient (Strauch & Meier, 1988). However, Hauri and Olmstead (1980) found that childhood insomnia persists into adulthood in some cases. They coined the term childhood onset insomnia to describe adult insomniacs whose problems started before age ten.

Sleep onset difficulties during early childhood may be manifested as bedtime struggle stemming from oppositional struggle with parents, fear of going to sleep, or difficulty in settling down. Distress at bedtime may be related to developmental changes that affect the prevalence of fears in children (Ollendick et al., 1985). One treatment approach for cases in which fear and anxiety are central to the child's difficulty in initiating sleep consists of cognitive rehearsal of appropriate bedtime behaviors during the day and positive reinforcement in the morning (Cashman & McCann, 1988). Children's anxiety at bedtime may also benefit from a relaxation routine designed to match their cognitive and attention levels. Relaxation routines designed for use with children typically include imagery such as a melting snowman as well as tense-release instructions (Oaklander, 1988; Ollendick & Cerny, 1981; Schumann, 1981). Older children may be helped by a comprehensive intervention based on self-management strategies that include relaxation, self-statements, self-assessment, and self-reinforcement (Graziano & Mooney, 1982). Sleep onset problems that, it is judged, stem primarily from oppositional factors are commonly treated by positive reinforcement or by paradoxical intention. When oppositional struggles mark daytime behavior, treatment focuses on the most urgent oppositional problem which often results in improvement at bedtime as well (Cashman & McCann, 1988). Stimulus control instructions (see later) can be tailored to school aged children when poor association between the bed and sleep are apparent.

The prevalence rate of sleep maintenance problems decreases sharply from 30 to 35% at ages four-five to about 15% at age six and continues to

decline to 8% at age ten (Klackenberg, 1982). Sleep maintenance problems during the preschool years are often found in conjunction with sleep onset problems and tend to disappear as the latter problems are solved (Mindell, 1990).

Parasomnias, including sleep walking, sleep talking, night terrors, and enuresis, are most prevalent in children aged five–twelve. The presence of parasomnias beyond the teens is commonly associated with psychopathology. Parasomnias are discussed in detail later in the chapter.

The Second Decade of Life. Physical and endocrinological maturation associated with puberty may result in an increase in sleep need (Carskadon & Dement, 1987). Nevertheless, there is a decline in total sleep time from 10 to 7 hours per night from pre- to late puberty. The reduction of total sleep time reflects the increasing demands on adolescents' time from school, work, and social interactions.

Epidemiological studies examining sleep-wake problems in adolescence found that the most common complaint is daytime sleepiness (Carskadon & Dement, 1987; Strauch & Meier, 1988). More than half of the adolescents surveyed complained of daytime sleepiness. The prevalence rate of daytime sleepiness, which is very low at preadolescence (Palm et al., 1989), increases with the onset of puberty and peaks at midpuberty.

Another common, though less prevalent, complaint is frequent or severe insomnia reported by about 12 to 14% of adolescents (Price et al., 1978; White et al., 1980). Henschel and Lack (1987) suggested the possibility that adolescent sleep onset difficulties may reflect a mild form of circadian rhythm disturbance. Life-style patterns typical in adolescence are likely to contribute to irregular sleep-wake schedules and to sleep deprivation on school nights. Teenagers who work after school and who have a heavy load of extracurricular activities are particularly sleepy during the day (Carskadon, Mancuso, & Rosekind, 1989). Nevertheless, in addition to psychosocial factors, the tendency to delay sleep in some cases is related to the biological pubertal process itself (Carskadon, Viera, & Acebo, 1993).

Sleep deprivation during adolescence may result in irritability, vulnerability to minor illness, inability to sustain attention, sleepiness, and fewer personal resources for dealing with emotional stresses. In addition, emotional stresses and alcohol and drug abuse are likely to amplify the effects of sleep deprivation.

To help meet the demands of adolescence and reduce sleepiness, teenagers should be encouraged to get more regular and longer durations of sleep (Ferber, 1990). The treatment of severe daytime sleepiness due to intrinsic sleep disorders such as narcolepsy and sleep apnea are discussed later. The treatment of disturbed sleep during adolescence is similar to its treatment during adulthood and is outlined later in this chapter.

Adults and the Elderly. From early adulthood to old age, sleep continues to change due to normal aging, psychosocial/life-style factors, and concomitant medical and/or psychiatric conditions (Vitiello, 1997). Although the sleep need of most individuals remains constant throughout adulthood, the ability to maintain uninterrupted sleep, unfortunately, diminishes with age (Ancoli-Isreal, 1997). Increased sleep disturbance at night often leads to increased daytime sleepiness and fatigue. People differ in the amount of sleep changes that are associated with aging; some show little change in their sleep patterns, whereas others experience dramatic deterioration (Webb, 1992).

The nightly amounts of total sleep, stage 4 sleep, and REM sleep level off at puberty, remain stable throughout adulthood, and decrease with advancing age (Smallwood, Vitiello, Giblin, & Prinz, 1983). Gross sleep architecture also remains relatively stable and is comprised of approximately 70–75% of NREM sleep and 20–25% of REM sleep relative to total sleep throughout adulthood (Carskadon & Dement, 1994). There are some differences in monthly sleep patterns between men and women that are likely to relate to hormonal changes associated with the menstrual cycle. As many as 15% of women experience a significant increase in sleep disturbance in the late luteal or premenstrual part of their cycles (Manber & Armitage, 1999).

During the middle-age years, most people first notice a shallowing of sleep along with a growing sense of fatiguing more easily in the daytime. Sleep becomes less continuous beginning in middle age and becomes progressively more fragmented with advancing age and declining health. Of all of the age-related changes in sleep, the reduction of slow wave sleep (SWS) is the most prominent. With the reduction in SWS, there is a corresponding increase in the lighter stages of non-REM sleep, especially stage 1, and increased time is spent awake during the nocturnal sleep period. A pattern of lighter, more fragmented sleep with frequent and prolonged awakenings is com-

mon in the elderly (Webb & Campbell, 1980; Bliwise, 2000a). Thus, the elderly get less total sleep at night than their younger counterparts, although they may spend more time in bed (Dement, Miles, & Carskadon, 1982). When sleep across the entire 24-hour day is accounted for (including naps), the elderly get about the same amount of total sleep as middle-aged adults.

The effect of aging differs in men and women. This gender difference emerges between ages thirty and forty. Men and women in their twenties have similar percentages of SWS, a significant reduction in the percentage of SWS occurs in men during their thirties, but not in women (Ehlers & Kupfer, 1997). Objective measures of sleep reveal that the sleep of women tends to be better preserved with aging than that of men. In contrast, the subjective rating of sleep is worse in elderly women than in elderly men; the former report more sleep complaints than the latter (Rediehs, Reis, & Creason, 1990).

There are many biological and psychological consequences of aging that may affect sleep, either directly or indirectly. Biological processes include decreased bladder control, degenerative diseases, dementing disorders, poor health, and sleep disorders such as sleep apnea and periodic leg movements. Psychological processes include bereavement, anxiety about health and financial security, and enforced changes from daily routine (Morgan, 1987). It has been commonly assumed that depression, anxiety, and poor health account for many instances of poor sleep in the elderly, but research on the healthy elderly has found that frequent awakenings and decreased amounts of stage 4 and REM sleep occur, even in the absence of depression, anxiety, or overt disease processes (Feinberg, Koresko, & Heller, 1967; Prinz et al., 1984).

The deterioration of sleep that parallels aging can also result directly from sleep disorders such as sleep apnea (see later section) and periodic limb movement disorder (PLMs; see later section). Sleep apnea and PLMs, which can be primary or secondary to other medical conditions, are increasingly prevalent with age and affect a high percentage of the geriatric population (Carskadon, van den Hoed, & Dement, 1980), and PLMs occur in up to 44% of residents of nursing homes (Ancoli-Israel, Kripke, Mason, & Massin, 1981). The rate of PLMs in the aged population is due in part to the high prevalence of renal disease, arthritis, diabetic neuropathy, iron deficiency anemia, and venous

insufficiency in this population; PLMs are often associated with these disorders (Bliwise, 2000a).

Some researchers believe that age-dependent changes in circadian rhythm also contribute to the gradual deterioration of sleep at night and the increased propensity to nap during the day seen in the elderly (Bliwise, 2000a). The sleep-wake pattern of many elderly, especially those in nursing homes, resembles the polyphasic sleep-wake cycle of infancy and may be secondary to the weak entrainment of the sleep-wake cycle into the circadian rhythm that occurs in these institutions (Dement, Miles, & Carskadon, 1982; Schnelle, Cruise, Alessi, et al. 1998). The most commonly described circadian rhythm disturbance in the elderly is a gradual phase advance of the sleep period relative to the desired sleep time (see section on advanced sleep phase syndrome). This phase-advanced rhythm results in early evening drowsiness and sleep and concurrent early morning awakening and difficulty returning back to sleep (Czeisler et al., 1986; Miles & Dement, 1980; Weitzman et al., 1982). Although the elderly show a clear phase advance in their circadian rhythms, this may not be due to differences between elderly and younger adults in the length of the endogenous daily rhythm. A recent study found no differences in age in the length of the endogenous rhythm, when no light cues were available (Czeisler et al., 1999). Age differences in sleep are more likely to be due to changes in sleep-wake schedules and changes in sleep architecture such as increased frequency of awakenings.

Naps are seldom reported in the 20-year-old working population, but nearly all 60-year-olds report some napping that averages approximately two naps per week (Webb, 1992). Two factors that may lead to daytime napping in the elderly are (1) attempts to compensate for lost sleep and (2) understimulation and weakening of social constraints (Morgan, 1987). In addition, napping may not interfere with nighttime sleep in the elderly to the same extent that it does in young adults (Feinberg et al., 1985; Morin & Gramling, 1989; see section on sleep-wake schedules). Although napping can be adaptive because it can supplement nocturnal sleep, excessive napping can disrupt the circadian entrainment of the sleep-wake cycle and exacerbate nocturnal sleep disturbance.

Changes in sleep patterns in the elderly do not necessarily lead to the subjective experience of insomnia. Some complain about sleep problems,

others notice but do not complain, and still others do not notice. Morin and Gramling (1989) compared self-identified poor and good older sleepers on measures of sleep, mood, life-style, health, and expectations of sleep requirements and found that the poor sleepers showed greater discrepancies between their current sleep patterns and expectations and acknowledged more depression and anxiety than the good sleepers.

Many biological and psychological consequences of aging may affect sleep, either directly or indirectly. Practice of good sleep hygiene, such as keeping a regular sleep-wake schedule, avoiding alcohol, tobacco, and caffeine, reducing excessive time awake in bed, and treating underlying sleep disorders will facilitate the preservation of good sleep.

Assessment of Sleep and Sleepiness

To identify sleep disorders, it is necessary to have reliable and valid measures of sleep and sleepiness. Although substantial information about sleep can be obtained from a detailed history, more direct assessment is usually desirable. There are many methods from which to choose, and each method has advantages and disadvantages.

Assessment of Sleep Variables

Polysomnography. As mentioned earlier, the progression of sleep stages throughout the night, as well as transitions from wakefulness to sleep, are typically assessed by all-night recording of brain wave activities at one or more sites (EEG) and by monitoring eye movements (EOG) and muscle activity from the chin (EMG). Additional physiological measures may be used for special purposes such as evaluating sleep apnea and periodic leg movements. Evaluating sleep apnea requires measuring respiratory effort, air flow, and blood oxygen saturation. Periodic leg movements are measured by recording EMG from the anterior tibialis muscles of the legs.

Several factors indicate the need for more than one night of recording in insomnia. Among these factors are night-to-night variability in sleep parameters and the fact that an unfamiliar sleep environment, such as a sleep laboratory, may result in disrupted sleep. This is often called a "first-night

effect." In addition, rare events, such as sleep terrors, may not be observed in a single night of recording.

Polysomnographic recording can be done in the sleep laboratory or at home. The effects of a unfamiliar setting on sleep can be reduced by using home recording (Palm et al., 1989). Recording at home can be by telephone transmission of the recording signals to the laboratory or by recording the signals on tape or computer for later analysis.

Auditory Event-Related Potentials. Neurophysiological assessment of sleep and waking states may also be conducted by using auditory event-related potential (ERP) measurements. ERPs are microelectrical EEG events that are elicited by and time-locked to the presentation of a stimulus. The ERP is comprised of a series of positive- and negative-going waves (components) labeled either sequentially or according to their peak amplitude latency (i.e., a positive wave at 300 ms is labeled the "P300"). The waking auditory ERP is comprised of a series of components which, labeled sequentially, are the P1, N1, P2, N2, and P3. The onset of stage 1 sleep is associated with increased amplitudes of the P1, P2, and N2 components, whereas the N1 and P3 amplitudes are diminished (Campbell, Bastien, & Bell, 1992). During sleep stages 2, 3, and 4, the amplitude and latency of the N2 increase dramatically and a large amplitude, non-REM-sleep-specific wave complex emerges, called the "evoked" K-Complex (N550-P900). ERP component structure in REM sleep resembles waking, however, amplitudes are reduced.

Auditory ERPs show reliable variations with states of consciousness and levels of cognitive processing. ERPs have shown enhanced cognitive processing in insomniacs, relative to good sleepers, during evening wakefulness and initial stage 2 sleep (Loewy & Bootzin, 1998). Cognitive impairment in healthy adults, due to prolonged sleep deprivation, is positively related to reductions in P300 amplitude (Morris, So, Lee, Lash, & Becker, 1992).

Activity Monitoring. When the focus of the evaluation is the distribution of sleep and wakefulness across the night, including sleep parameters such as sleep latency, time awake after sleep onset, and total sleep time, it is possible to use activity monitoring devices that are typically worn on the wrist. A wrist actigraph is a small, solid-state, computerized movement detector that continuously records wrist movement throughout the

night. Several studies support the reliability and validity of the assessment of different sleep parameters based on actigraphs and its validity as an assessment tool of sleep disorders (ASDA, 1995b; Sadeh et al., 1989, 1991). A wrist actigraph provides a relatively unobtrusive, objective, all-night measure of several sleep parameters that allows monitoring the patient's sleep for extended periods of time in the patient's own environment. To evaluate circadian rhythm disturbances, some versions of wrist actigraphs can be equipped with light meters that allow continuously measuring light exposure. When worn continuously, day and night, actigraphs can be used to evaluate rest-activity behaviors, and versions that are equipped with a behavioral response capacity can assess reaction time upon a prompt and assist in evaluating alertness.

Sleep Questionnaires. Sleep questionnaires provide valuable information about the perceived severity of a presenting sleep complaint, as well as the perceived efficacy of treatment. In addition, they allow collecting data on a wide variety of behavioral variables. However, the retrospective nature of the questionnaires may introduce intentional or unintentional biases (Bootzin & Engle-Friedman, 1981). Therefore, though sleep questionnaires are of value in providing adjunctive data, they should not be used alone in assessing sleep. The use of multiple measures (e.g., collateral reports, mechanical devices, or PSG) will improve reliability and validity.

Daily Sleep Diaries. Daily sleep-wake diaries are a valuable assessment tool that can provide continuous daily information on sleep parameters, as well as on daytime functioning. Unlike polysomnography that usually records only one or two nights of sleep, sleep diaries can provide information about sleep behavior for weeks and even months. Although insomniacs often overestimate sleep onset latency and underestimate total sleep, compared to polysomnography, the correlation between diaries and polysomnography is substantial (e.g., Carskadon et al., 1976). The validity of diaries with other measures increases over time. Individuals become more exact at assessing their sleep as they continue to monitor it (Franklin, 1981).

To be maximally useful, care must be taken to ensure that daily sleep diaries are completed each morning. If diaries are collected infrequently, patients may not fill them out until immediately

before they are collected. Under these circumstances, the diaries would be no more useful than retrospective questionnaires (Bootzin & Engle-Friedman, 1981). One way to eliminate this problem is to have patients call in their data each morning to a telephone answering machine (Spielman, Saskin, & Thorpy, 1987). In this way, problems with compliance can be detected immediately, and corrective actions can be taken.

Observers. Observers such as nurses, spouses, or parents can be used to assess sleep onset, movement, respiration, and reaction to noise. In addition to general problems common to observational data, some specific problems arise in using observers to assess sleep-related variables. For example, spouses may fall asleep before their to-be-observed partners and may be unaware of their sleep later at night. Sleep reports by parents and children are similarly often in poor agreement (Clarkson et al., 1986). The relatively low validity of observer data suggests using observers primarily as supplemental, rather than primary sources of information.

Assessment of Daytime Sleepiness

The measurement of sleepiness is complex because it is an inferred construct that has multiple indicators. There are cognitive, physiological, and behavioral indicators of sleepiness that are reflected in self-report, physiological, and performance measures. Further, there are a number of related constructs such as fatigue and lowered arousal that, although they overlap with sleepiness, are not identical. In addition, daytime sleepiness is not solely a function of the length and quality of the previous night's sleep. Sleepiness and alertness are strongly influenced by the sleep-wake circadian rhythm and by factors such as threat, motivation, and interest in the activities being undertaken.

Stanford Sleepiness Scale (SSS). The subjective evaluation of an individual's current level of sleepiness is most commonly measured by the SSS, which consists of seven descriptively anchored points (Hoddes et al., 1973). The statements reflect the severity of sleepiness from "Feeling active and vital; alert and wide awake" to "Almost in reverie; sleep onset soon; lost struggle to remain awake." Hoddes et al. (1973) found that the scale was sensitive to sleep loss and validated it with performance measures when mental tasks

were long (at least an hour), monotonous, and boring. Polysomnographically measured sleep latency, it has also been shown, correlates highly with the subjective feeling of sleepiness, as measured by the SSS.

Epworth Sleepiness Scale (ESS). In a clinical setting, it is often useful to have a measure of the extent to which individuals exhibit excessive sleepiness in different situations. The ESS (Johns, 1991) asks respondents how likely they are to doze off or fall asleep in different situations such as while a passenger in a car for an hour or while sitting or talking to someone. The test-retest reliability during five months is .81, and the correlation between spouses and respondents is .74 (Johns, 1994). Self-report measures, such as the ESS, are useful as quick screens for sleepiness and as a supplement to objective measures.

Multiple Sleep Latency Test (MSLT). The MSLT is arguably the most important assessment device for quantifying daytime sleepiness in human subjects. Since its development at Stanford University in the mid 1970s, it has been used to measure sleepiness in a wide range of experiments that examined normal and abnormal functioning (Carskadon, 1994).

The MSLT measures how long it takes to fall asleep on multiple opportunities throughout the day. It is intended to be a standardized set of procedures for obtaining an objective measurement of an individual's "physiological sleepiness" at different times of the day. Physiological sleepiness should be distinguished from "manifest sleepiness," an individual's behavioral or subjective level of arousal. Manifest sleepiness is influenced by other physiological needs, motivation, and demands from the immediate environment.

The MSLT consists of a series of four to seven polysomnographically monitored naps, administered every 2 hours (see Carskadon et al., 1986, for detailed procedures). Subjects should not be given caffeine or alcohol during the day of MSLTs to avoid confounding effects on sleep latency. Similarly, investigators should be aware of any medications being taken by the subject that might influence the latency to sleep onset.

The nap is considered to have begun as soon as the lights are turned off and is terminated after 20 minutes, three consecutive 30-second periods of stage 1 NREM sleep, or one 30-second period of any other sleep stage. The latency to sleep is

defined as the amount of time between "lights out" and the first 30-second period of any sleep stage.

Different average MSLT scores indicate different levels of sleepiness, and shorter scores indicate a higher degree of physiological sleepiness. MSLT averages less than 5 minutes are considered "pathological" and indicate a severe degree of sleepiness. Scores in this range are often seen in individuals with narcolepsy, sleep apnea, and those with either acute or chronic sleep deprivation (Carskadon & Dement, 1981; Dement, Carskadon, & Richardson, 1978; Richardson et al., 1978). Pathological levels of sleepiness, it has been found, correlate with performance deficits (Carskadon, Littell, & Dement, 1985). Nocturnal values such as sleep duration on the previous night, respiratory disturbance index, and lowest oxygen desaturation do not correlate well with MSLT measures and account for less than 25% of the variance in MSLT scores (Pollak, 1997). A greater percentage of the variance can be explained (over 40%) if multivariate (rather than bivariate correlations) analyses are used. In a community sample, six variables (chronic daytime tiredness, body-mass index, psychological distress, nocturnal motor activity, serum thyrotropin level, and age) independently and significantly predicted MSLT scores (Kronholm, Hyypä, Alanen, Halonen, & Partinen, 1995).

Although the MSLT has been helpful in identifying excessive sleepiness due to narcolepsy and sleep apnea, it is not a pure measure of physiological sleepiness in all individuals. There are determinants, in addition to sleepiness, that affect the capacity to fall asleep. Insomniacs tend to take a long time to fall asleep on the MSLT, even following a poor night's sleep. The same variables that produce insomnia at night result in elevated MSLT scores. On the other hand, many individuals who fall asleep quickly at night can fall asleep quickly on the MSLT, even when they are not sleep deprived (Dorsey & Bootzin, 1987). Thus, the MSLT measures both sleepiness and individual differences in sleep tendency.

Maintenance of Wakefulness Test (MWT). The MWT, a variant of the MSLT, measures the ability to remain awake, rather than the ability to fall asleep (Mitler, Gujavarty, & Browman, 1982). This test has been used clinically to assess daytime sleepiness and treatment efficacy. The procedure involves sitting in a comfortable chair or sitting up

in bed in a darkened room for either a 20- or 40-minute period or until the beginning of sleep onset. The criteria used for sleep onset includes either the first consecutive 10 seconds of sleep or the same criteria as in the MSLT: three consecutive 30-second epochs of NREM stage 1 or a single epoch of any other stage of sleep. The first trial occurs 2 hours following the final morning awakening and is repeated three more times every 2 hours.

A normative study found that healthy sleepers had an average sleep latency of 18.1 minutes for a 20-minute MWT and 32.6 minutes for a 40-minute MWT (Doghramji et al., 1997). Sleep latency values in clinical populations (e.g., narcolepsy and obstructive sleep apnea syndrome) are significantly lower. Using a statistical criterion of two standard deviations below the mean, the lower limit of the normal range is 10.9 and 12.9 minutes for a 20- and 40-minute MWT, respectively, using the first 30-second epoch of stage 1 as the criterion for sleep onset. Using the more stringent criterion, the lower limit of the normal range is 13.5 and 19.4 minutes, respectively. Based on their normative data, Doghramji and colleagues (1997) recommend the 20-minute over the 40-minute protocol because it is not as susceptible to age effects (older people can maintain wakefulness longer than younger people) and is more cost effective.

The MWT is more sensitive than the MSLT to the effects of treatment. Many patients' MSLT scores remain pathological after treatment. In people with disordered sleep (i.e., obstructive sleep apnea, narcolepsy, idiopathic hypersomnia, depression, periodic limb movement, and head trauma), MSLT scores showed a slight, nonsignificant increase after treatment, whereas the MWT scores showed large increases 1–6 months after treatment (Sangal, Thomas, & Mitler, 1992).

Pupillometry. The pupil is fully dilated in a darkened room but constricts as the individual begins to fall asleep. This has led to measures of sleepiness based on the degree of constriction and the degree of stability of pupil size. Untreated patients with excessive sleepiness have pupils of smaller diameter than normals, and their pupils show frequent constrictions and dilation, whereas normals show only minor changes in pupil diameter (Lin et al., 1990; Yoss, 1969). Research on the pupillary light reflex, which measures the time taken for a pupil's diameter to dilate to baseline levels after light flashes, indicates that sleep apnea patients show increased latencies to recovery with

increased sleepiness, as measured by the MSLT (Pressman & Fry, 1989). Although there have been encouraging results with pupillometry for those who are severely sleepy during the day, such as those with narcolepsy and severe sleep apnea, it has been less consistently useful for use with other sleep disorders.

Performance Measures. Performance measures provide objective data in assessing the effect of sleepiness and can be used to evaluate the efficacy of treatment. The most commonly used performance measures are reaction time, attention and vigilance, mental arithmetic, tracking and memory tasks (see Bootzin & Engle-Friedman, 1981). Slow reaction time, lack of response, or errors are indicators of sleepiness. A common finding in sleep deprivation studies is that sleep loss impairs performance in most cognitive and sustained attention tasks. Such impaired performance is most consistently documented when the task is long (30–60 min), repetitive, and boring. In general, when severely sleep deprived subjects are motivated, they can sustain attention for short periods of time and perform no differently than nonsleep deprived subjects. Even on simple tasks of short duration (3–10 min), however, researchers have found performance decrements in sleepy subjects (Dinges, 1992). Lapsing, which refers to a period of marked response delay or response omission, is the foremost effect of sleep loss. Characteristic performance patterns in sleep deprived individuals include a slowing in self-paced cognitive tasks and the speed of the fastest response time, progressive and accelerated performance degradation, increased variability in response time, and erratic or unevenness in performance across trials (Kribb & Dinges, 1994; Dinges, 1992).

Sleep Disorders

In providing a review of sleep disorders, we will use the diagnostic categories of the recently published, *International Classification of Sleep Disorders, Revised: Diagnostic and Coding Manual* (ASDA, 1997). The major categories are dyssomnias, parasomnias, and sleep disorders associated with medical or psychiatric disorders.

Dyssomnias

Dyssomnias include disorders of initiating and maintaining sleep and disorders of excessive sleepi-

ness. There are three major categories: circadian rhythm disorders, intrinsic sleep disorders, and extrinsic sleep disorders.

Circadian Rhythm Disorders

Circadian rhythm disorders occur when individuals attempt to sleep at times that are inconsistent with their underlying biological clocks. Intrinsic circadian rhythm disorders refer to desynchronies between attempts to sleep and the sleep-wake circadian rhythm that are due presumably to internal rather than external causes. These disorders might result from a weak circadian rhythm or from an inability to entrain the rhythm to the environment. Extrinsic circadian rhythm sleep disorders occur when environmental conditions, such as working night shifts or traveling across time zones, result in disrupted sleep-wake circadian rhythms.

Intrinsic Circadian Rhythm Disorders.

Delayed Sleep Phase Syndrome (DSPS). In DSPS, the sleep-wake circadian rhythm is delayed compared to the time the individual attempts to sleep. DSPS was first identified by Weitzman et al. (1981) as a "chronobiological disorder with sleep-onset insomnia." Individuals report difficulty falling asleep at a desired bedtime but have normal sleep if they attempt to sleep a few hours later. Daily sleep-wake diaries of individuals with DSPS show late sleep onset, few awakenings, early wake-up times when work or social demands are present, and late (midafternoon) wake-up times when there are no such demands on their time. The disorder is associated with daytime sleepiness that is most pronounced in the morning (Thorpy et al., 1988). Polysomnography shows that, compared to age matched norms, patients with DSPS have longer latencies to stages 2 and 3 and decreased sleep efficiency (Allen et al., 1989). In addition, DSPS patients have more awakenings and less slow-wave sleep in the first part of the night. These findings indicate a reduced depth and quality of sleep in the first part of the night which is consistent with the phase delay.

Delayed sleep phase individuals commonly identify themselves as "night people" and report being most alert during the late evening and night hours. Many case study reports on the disorder come from adolescent and young adult populations (Ferber, 1985). Adults who suffer from DSPS often report childhood onset of the symptoms (Weitzman et al., 1981). The prevalence of the diagnosis among patients in sleep disorders cen-

ters is estimated at 7%. The prevalence of the disorder in the general population is unknown, but some researchers estimate that the prevalence is higher, particularly with adolescents and young adults (Henschel & Lack, 1987; Thorpy et al., 1988).

Although patients with delayed sleep phase experience an inability to phase advance their rhythm, they usually have no such difficulty with phase delay. This is the basis for chronotherapy (Czeisler et al., 1981). In chronotherapy, bedtime is successively delayed by daily increments of 3 hours until a desired bedtime is reached. This strategy is often augmented with appropriately timed light exposure (see later). Although chronotherapy with or without light exposure is effective (Czeisler et al., 1981), it requires high motivation and, in the case of adolescents, clear behavioral contracts and monitoring (Dahl, 1992). The efficacy of chronotherapy with adolescents who manifest school refusal or when other motivational factors are present is not very high (Ferber, 1985). In these cases, treatment needs to explicitly address intrinsic and environmental factors that reinforce the delayed bedtime behavior. Even when treatment successfully shifts the sleep-wake rhythm to a desired time, the risk of relapse is high, and maintaining a regular sleep-wake schedule is important to prevent relapse.

Advanced Sleep Phase Syndrome (ASPS). Patients with ASPS present with a set of complaints converse from those with DSPS, namely, inability to stay awake until the desired bedtime and inability to remain asleep until the desired wake-up time. Other than a shift in the major sleep episode toward earlier sleep-onset time with respect to a 24-hour day, the sleep of individuals with ASPS is normal in quality and duration. Typical sleep-onset times are between 6 P.M. and 8 P.M., and no later than 9 P.M., and wake times are between 1 A.M. and 3 A.M., and no later than 5 A.M. Unlike other sleep maintenance disorders, early morning awakening occurs after a normal amount of otherwise undisturbed sleep (ASDA, 1997).

As with DSPS, individuals afflicted with ASPS come to clinical attention only when the inherent sleep-wake schedule interferes with social activities and/or a work schedule. Problems may also occur as a result of attempting to adhere to a conventional sleep schedule. For example, when a patient attempts to remain awake until the desired bedtime, the early awakening aspect of the syndrome can lead to chronic insufficient sleep and

excessive daytime sleepiness (Richardson & Malin, 1996).

ASPS is much more common in older individuals than in the young, and the complaint of waking up too early in the morning may be confused with depression. It is thought that the higher prevalence of ASPS in elderly individuals is due to shortening of the endogenous circadian timing system that accompanies normal aging. However, sleep maintenance insomnia in the elderly may be due to an intrinsic sleep disorder or secondary to a mental, neurological, or other medical disorder (see the sections on intrinsic sleep disorders and sleep disorders associated with neurological disorders). Some types of depression, for example, also exhibit phase-advance features. The early morning awakening of patients with depression is usually accompanied by other sleep and somatic symptoms and altered mood (see the section on depression).

The current approach to treating ASPS is bright light exposure in the evening and avoidance of light exposure (e.g. wearing dark, wraparound sunglasses) in the morning. Bright light exposure in the evening and the avoidance of bright light in the morning, it is thought, help to reentrain the sleep-wake cycle into the circadian rhythm (Allen, 1991; Wagner, 1996; see the section on light treatment).

Irregular Sleep-Wake Pattern. This rare disorder is characterized by a variable and disorganized sleep-wake pattern that suggests the absence of circadian rhythmicity. Sleep is broken into several short sleep episodes, but the cumulative sleep for a 24-hour period is at normal levels. Polysomnographic studies show no abnormalities in sleep parameters except for the short duration of each episode (Roehrs, Zorick, & Roth, 1994). The absence of a sleep-wake rhythm is confirmed by the absence of a temperature rhythm. This pattern, it has been found, is common in elderly people with dementia compared to age matched controls (Okawa, Mishima, Hishikawa, Hozumi, Hori, & Takahashi, 1991). Treatment consists of a gradual decrease in the number and duration of daily naps. Increase in activity levels and social interaction is recommended to facilitate the process (Hauri, 1982; Okawa et al., 1991).

Non-24-Hour Sleep-Wake Syndrome. This is a disorder in which individuals are unable to entrain to a 24-hour day and instead maintain 25- to 27-hour sleep-wake cycles. Some individuals with

this syndrome tend to progressively phase delay. The disorder is rare in the general population and is assumed to have higher prevalence among blind people (Miles et al., 1977). Treatment focuses on entraining the circadian rhythm to a 24-hour day through social interaction, exposure to light, and melatonin. Melatonin has been successful in treating this disorder in blind individuals (Palm, Blenow, & Wetterberg, 1997).

Extrinsic Circadian Rhythm Disorders.

Shift Work. Because of family and social demands, night shift workers usually attempt to live their days off on a schedule different from that of their workdays. A disrupted sleep-wake schedule often results in disturbed and shortened sleep, sleepiness on the job, reduced performance levels, and psychological distress due to disruptions in family and social life. Workers on rotating shift schedules have greater difficulty than those on permanent night shifts. The severity of the problem increases with age. Ascoff (1978) and Reinberg et al. (1978) found that individuals whose temperature rhythm had low amplitude could better adapt to shift work.

Polysomnographic studies of the sleep and sleepiness of night shift workers show short durations of sleep following work nights (5 to 6 hours) and reduced sleep efficiency (Walsh et al., 1984), reduced amounts of stage 2 and REM sleep (Akerstedt, 1985), and increased sleepiness on the MSLT during waking hours (Akerstedt et al., 1982).

Many researchers recommend that rotating shift schedules should be designed to be consistent with the natural tendency to phase delay, that is, the direction of rotation should be progressively later, and the duration of the shift should be long enough to allow adaptation (Roehrs, Zorick, & Roth, 1994). European researchers, on the other hand, prefer a very rapidly rotating system of two days on each shift because that allows the circadian rhythm to remain constant (Akerstedt, 1985). A variety of methods for enhancing alertness and performance among shift workers have been suggested (Penn & Bootzin, 1990). The optimal timing of work breaks, social activity during breaks, bright light and other sensory stimulation have the most potential for short-term alerting effects. Stress coping techniques, sleep hygiene information, and family counseling have the most potential for addressing the long-term effects of shift work.

Time-Zone Change Disorders. Dyssomnia associated with rapid time-zone change ("jet lag") is due to desynchrony between the endogenous sleep-wake rhythm and the light/dark cycle. Symptoms include an inability to sustain sleep and excessive sleepiness. For most people, these symptoms subside after a few days, depending on the number of time zones crossed. Frequent travelers, such as transatlantic airline crews, may experience more persistent difficulties. Westward travel is associated with disturbed sleep at the end of the sleep period, which coincides with habitual wake-up time, and eastward travel is associated with sleep onset insomnia (Roehrs, Zorick, & Roth, 1994). Due to the natural tendency to phase delay, travel westbound is easier to adjust to than travel eastbound.

Light Treatment. Results show that properly timed exposures to bright light (7,000–12,000 lux) for 2 to 3 days can shift the phase of the sleep rhythm (Czeisler et al., 1989). For comparison, typical indoor room light is less than 500 lux; sunlight produces about 2500 lux a few minutes after dawn; and at noon, sunlight is in the 100,000 lux range (Terman, 1994). The direction of the shift depends on the timing of the exposure to light. A phase advance is achieved by light exposure in the morning, and a phase delay is achieved by light exposure in the evening. In addition to the proper timing of bright light, it is also important to have periods of darkness during which no bright light is allowed (Czeisler et al., 1989; Rosenthal et al., 1990).

Preliminary results indicate that bright light treatment may be effective for a number of circadian rhythm sleep disorders. Bright light treatment during night shift work resulted in increased duration of daytime sleep and improved alertness on the job (Czeisler et al., 1990). Bright light treatment, it has also been shown, benefits jet lag sufferers (Daan & Lewy, 1984; Sasaki et al., 1989), insomnia during the "dark period" in northern Norway (Lingjaerde et al., 1985), early morning awakening (Lack & Wright, 1993), and delayed sleep phase syndrome (Rosenthal et al., 1990).

The disruptive effects of time-zone travel on circadian rhythms can also be alleviated through melatonin administration about an hour before bedtime in the new time zone. Melatonin is a circadian-setting hormone released by the pineal gland and, it has been shown, induces drowsiness and shortens sleep latency. Thus, timely adminis-

tration may advance or delay the circadian phase. However, research concerning the optimal dose and the effects of long-term use are lacking (Chase & Gidal, 1997; Sack, Hughes, Edgar, & Lewy, 1997).

Intrinsic Sleep Disorders

Intrinsic sleep disorders are those due primarily to internal mechanisms. They include insomnia, narcolepsy, sleep apnea, periodic limb movements, and restless legs.

Insomnia. Insomnia includes difficulty falling asleep, frequent or prolonged awakenings during the night, early morning awakenings, and the experience of poor quality sleep. Epidemiological surveys indicate that about 15% of adults report severe or frequent insomnia and another 15% report mild or occasional insomnia (Bixler et al., 1979; Mellinger, Balter, & Uhlenhuth, 1985). The prevalence of insomnia increases with age. More than 25% of those over 65 years of age report having had considerable difficulty in falling or staying asleep during the preceding 12 months (Mellinger et al., 1985). The two most common types of intrinsic insomnia are psychophysiological insomnia and sleep state misperception.

Psychophysiological Insomnia. Psychophysiological insomnia refers to sleep disturbances that can be verified by objective measures (such as polysomnography) and are not associated with either extrinsic determinants such as noise or drugs or with other disorders such as major depression. About 15% of patients seen at sleep disorder centers with complaints of insomnia receive this diagnosis (ASDA, 1997).

The major determinants of psychophysiological insomnia are stress, expectations of disturbed sleep, and poor sleep habits. Other determinants such as circadian rhythm disturbances, changes associated with aging, drug abuse, and misinformation about sleep may contribute to the problem. Learned sleep-preventing associations are often central in psychophysiological insomnia and may also contribute to exacerbating and maintaining other sleep disturbances.

Insomniacs frequently engage in activities at bedtime that are incompatible with falling asleep. Many insomniacs organize their activities around their bedrooms with television, telephone, books, and food within easy reach. For others, bedtime is the first time during the day that is available to

think about the day's events and to plan and worry about the next day. Under these conditions, bed and bedtime become cues for arousal rather than cues for sleep (Bootzin & Nicassio, 1978).

Another source of arousal for the insomniac is that the bedroom can become a cue for the anxiety and frustration associated with trying to fall asleep. Insomniacs can often sleep any place other than their own beds. They may fall asleep in chairs or on couches and often have less difficulty sleeping away from home. In contrast, good sleepers often have difficulty in strange surroundings. For them, there are strong cues for sleep associated with their beds and they have difficulty sleeping only when these cues are not available (Bootzin & Nicassio, 1978).

Sleep State Misperception. Sleep state misperception is the most recent label for instances in which the complaint of insomnia is not verified by objective measures. In the past, this disorder has been called pseudoinomnia, subjective insomnia, and disorder of initiating or maintaining sleep without objective findings. Fewer than 5% of patients seen at sleep disorder centers for complaints of insomnia receive this diagnosis (ASDA, 1997).

A number of investigations have indicated that insomniacs of all types overestimate sleep latency and underestimate total sleep and the number of nocturnal awakenings, compared to polysomnography (e.g., Borkovec & Weerts, 1976; Carskadon et al., 1976). Those with sleep state misperception are the most extreme on this dimension. It should be emphasized that this diagnosis is not the sleep equivalent of hypochondria. Sleep state misperception often involves perceptual and cognitive dysfunctions that are not detected by polysomnography.

Some patients who have this diagnosis have difficulty distinguishing sleep states from wake-sleep transition states (Perlis et al., 1997) due perhaps to increased access to cognitive rumination during sleep. Other patients are hypervigilant to environmental stimuli during sleep and can remember and report on their occurrence (Anch, Saskin, & Moldofsky, 1989; Loewy & Bootzin, 1998).

CAPS and Alpha Sleep. Two arousal-related electrophysiological patterns have been found in the sleep of insomniacs: cyclic alternating pattern sequences (CAPS) and alpha sleep. CAPS, a biphasic electrical pattern that is found in the microstructure of NREM sleep stages (Terzano, Mancina, Salati, Costani, Decembrino, & Parrino, 1985),

consists of an arousal phase (composed of arousal-related phasic events distinct to each particular NREM sleep stage) that lasts between 2 and 60 seconds and is followed by a return to tonic or baseline activity. CAPS are a normal pattern of NREM sleep. Such arousal and de-arousal patterns occupy about 25% of NREM sleep in young, healthy, adult sleepers. CAPS are significantly more elevated (68%) in the sleep of insomniacs and suggest a hyperaroused state during sleep. The exact relationship of CAPS to the pathophysiology of insomnia is currently unknown, however, treatment of insomnia with hypnotics, it has been shown, reduces CAPS to a normal level (Terzano & Parrino, 1992).

Alpha rhythm, 8–12 Hz, is the dominant electrical pattern found in people who are awake, but relaxed. Many hypervigilant patients with insomnia have simultaneous alpha and sleep EEG waves. This has been called alpha-delta sleep (Hauri & Hawkins, 1973) or, more recently, alpha sleep. During wake, alpha is seen primarily from occipital leads, whereas during sleep, the alpha rhythm is more frontal and central. Alpha sleep is often experienced as nonrestorative sleep (i.e., not feeling rested after sleeping). Alpha sleep has been found in insomnia-affected patients who have fibromyalgia, rheumatoid arthritis, posttraumatic stress disorder, chronic pain disorders, depression, chronic fatigue syndrome, AIDS, and alcoholism (Fredrickson & Krueger, 1994; Moldofsky, Scarisbrick, England, & Smythe, 1975; Norman et al., 1992; Ware, Russell & Campos, 1986; Whelton, Saskin, Salit, & Moldofsky, 1988; for additional information, see the section on fibromyalgia).

Treatment of Insomnia. The prescription of sedative/hypnotics is the most frequently used treatment for insomnia. About 4.3% of adults in the United States use medically prescribed psychoactive medication to promote sleep (i.e., hypnotics, anxiolytics, and antidepressants; Mellinger, Balter, & Uhlenhuth, 1985). Of the sedative/hypnotics, benzodiazepines are the most frequently prescribed and have almost completely replaced barbiturates (Morin & Kwentus, 1988). Five principles of pharmacotherapy for persistent insomnia have been summarized by Kupfer and Reynolds (1997): use the lowest effective dose, use intermittent dosing to delay tolerance (two to four times weekly), prescribe medication for short-term use, discontinue medication gradually, and be alert for rebound insomnia following discontinuation. The use of sedative/hypnotics to in-

duce sleep is effective for short-term use; effects last 2–4 weeks. However, there have been no published randomized clinical trials of hypnotics for periods longer than 35 days (Kupfer & Reynolds, 1997). Thus, long-term effectiveness is unknown, and long-term use of hypnotics has generally been discouraged because of problems of tolerance, side effects, and dependence (see the section on hypnotic-dependent sleep disorder).

A number of nonpharmacological treatments, it has been found, are effective for insomnia. In a recent review by the American Academy of Sleep Medicine, the task force report concluded that nonpharmacological therapies produce reliable and durable changes in sleep and that between 70 and 80% of patients improve (Morin, Hauri, Espie, et al., 1999). The most frequently used nonpharmacological treatments include stimulus control instructions, sleep restriction, relaxation training, paradoxical intention, and cognitive therapy.

Stimulus control instructions consist of a set of instructions designed to help the insomniac establish a consistent sleep-wake rhythm, strengthen the bed and bedroom as cues for sleep, and weaken them as cues for activities that might interfere with sleep. The following rules constitute the stimulus control instructions (Bootzin, 1972, 1977; Bootzin, Epstein, & Wood, 1991).

1. Lie down intending to go to sleep only when you are sleepy.
2. Do not use your bed for anything except sleep, that is, do not read, watch television, eat, or worry in bed. Sexual activity is the only exception to this rule. On such occasions, the instructions are to be followed afterward when you intend to go to sleep.
3. If you find yourself unable to fall asleep, get up and go into another room. Stay up as long as you wish, and then return to the bedroom to sleep. Although we do not want you to watch the clock, we want you to get out of bed if you do not fall asleep immediately. Remember the goal is to associate your bed with falling asleep *quickly*! If you are in bed more than about 10 minutes without falling asleep and have not gotten up, you are not following this instruction.
4. If you still cannot fall asleep, repeat Step 3. Do this as often as is necessary throughout the night.
5. Set your alarm, and get up at the same time every morning irrespective of how much

- sleep you got during the night. This will help your body acquire a consistent sleep rhythm.
6. Do not nap during the day.

Stimulus control therapy, it has been found, is effective for both sleep onset and sleep maintenance insomnia. Meta-analyses of the treatment outcome literature for insomnia have found that stimulus control is one of the most effective of the nonpharmacological treatments (Morin, Culbert, & Schwartz, 1994; Murtagh & Greenwood, 1995).

Sleep restriction (Spielman, Saskin, & Thorpy, 1987) is based on the observation that many insomniacs have low sleep efficiency, that is, the proportion of time during which they are in bed and are actually asleep is less than 85%. To help consolidate sleep, insomniacs are instructed to limit the time during which they are in bed to the number of hours of sleep that they normally obtain. At first, patients experience partial sleep deprivation because they usually underestimate how much sleep they normally get. Sleep deprivation, however, helps to consolidate sleep. Patients are then instructed to follow a gradual schedule of increasing the amount of time spent in bed while maintaining the improved sleep efficiency. Sleep restriction has been effectively used in combination with sleep education and stimulus control instructions for treating sleep maintenance insomnia in older adults (Hoelscher & Edinger, 1988).

A commonly recommended treatment for insomnia is some type of relaxation training. This includes a variety of procedures such as progressive relaxation, autogenic training, transcendental meditation, yoga, hypnosis, and EMG biofeedback. As treatments for insomnia, all of these procedures are based on the same premise: if people can learn to be relaxed at bedtime, they will fall asleep faster. Because many insomniacs are aroused and anxious during the day, relaxation training may provide a double benefit—first, to help induce sleep, and second, as a general coping skill for dealing more effectively with the stresses of the day (Bootzin & Nicassio, 1978). The different types of relaxation procedures have all been found about equally effective in controlled studies (Bootzin & Rider, 1997).

Progressive relaxation training has been found effective in producing sleep onset latency improvement in both sleep state misperception and psychophysiological insomniacs (Borkovec et al., 1979). Improvement of the sleep state misperception patients was found for daily sleep diaries and

subjective estimates while in the sleep laboratory. Because these patients did not exhibit a problem on polysomnographic measures, no improvement was observed on those measures. Improvement of psychophysiological insomniacs, on the other hand, was found on both sleep diaries and polysomnography.

Cognitive treatments have focused on patients' beliefs and expectations. Insomniacs often subscribe to a number of irrational beliefs about sleep. Examples of these beliefs are that the individual must get at least 8 hours of sleep to feel refreshed and function well the next day; the worry that if individuals go for one or two nights without sleep, they will have nervous breakdowns; or the belief that individuals should avoid or cancel social, family, and work obligations after a poor night's sleep (Morin, 1993). Treatment involves providing accurate information and having the insomniac identify and rehearse alternative belief statements. These techniques have been effective as part of multicomponent treatments (Morin et al., 1999; Morin, Stone, McDonald, & Jones, 1994).

Paradoxical intention (PI) is a cognitive intervention that has been frequently evaluated. Many insomniacs exacerbate their problem by worrying whether they will be able to fall asleep. To reduce the anticipatory anxiety associated with "trying" to fall asleep, insomniacs are instructed to stay awake as long as possible. Controlled evaluations of PI for sleep onset insomnia have been mixed. The rationale provided by the therapist for the paradoxical instruction may be a crucial component of its effectiveness. In a meta-analysis of the application of PI to a number of different problems, Shoham-Salomon and Rosenthal (1987) found that rationales that emphasize a positive benefit or the positive qualities of the person who has the problem are more effective than rationales that are neutral or that emphasize negative aspects of the problem.

Many controlled studies have examined the efficacy and durability of psychological treatments for chronic insomnia. Two separate meta-analyses have been published (Morin, Culbert, & Schwartz, 1994; Murtagh & Greenwood, 1995). Both meta-analyses concluded that psychological treatments improve the sleep of insomniacs over control conditions, and improvements were maintained at 6-month follow-ups. Murtagh and Greenwood (1995) concluded that there are few differences between different active treatments, although stim-

ulus control instructions had the strongest effects. Morin, Culbert, & Schwartz (1994) concluded that both stimulus control instructions and sleep restriction, as single-component treatments, had the strongest effects.

In recent years, the focus has shifted from efficacy studies of single-component treatments to effectiveness studies of multicomponent treatments. In one study, primary care nurses within a community general medical clinic were trained to deliver a multicomponent treatment consisting of stimulus control instructions, sleep restriction, and cognitive therapy (Espie, Inglis, Tessier, & Harvey, 2001). The treatment was more effective than a control condition in improving sleep, and 84% of patients who were initially using hypnotics remained drug-free during the follow-up period. Another innovative intervention presented a course of eight television programs broadcast in the Netherlands. About 200,000 people viewed the course of whom 23,000 ordered course materials. An evaluation of a sample of those who participated found that the course produced improvements in sleep latency and total sleep and decreases in hypnotic drug use (Oosterhuis & Klip, 1997).

Narcolepsy

Narcolepsy is characterized by excessive daytime sleepiness and abnormal manifestations of REM sleep (ASDA, 1997). The REM abnormalities associated with narcolepsy include sleep onset REM periods and dissociated REM processes such as cataplexy, sleep paralysis, and hypnagogic hallucinations.

Narcolepsy has a prevalence of between 5 and 10 per 10,000 individuals (Guilleminault, 1994a). Age at onset can range from childhood to the fifth decade, but it peaks in the second decade. Researchers have documented a strong association between narcolepsy and the human leukocyte antigen HLA-DR2 phenotype that lends support to genetic theories of narcolepsy (Honda, Asaka, Tanimura, & Furusho, 1983). However, it has not been a useful diagnostic measure because as many as 25% of nonnarcoleptics also have the HLA-DR2 phenotype. The gene for canine narcolepsy, which is characterized primarily by symptoms of cataplexy (see later), is due to a recessive gene that affects the hypocretin (orexin) receptor 2 gene (Lin et al., 1999). Although genetics is definitely involved in the development of narcolepsy, there

is also a strong environmental component because only 30% of identical twins are concordant for narcolepsy (Mignot, 1998).

Narcolepsy is classified as a disorder of excessive somnolence. However, narcoleptics do not sleep abnormally long within a 24-hour period. Narcoleptics may sleep 8 hours a night and be awake 16 hours during the day, but they will have repeated naps or lapse into sleep of short duration that lasts about 10 to 20 minutes. They awaken feeling refreshed but begin to feel sleepy again within 2 to 3 hours, at which point the pattern repeats itself (ASDA, 1997). These sudden and irresistible sleep attacks, also called excessive daytime sleepiness (EDS), are most common in, but not limited to, sleep-inducing circumstances such as sedentary activities. They may occur when the individual is actively involved in a task such as taking an examination, eating, walking, driving, or talking.

An accurate diagnosis of narcolepsy depends on differentiating it from two other medical conditions associated with the symptoms of excessive somnolence, breathing disorders during sleep, and central nervous system hypersomnia (Guilleminault, 1994a). The four classic symptoms of narcolepsy include (1) sleep attacks—characterized by an irresistible urge to sleep; (2) cataplexy—an abrupt and reversible decrease or loss of muscle tone that ranges in severity from mild weakness to complete postural collapse, with no loss of consciousness, elicited by emotion (usually pleasant or exciting emotions, e.g., laughter, pride, anger, and surprise) and ranging from a few seconds to several minutes; (3) hypnagogic hallucinations—frightening and vivid visual or auditory hallucinations that occur at the onset of sleep; and (4) sleep paralysis—muscle paralysis upon falling asleep or awakening, characterized by the inability to move limbs, speak, or breathe deeply, that lasts from one to several minutes, and is often a frightening experience. Only 20–25% of narcoleptics have all four of the core symptoms, and the latter three typically decrease over time. Sleep disruption and frequent nocturnal awakenings are common, as are reports of memory problems and automatic behavior (ASDA, 1997).

A positive diagnosis of narcolepsy requires either irresistible sleepiness or cataplexy plus sleep onset REM episodes documented by polysomnogram (ASDA, 1997). On the basis of polysomnographic recording, confirmatory diagnosis can

be made if the mean MSLT score is less than 5, two or more sleep onset REM periods occur during a MSLT, and REM sleep occurs within 20 minutes of sleep onset during a nighttime recording (Association of Professional Sleep Societies, 1986). Caution must be exercised, however, because individuals without complaints of daytime sleepiness occasionally have two or more sleep onset REM periods (Aldrich, Chervin, & Malow, 1997; Bishop, Rosenthal, Helmus, Roehrs, & Roth, 1996) and some individuals with narcolepsy do not have multiple sleep onset REM periods on the first day of a MSLT (Choo & Guilleminault, 1998).

Conventional treatment of narcolepsy focuses on the separate symptoms. Stimulants (methylphenidate and dextroamphetamine) are often used to treat EDS, and antidepressants (protriptyline and viloxazine) are used for the REM-related symptoms of cataplexy, sleep paralysis, and hypnagogic hallucinations (Guilleminault et al., 1986; Mitler et al., 1986). A routine of medication and naps (Roehrs et al., 1986) can reduce sleep attacks from three per day to one or two per month (Mitler, Nelson, & Hajdukovich, 1987). Support groups (Guilleminault, 1994a) and counseling for the families of narcoleptics (Karacan & Howell, 1988) are useful in helping patients and their families deal with the psychological and social effects of narcolepsy, including loss of self-esteem, depressive reactions, and family discord.

Sleep Apnea

Sleep apnea is a respiratory disorder characterized by repetitive episodes of cessation of airflow that last at least 10 seconds. Sleep apnea is one of the most common causes of sleep disturbance. The prevalence is higher in men than in women and increases with age. An occasional pause in breathing is normal, but sleep apnea becomes a health problem when apneas occur frequently and are associated with significant reduction in blood oxygen saturation, cardiac arrhythmia, or impaired daytime functioning secondary to frequent arousals and fragmented sleep. In general, more than five apneas per hour of sleep in adults is considered abnormal (Guilleminault & Dement, 1988). Three types of sleep apnea have been defined: (1) *obstructive*—cessation of airflow secondary to upper airway obstruction; (2) *central*—cessation of airflow secondary to lack of ventilatory effort; (3) *mixed*—cessation of airflow in a

pattern that suggests lack of ventilation effort initially and subsequent upper airway obstruction. As mentioned, the term *apnea* refers to a complete cessation of airflow; *hypopnea* refers to a partial reduction in airflow, again usually accompanied by an arousal. Hypopnea and apnea have similar clinical features (e.g., unrefreshed sleep, excessive daytime sleepiness). Patients with obstructive sleep apnea can demonstrate obstructive, central, or mixed apneas, in addition to hypopneas throughout the night. Thus, the severity of the disorder is measured by combining all of these events in a total score, referred to as the respiratory disturbance index (RDI). Many individuals with sleep apnea have obstructive, central, and mixed events in one night and as many as 300 such events per night.

Obstructive Sleep Apnea (OSA). OSA is the most common of the three types of sleep apnea. The term *sleep disordered breathing* (SDB) is sometimes used synonymously for OSA. A recent epidemiological study reported that the prevalence of OSA is higher than previously estimated, approximately 4 and 2% in middle-aged men and women, respectively (Young et al. 1993). On the basis of a group of community dwelling adults ages 40–60 years, Kripke et al. (1997) estimated that the prevalence of OSA is even higher at 9.3% for men and 5.2% for women. Patients with OSA are often overweight. Although OSA is a common disorder in middle-aged adults and increases the risk of or exacerbates already existing cardiovascular diseases, it remains underrecognized and underdiagnosed (Young et al., 1997; Chan et al., 1998; Partinen & Guilleminault, 1990). The onset of OSA is usually insidious, and if untreated, complications including mortality can ensue (Redline & Strohl, 1998).

During sleep, the upper airway musculature relaxes, reducing the caliber of the airway and leading to increased respiratory effort. Snoring, which has been reported in up to 50% of males over age 40, is an indication of partial airway obstruction and is produced by the vibration of pharyngeal tissues on inspiration, as the airflow becomes increasingly turbulent in the narrowed oropharyngeal space. Further narrowing produces hypopnea or with complete obstruction, apnea. Factors that reduce the diameter of the upper airway and predispose patients to snoring and OSA include obesity (via fat deposition), enlarged tonsillar tissue mass, and craniofacial abnormalities. In addition, excessive upper airway muscle relaxation and narrow-

ing occur from using alcohol, or other respiratory depressants (Bootzin, Quan, Bamford, & Wyatt, 1995; Redline & Strohl, 1998).

Patients with obstructive sleep apnea usually snore loudly, as reported by their bed partners, and their snoring is irregular and interrupted by pauses. These pauses end with a loud snort as the patient's progressively stronger ventilatory efforts finally produce arousals, contraction of the upper airway muscles, and normal breathing. Arousals can be brief and not recalled by the patient or prolonged with complete awakening. As the patient returns to sleep, the cycle of progressive upper airway narrowing begins again.

In addition to the hallmark symptom, loud snoring, nighttime symptoms of OSA may include restlessness, frequent awakenings, choking, tachycardia, heartburn, enuresis, nocturia, and profuse sweating. Daytime symptoms include waking up feeling unrefreshed with feelings of disorientation or grogginess, sometimes accompanied by a headache. Additionally, some patients may also experience decreased libido and changes in personality (e.g., increased irritability, depression, and aggressiveness) (Guilleminault, 1994b; ASDA, 1997). Daytime sleepiness is common and can range from fatigue to involuntary sleep attacks, which can occur while the patient is driving or conversing. Definitive diagnosis and determination of appropriate treatment require that the patient undergo a polysomnographic study.

The treatment of OSA depends on the severity of the condition, as expressed by disturbance in nocturnal sleep, cardiac or neurological complications, and daytime symptoms. The goals of treatment are to eliminate snoring and upper airway obstruction, maintain nocturnal oxygenation and ventilation, and normalize sleep architecture (Chan et al., 1998). Several treatment modalities are available for OSA, including behavioral, medical, and surgical interventions. Behavioral interventions to modify risk factors generally are considered first or are sometimes recommended as adjuncts to more aggressive therapies. In patients with mild to moderate OSA weight loss (Brownman et al., 1984), avoidance of alcohol and other CNS depressants (Issa & Sullivan, 1982; Robinson & Zwillich, 1985) and position therapy (measures designed to keep the patient in the lateral rather than the supine position when asleep) (Cartwright, Lloyd, Lilie, & Kravitz, 1985) can be effective interventions.

Because the pathophysiology of OSA is due

primarily to the intermittent collapse of a narrowed airway, mechanical or surgical techniques to enlarge the airway are the most logical treatment approach. Nasal continuous positive airway pressure (CPAP) is by far the treatment of choice for moderate to severe OSA. CPAP is applied by an airtight nasal mask connected to a flow generator and acts as a pneumatic internal splint of the upper airway to prevent it from collapsing. Nasal CPAP is highly effective in abolishing apneic events and produces immediate improvement in symptoms, quality of life, and cognitive function (Engleman, Martin, Deary & Douglas, 1997; Sullivan, Issa, Berthon-Jones, & Eves, 1981). Many patients, however, do not tolerate the CPAP appliance, which leads to poor compliance. Kribbs and colleagues (1993) have reported that although the majority of patients claim to use CPAP nightly, only sixteen of thirty-five (46%) in their study met criteria for regular use. And when used, the mean duration of CPAP use was less than 5 hours per night.

Surgical procedures for OSA include tonsillectomy, nasal surgery (e.g., correcting deviated septum, removing nasal polyps), and uvulopalatopharyngoplasty (UPPP). The long-term efficacy of UPPP is highest in patients with mild to moderate disease, but even in this population, satisfactory results occur in less than 50% of patients (Conway, Fujita, Zorick, et al., 1985). Mandibular advancement devices (MRD) that reposition the mandible, the tongue, and other structures to increase the upper airway dimensions are effective in treating snoring and mild OSA. The long-term efficacy of MRD, however, is still unclear (Chan et al., 1998; Chervin & Guilleminault, 1996).

Central Sleep Apnea (CSA). CSA represents a loss of ventilatory drive or rhythmicity. Most CSA episodes occur at sleep onset and are benign. CSA is considered pathological only when the events are sufficiently frequent to disturb sleep, result in hypoxemia or cardiac arrhythmias, or disturb daytime functioning. The severity of CSA and the extent of sleep disturbance depend partially on the underlying pathophysiology. Clinical presentation of patients with CSA differs from patients with OSA in a number of ways, however, there is also considerable overlap. Pure CSA is rare; patients with this condition constitute fewer than 10% of patients evaluated in sleep laboratories. Compared to patients with OSA, CSA patients less commonly complain of daytime hypersomnolence; although obesity and snoring are sometimes present,

they are not prominent features. The primary complaints of CSA patients are usually insomnia and frequent awakenings during the night, sometimes accompanied by a gasp for air and shortness of breath. Daytime symptoms may include morning headache, tiredness, fatigue, sleepiness, difficulty in memory and other cognitive functions, sexual dysfunction, and depression (ASDA, 1997).

CSA occurs secondary to lesions that affect the neural systems involved in ventilation (White, 1994). For example, CSA is a known complication of several neuromuscular diseases (e.g., amyotrophic lateral sclerosis (ALS), motor-sensory neuropathy, and myotonic dystrophy). These patients usually demonstrate daytime hypoventilation manifested by an elevated blood carbon dioxide level. At night, at the onset of sleep, loss of the behavioral control of ventilation, the so-called "wakefulness" stimulus, leads to further hypoventilation and oxygen desaturation. Typically, CSA worsens during REM sleep because these patients lose the use of accessory muscles of respiration that compensate for diaphragmatic weakness due to the muscle atonia that occurs in REM sleep. Profound hypoxemia can result (Guilleminault & Robinson, 1996).

Because CSA remains a disorder that is not well understood, currently available treatments are not entirely satisfactory. Central respiratory stimulants such as medroxyprogesterone are effective in central sleep apnea for a short time, but result have been variable in long-term use (Bootzin et al., 1995). Tricyclic antidepressant agents that suppress REM sleep and increase respiratory musculature tone have been used with little success to treat both CSA and OSA (Guilleminault & Robinson, 1996). Oxygen therapy helps some patients by decreasing the wide swings in blood oxygen content that characterize some forms of CSA and affect central nervous system rhythmicity. Night-time ventilatory support, usually administered through appliances similar to CPAP devices, can be effective treatment for patients with CSA secondary to neuromuscular disorders. The boost in ventilation provided compensates for muscle weakness, corrects oxygen and carbon dioxide abnormalities, leading to none consolidated sleep.

Periodic Limb Movements and Restless Legs Syndrome

Periodic limb movement (PLM) disorder is characterized by periodic episodes of repetitive

and stereotypic limb movements during sleep. Also known as nocturnal myoclonus, periodic movements during sleep, and periodic leg movements, PLMs are described as episodes of rhythmic extensions of the big toe and dorsiflexions of the ankle, sometimes with flexions of the knee and hip.

The most common sleep characteristics associated with PLMs are frequent arousals and complaints of nonrestorative sleep. Patients are often unaware of PLMs and present with complaints of insomnia or excessive daytime sleepiness or seek help as a result of a bed partner's complaints of excessive nighttime movement.

Accurate diagnosis of PLMs is complex. The incidence of PLMs increases with age. It is known to exist concurrently with other disorders of excessive somnolence such as narcolepsy, sleep apnea, or restless legs syndrome (Moore & Gurakar, 1988) and may be associated with medical conditions such as chronic uremia, anemia, chronic lung disease, and fibromyalgia (Montplaisir et al., 1994). PLMs may be induced or aggravated by using tricyclic antidepressants and monoamine oxidase inhibitors, as well as by withdrawal from drugs such as anticonvulsants, benzodiazepines, barbiturates, and other hypnotic agents (ASDA, 1997). A polysomnogram with leg EMG is necessary to establish a final diagnosis of PLMs.

Polysomnographic recording of PLMs reveals repetitive episodes of muscle contraction measured by EMG that occur every 20 to 40 seconds (ASDA, 1997). These episodes usually occur in stages 1 and 2 sleep, decrease in stages 3 and 4, and are usually absent during REM sleep (Montplaisir et al., 1985). A PLM index (number of PLMs per hour of sleep) greater than 5 is considered pathological.

Restless legs syndrome (RLS) is a disorder characterized by irresistible leg movements usually before sleep onset (ASDA, 1997) and often described as an "aching" sensation. The most prominent characteristic of this disorder is the partial or complete relief of the sensation with leg motion and return of the symptom with cessation of movement. Symptoms are often exacerbated soon after getting into bed and tend to cease long enough for the patient to fall asleep, only to reappear later in the night. However, RLS may occur at times during the day after prolonged periods of sitting. The severity of symptoms with RLS may wax and wane throughout a patient's lifetime. Remissions may last for years, and symptoms

reappear suddenly without warning. Most patients with RLS also show PLMs during sleep. Symptoms are associated with a number of conditions such as the last trimester of pregnancy, caffeine intake, fatigue, exceptionally warm environment, prolonged exposure to cold (Montplaisir et al., 1994), anemia, and rheumatoid arthritis (ASDA, 1997).

Treatment for PLMs and RLS is pharmacological. The most effective drugs to date are carbidopa/levodopa, benzodiazepines (clonazepam, temazepam, lorazepam, and nitrazepam), and opioids. Carbidopa/levodopa are considered the drugs of choice and, it has been shown, reduce the quantity of movements and increase the quality of sleep (Bootzin, Quan, Bamford, & Wyatt, 1995). Benzodiazepines may be considered in milder cases (Mitler, Brownman, Gujavarty, Timms, & Menn, 1984; Moldofsky, Tullis, Quance, & Lue, 1985), however, their use should be considered carefully, especially in the elderly, because they may induce or exacerbate sleep apnea and prevent arousal from apneic episodes (Montplaisir et al., 1994).

Extrinsic Sleep Disorders

External factors such as sleep schedules, light, noise, drugs, nicotine, alcohol, and activity levels may cause disrupted sleep. In some instances, even chronic insomnia may be due to these factors.

Inadequate Sleep Hygiene. Inadequate sleep hygiene is defined as "a sleep disorder due to the performance of daily living activities that are inconsistent with the maintenance of good quality sleep and full daytime alertness" (p. 73, ASDA, 1997).

The likelihood that sleep disorders will be produced by inadequate sleep hygiene depends on predisposing factors, on the persistence of the behavior, and on the degree to which it deviates from normal practices. For example, some individuals who maintain highly irregular sleep-wake schedules never experience sleep disturbances, but others will report great difficulties in initiating or maintaining sleep even when their schedules are less irregular. The probability that an individual will engage in behavior that is inconsistent with maintaining good sleep is increased for individuals with low tolerance for daytime sleepiness. Such individuals may take naps, increase caffeine consumption, or go to bed too early. Although these behaviors may increase alertness in the short

run, they may weaken the underlying biological clock and lead to insomnia when practiced for a long time.

Three aspects of sleep hygiene will be discussed: (1) the regularity of sleep-wake schedules, (2) regular exercise, and (3) the use of caffeine and nicotine.

Sleep-Wake Schedules. The relationship between biological rhythms and the sleep-wake cycle is the basis for the common recommendation to maintain a regular sleep schedule. Those who keep irregular schedules for long periods of time are at risk of developing sleep disturbances. Conversely, those with sleep disturbances frequently benefit from regularizing their sleep schedules. Indeed, when irregular sleepers regularize their nocturnal sleep and at the same time make sure their sleep is adequately long, their sleep and daytime alertness improve, and these improvements are greater than those observed when an intervention includes only the provision of adequate sleep duration without attempts to regularize the sleep schedule (Manber, Bootzin, Acebo, & Carskadon, 1996).

The role of naps within the sleep-wake schedule is complex. In polysomnographic terms, afternoon and evening naps begin the night's sleep, and morning naps are a continuation of the previous night's sleep. Thus, afternoon and evening naps have more slow-wave sleep, and morning naps have more REM sleep. The sleep on a night that follows an afternoon nap resembles sleep in the latter part of a normal night, which is lighter and has more awakenings. Thus, afternoon and evening naps should be avoided to preserve the quality of sleep at night. If they are taken, they should be short and should be made a regular part of the daily schedule at about the same time each day.

Regular Exercise. For exercise to be effective in improving sleep, individuals have to engage in programs of regular exercise. Recommendations to exercise are not always effective because of variability in compliance. A meta-analysis concluded that exercise must last for at least an hour to have reliable effects on sleep (Youngstedt, O'Connor, & Dishman, 1997). Regular exercise programs in older men produce increased continuous sleep, increased slow-wave sleep, and decreased nighttime awakenings (Edinger et al., 1993; Vitello et al., 1992).

Use of Caffeine and Nicotine. Caffeine and nicotine are central nervous system stimulants that lighten sleep and produce arousals (ASDA, 1997).

Caffeine is present in chocolate and in coffee (100–200 mg, depending on the strength of the brew), tea (50–75 mg), and many carbonated beverages (50–75 mg). There are individual differences in the degree of sensitivity to caffeine. Some individuals may experience sleep disturbances from consuming chocolate and soft drinks alone. Other medications, including analgesics (those that contain caffeine), bronchodilators, decongestants, and appetite suppressants, are or contain stimulants that increase sleep latency, decrease total sleep time, and increase spontaneous awakenings (ASDA, 1997; Brown et al., 1995). Cessation of caffeine or nicotine intake may cause withdrawal symptoms such as sleepiness, irritability, lassitude, and severe depression (ASDA, 1997).

Complaints of insomnia and/or anxiety may be due to excessive ingestion of caffeine, nicotine, or other stimulants. Because caffeine has a plasma half-life of approximately 6 hours, individuals continue to experience its effects long after it has been ingested. Reducing or eliminating the intake of caffeine, particularly in the afternoon and evening, and quitting smoking can lead to substantial improvement in sleep. However, an increase in disturbed sleep can be expected during the initial period of smoking withdrawal (Wetter, Fiore, Baker, & Young, 1995).

Environmental Sleep Disorders. Among the many environmental factors that affect sleep are noise, temperature, room or bed sharing, institutionalization, and the need for vigilance during sleep. The presenting complaints consist of insomnia symptoms or marked impairment of daytime functioning. This diagnosis is given only when the environmental causes are judged the primary cause for the complaints. Its prevalence rate in patients seen in sleep disorder centers is estimated at less than 5% (ASDA, 1997). Sensitivity to environmental factors increases with age and is subject to great individual variability.

Noise decreases the amount of deep sleep and the continuity of sleep. There is an increase in body movements and sleep stage shifts. Studies show that a presentation of an auditory stimulus is often followed by very brief arousal (3–15 seconds). The fragmentation of sleep often leads to increased daytime sleepiness (Stepansky et al., 1984). Unpredictable noise is particularly disturbing (Sanchez & Bootzin, 1985). Thus, continuous white noise, such as that from a fan, is often useful for noisy environments.

People can adjust to a wide range of room temperatures but have more difficulty adjusting to cold than to heat. Uncomfortable room temperatures, particularly cold rooms, affect the quality of sleep more than the capacity to fall asleep (Haskell et al., 1981).

Recommendations for reducing environmental disturbances and strengthening good sleep hygiene have become an integral part of many treatments for insomnia. Frequent recommendations include maintaining regular sleep-wake schedules, establishing an environment conducive to sleep (quiet, dark, and secure), increasing exposure to light and other sensory stimuli upon awakening, and carefully timing and limiting the use of caffeine and alcohol. The importance of a comprehensive treatment approach, based on a thorough analysis of the problem, should be emphasized.

Drug-Dependent Sleep Disorders. Chronic use of drugs to induce or to suppress sleepiness may cause adverse effects. Although alcohol and sedative/hypnotics, it is thought, induce a state of unconsciousness that resembles sleep, in fact the resemblance to natural sleep is weak. Hypnotics produce disruptions in sleep architecture and increases in arousal threshold (Kay & Samiuddin, 1988). Using stimulants to suppress sleep can produce persistent insomnia.

Hypnotic-Dependent Sleep Disorder. Hypnotic-dependent sleep disorder is characterized by insomnia or excessive sleepiness associated with the tolerance to or withdrawal from hypnotic medications (ASDA, 1997).

Sedative/hypnotics are the most frequently used method for treating insomnia. With continued use, tolerance rapidly develops, and larger doses are required to achieve a soporific effect. As dosage is increased to offset tolerance, daytime carryover effects also increase and may include symptoms such as excessive sleepiness, poor motor coordination, visual-motor problems, and late afternoon restlessness (ASDA, 1997). These symptoms promote psychological dependency as the individual becomes convinced that the daytime effects are symptoms related to poor sleep the night before. This leads to a continued search for pharmacological relief from the insomnia, possibly by consulting several physicians or trying a variety of sleep-inducing medications. Polysomnographic monitoring of chronic sedative/hypnotic users shows decreases in stages 1, 3, 4, and REM sleep, an increase in stage 2 sleep, and fragmented

NREM and REM sleep with frequent stage changes (ASDA, 1997).

Once benzodiazepine hypnotics or anxiolytics are begun, it is often difficult for individuals to withdraw. In a study of abrupt discontinuation by individuals who had been taking benzodiazepines for 1 year or longer, 56% who took long half-life and 62% who took short half-life benzodiazepines failed to remain free of drugs during a 5-week follow-up (Rickels et al., 1990). In a companion study of gradual taper, 32% of long half-life and 42% of short half-life benzodiazepine-treated patients failed to achieve a drug-free state (Schweizer et al., 1990).

Cessation of sedative/hypnotics results in withdrawal symptoms that may also promote psychological dependence. Insomnia, it has been shown, is among the most frequent withdrawal symptoms from the long-term use of benzodiazepines (Busto et al., 1986; Schneider-Helmert, 1988). Other withdrawal symptoms include a dramatic increase in REM and stage 2 sleep percentages and daytime sleepiness (Schneider-Helmert, 1988). Total sleep time does not decrease with the withdrawal of medication, but the subjective perception of rebound insomnia is judged much worse than before drug therapy and often leads the patient to resume sedative/hypnotic use.

Alcohol-Dependent Sleep Disorder. About 10–15% of patients with chronic insomnia have problems with substance abuse, particularly alcohol and other sedatives (Gillin & Byerley, 1990). Alcohol, like other depressants, is a REM suppressant. Withdrawal from heavy drinking produces a REM rebound effect that is accompanied by restless sleep and nightmares. Alcohol also exacerbates sleep apnea because it affects ventilation during sleep by increasing upper airway resistance (Issa & Sullivan, 1982; Taasan et al., 1981). The effects of alcohol on sleep can persist as long as 2–3 hours after plasma alcohol levels return to zero (Zarcone, 1994).

Alcohol-dependent sleep disorder is characterized by the use of alcohol for initiating sleep onset (ASDA, 1997). Usually, the ingestion of alcohol begins about 3–4 hours before bedtime, and consumption is equivalent to about 6–8 ounces of liquor. This condition is not associated with other alcoholic patterns of drinking (drinking during the day and related socioeconomic problems) and is usually considered clinically relevant if the alcohol has been used daily for a minimum of 30

days. Continued use results in tolerance to alcohol as a sleep-inducing agent, and sleep fragmentation becomes more prominent. Often, patients will become desperate and increase the amount of alcohol or add other sedatives to sleep. Patients will often report that they have no sleep disturbance, as long as they continue to take the alcohol nightly.

Polysomnographic monitoring of this type of alcohol user shows an increase in stages 3 and 4, fragmentation of REM sleep, and frequent awakenings and sleep stage transitions (ASDA, 1997). Frequent sleep transitions are usually seen later in the sleep period, as the alcohol blood level begins to decline. In addition to polysomnogram recordings, diagnosis is confirmed if the patient complains of insomnia, has unsuccessfully attempted to withdraw from bedtime alcohol ingestion, and there is no evidence of medical or psychiatric disorder responsible for the insomnia (ASDA, 1997).

Stimulant-Dependent Sleep Disorder. Stimulant-dependent sleep disorder is characterized by the reduction of sleepiness or the suppression of sleep through the use of central stimulants that result in alterations in wakefulness following drug abstinence (ASDA, 1997). Many stimulants are used to combat daytime sleepiness. Cocaine, amphetamines, and inhalants have sleep suppressing effects. They increase the time to fall asleep and REM sleep latency and decrease total sleep time and REM time (Gillin, 1994). Tolerance may develop with chronic use and results in increased dosages. During episodes of stimulant abuse, individuals may go for days without sleep followed by periods of hypersomnia and accompanied psychological and mood problems of paranoia, psychosis, social withdrawal, and sleep disturbances. Individuals may use sedatives or alcohol to counteract the sleep suppressing effects of stimulants and reduce anxiety.

Withdrawal from stimulants is associated with hypersomnia and depression that can last 2 weeks (Gillin, 1994). At the end of the 2-week period, the individual may experience a few days of insomnia and poor quality sleep. Both sleep disturbances and hypersomnia may be risk factors for the reuse of stimulants or the use of other drugs.

Parasomnias

Parasomnias are phenomena that intrude into sleep, although they are not primarily part of sleep *per se*. The more common examples include sleep

talking, sleepwalking, sleep terrors, enuresis, and bruxism. These disorders reflect central nervous system activation and are divided into the following categories: (1) arousal disorders, (2) sleep-wake transition disorders, (3) parasomnias usually associated with REM sleep, and (4) other parasomnias.

Arousal Disorders

Arousal disorders, such as sleep terrors and sleepwalking occur during arousal from slow-wave sleep.

Sleep Terrors. Sleep, or night, terrors, also called “pavor nocturnus” in children and “incubus” in adults, arise out of slow-wave sleep. They are characterized by the subjective experience of panic, rapid autonomic arousal, and behavioral activation. The individual will appear to be in great distress, emit a piercing scream, frequently will sit up, and may flee from the bedroom.

Despite behavioral activation and the experience of intense emotion, the individual may have either partial or total amnesia for the details of the event. If awakened during the sleep terror, the individual is likely to be confused, may report a sense of terror or dread, but reported sleep mentation will be vague, unlike the detail that occurs during nightmares. Because sleep terrors arise out of slow-wave sleep, they tend to occur during the first few hours of sleep. Nightmares, in contrast, are REM phenomena and are more likely to occur during the latter half of the night. Sleep terrors need also to be distinguished from nocturnal panic episodes, though the latter are usually not associated with screaming and do not produce vivid fearful imagery. Another differential diagnosis for sleep terrors is nocturnal seizures. Like sleep terrors, they are associated with difficulty to arouse during the event and with confusion upon arousal. However, whereas nocturnal seizures are often associated with daytime sleepiness, sleep terrors usually are not. Sleep terrors are not associated with daytime EEG abnormalities. Unless the clinical presentation suggests the possibility of a seizure disorder or other sleep disorders, an all night sleep study is not necessary to diagnose sleep terrors.

Recurring episodes of sleep terrors occur in from 1–6% of prepubertal children, and the typical age range for the disorder is from 5–7 years (Thorpy

& Glovinsky, 1987). Sleep terrors occur in about 1% of the adult population (Thorpy & Glovinsky, 1987). Although sleep terrors tend to abate after the onset of puberty, sleepwalking sometimes occurs or persists in those who had sleep terrors during childhood.

Pharmacological treatment of sleep terrors is based upon attempts to reduce the amount of slow-wave sleep experienced and usually involves using benzodiazepines or tricyclic antidepressants (Thorpy & Glovinsky, 1987). More recently, non-pharmacological treatments have also shown promise. Self-hypnosis (Hurwitz, 1986; Hurwitz & Mahowald, 1988) and scheduled awakenings with children (Lask, 1988) have been reportedly effective. In the scheduled awakening treatment, parents note how long after the child goes to sleep that a sleep terror is typically experienced. On subsequent nights, the parents are instructed to awaken the child 10–15 minutes before the sleep terror would have occurred. This procedure has been reportedly highly successful and may disrupt and lighten slow-wave sleep. It is also easier to comfort a child after a planned awakening than from one in which the child is frightened. Because both insufficient sleep and increased stress often exacerbate disorders of partial arousal (Guilleminault et al., 1995; Moldofsky et al., 1995), including sleep terrors, treatment should include education about the contribution of these factors and specific suggestions for managing stress and ensuring sufficient sleep.

Sleepwalking. Sleepwalking, or somnambulism, occurs during the first few hours of sleep, out of slow-wave sleep, not REM. Thus, sleepwalkers are not acting out their dreams. Their movements are coordinated with their environments, they typically avoid objects, may go to the bathroom, and even return to bed, if left alone. If awakened, sleepwalkers are confused and have little memory of dream mentation. Sleepwalking episodes may last from 15 seconds to 30 minutes (Aldrich, 2000a). Sleepwalking should be differentiated from REM behavior disorder (see parasomnias associated with REM) in which individuals lack the muscle atonia that accompanies REM, so that they do act out their dreams.

Sleepwalking is more common among children than adults. It is estimated that 15–30% of healthy children have at least one episode and 2–3% have more frequent episodes (Thorpy & Glovinsky, 1987). Generally, sleepwalking first occurs during prepubescence, reaches a peak prevalence at 12 years of age, and only infrequently occurs in chil-

dren older than 15 years old. The prevalence in adults is less than 1%. There do not appear to be sex-related differences, but there is evidence for a familial tendency. Sleepwalking occurs ten times more frequently among first-degree relatives than in the general population (Karacan, 1988).

There is no known pathophysiology that corresponds to sleepwalking. Fatigue, stress, sleep deprivation, and drug use (especially sedative/hypnotics) may precipitate episodes. Psychopathology is not usually associated with sleepwalking in children, but it is in adults. Kales, Soldatos, Cadwell, et al. (1980) reported that adult sleepwalkers had elevated MMPI profiles (Pd, Sc, and Ma) and 72% of his sample had psychiatric diagnoses.

Parents of sleepwalking children should be cautioned to take safety precautions such as locking doors and windows. It is usually better to direct sleepwalkers back to bed rather than to awaken them. The very process of awakening may frighten and confuse them. When sleepwalking occurs frequently and is associated with potentially injurious or harmful behaviors, the intervention and preventive measures that are used for sleep terrors are also effective with the sleepwalker. These include preventing sleep deprivation, introducing stress coping strategies, and using scheduled awakening (Stores, 1990; Thorpy & Glovinsky, 1987).

Although there is a higher incidence of psychopathology among adults who sleepwalk than among those who do not, a complaint of sleepwalking does not necessarily indicate psychopathology. Sometimes sleepwalking persists well into the second decade of life, particularly among individuals with a history of parasomnias who report being sound sleepers and difficult to arouse. These individuals are likely to need more sleep, to have higher than average slow-wave sleep, and to suffer from sleep deprivation. Nevertheless, a complete psychological evaluation is often recommended for adults who sleepwalk. For sleepwalking adults, a motion-detection alarm is often useful. In addition to the other nonpharmacological interventions described earlier, pharmacological therapy is indicated when the sleepwalker is in particular danger. It includes medications such as benzodiazepines and antidepressants that suppress slow-wave sleep and reduce nocturnal arousals (Karacan, 1988).

Sleep–Wake Transition Disorders

This category includes sleep talking and sleep starts. These disorders usually occur in the transitions between wakefulness and sleep and, more

rarely, in the transitions between sleep stages. They occur in otherwise healthy subjects (ASDA, 1997).

Sleep Talking. Sleep talking, also called somniloquy, occurs during all stages of sleep. About 80% of sleep talking takes place during NREM sleep (Arkin, 1978). Dream mentation is recalled in association with 79% of the episodes that occur in REM sleep, 46% of the episodes that occur in stage 2, and 21% of the episodes that occur during slow-wave sleep (ASDA, 1997). Usually, sleep utterances occur spontaneously, are brief, and are devoid of signs of emotional distress. Occasionally, sleep talking may be induced or prolonged by conversation with the sleeper. Laughing, singing, and crying occasionally occur during sleep, as well (Anch et al., 1988).

Almost everyone has experienced an episode of sleep talking. In a survey of 1508 college undergraduates, 83% reported having had at least one episode of sleep talking (Perlis, 1989). Sleep talking may be precipitated by emotional distress or physical illness and may also accompany other parasomnias. Sleep talking is considered benign, so there is no recommended treatment.

Sleep Starts. Sleep starts, also called hypnic jerks, are sudden brief contraction of the legs, sometimes also involving the arms and head, that occur during the transitions from wakefulness to sleep. They occur mainly at the beginning of the sleep episode. Sleep starts are sometimes associated with sensory experiences, including the subjective impression of falling, a visual hypnagogic dream, and fragmentary auditory (e.g., loud bangs, snapping noises) or somesthetic (e.g., pain, floating) hallucination. Sleep starts are considered a normal phenomenon of the sleep onset process and should not be confused with seizures or movement disorders that occur at sleep onset or during sleep. Prevalence of 60–70% in the population has been reported (ASDA, 1997; Mahowald & Schenck, 1998).

Sleep starts may be exacerbated by excessive caffeine, the use of stimulants, strenuous exercise prior to sleep, and stress. Although sleep starts are generally considered of little consequence, if they occur frequently and cause repeated awakenings of the sleeper or bed partner, they may lead to sleep onset insomnia.

Parasomnias Usually Associated with REM

This category includes nightmares, sleep paralysis, and REM sleep behavior disorder. These disorders are associated with or occur during REM sleep.

Nightmares. Nightmares are frightening dreams. They are often long and complicated, become increasingly frightening, and wake up the dreamer. Fear or anxiety are always associated with nightmares but sometimes seem out of proportion to the content being reported.

Nightmares occur during REM sleep, whereas sleep terrors and sleep panic attacks occur during NREM sleep. Two important features that differentiate nightmares are the time of the night when they occur and the detail of dream content that is reported. Nightmares, as REM sleep phenomena, are more likely to occur during the latter half of the night, and the dream content can be recalled in detail. Sleep terrors, associated with slow-wave sleep, and sleep panic attacks, associated with transitions between stages 2 and 3, are more likely to occur during the first half of the night. In both sleep terrors and sleep panic attacks, the sleeper awakens very frightened but is able to recall only fragmentary images, if any, and general feelings of fear and anxiety or of being attacked or suffocated.

Nightmares are a common feature of sleep. From 10–50% of children aged three to five have frequent enough nightmares to concern their parents (ASDA, 1997), and 5–8% of adults report having problems with nightmares (Bixler et al., 1979; Klink & Quan, 1987). The frequency of nightmares decreases with age. About 10% of adolescents (Muller & Wood, 1991) and college students (Wood & Bootzin, 1990) have at least one nightmare a week, compared to about 1% of healthy elderly (Salvio, Wood, & Schwartz, 1991).

The occurrence of frequent nightmares in adults has been considered a primary diagnostic criterion for anxiety and stress disorders. However, no relationship was found between frequent nightmares and trait anxiety in a study of college students (Wood & Bootzin, 1990). This suggests that other criteria, in addition to nightmares, are necessary to diagnose anxiety disorders.

Sleep Paralysis. Sleep paralysis, also called familial sleep paralysis or hypnagogic or hypnapompic paralysis, is a phenomenon during which individuals cannot perform voluntary movements at either sleep onset (hypnagogic paralysis) or upon awakening from sleep (hypnapompic paralysis). Although temporary, the paralysis immobilizes the head, trunk, limb and, sometimes, speech-related musculature. Episodes usually last less than 5 minutes and can sometimes be terminated by intense efforts to move (Anch et al., 1988). Sleep paralysis, it is hypothesized, is due to a dysfunction in REM sleep mechanisms in which

the muscle atonia associated with REM sleep occurs during wake-sleep transitions. Sleep paralysis resembles cataplexy seen in narcolepsy. The two states differ in that sleep paralysis occurs during sleep-wake transitions, whereas cataplexy occurs during the day and is often triggered by an intense emotional stimulus. Both cataplexy and sleep paralysis may be symptoms of narcolepsy.

As an isolated symptom, sleep paralysis occurs in 40–50% of normal individuals sometime during their lifetimes (ASDA, 1997). Recurrent episodes of sleep paralysis, in the absence of a primary diagnosis of narcolepsy, are rare. From 17–40% of narcoleptics experience frequent episodes of sleep paralysis. Irregular sleep habits, sleep deprivation, stress, and sleep position have all been reported as predisposing factors for sleep paralysis.

REM Sleep Behavior Disorder (RBD). RBD is characterized by the intermittent loss of muscle atonia during REM sleep. Individuals with RBD may engage in elaborate behavioral sequences during REM sleep. If awakened during an episode, individuals are likely to report dreams that correspond to their behavior. Episodes typically occur once a week but may occur several times per night on consecutive nights. Polysomnographically, REM behavior disordered individuals exhibit normal, more rapid eye movements than usual, and substantial muscle tonus.

Little is known about the overall prevalence of RBD; the largest series of cases consists of sixty-eight patients (Schenck & Mahowald, 1990). The disorder occurs primarily in elderly men, and there is some evidence of a familial pattern (ASDA, 1997).

RBD has been considered a human analog of experimental work in animals that found that REM without atonia could be produced by ablating regions in the pons and medulla (Morrison, 1988). Extensive neurological and neuropsychological evaluation of twenty-one RBD patients revealed that 38% evidenced discernible brain damage and the remaining were classified as “idiopathic” (Mahowald & Schenck, 1994).

Other Parasomnias

Other parasomnias that are not easily classified include sleep enuresis, sleep bruxism, and sudden infant death syndrome.

Sleep Enuresis. Sleep, or nocturnal, enuresis is involuntary urination during the night that occurs primarily in children. Enuretic children are com-

monly described by their parents as very deep sleepers, a report consistent with laboratory findings of increased duration of slow-wave sleep relative to nonenuretic children (Andres & Weinstein, 1972). Enuresis should not be considered an indication of psychopathology in children under age five, particularly boys, because its prevalence among 4-year-old boys is 14–38% (Feldman, 1983).

There are two types of sleep enuresis, primary and secondary. A child with primary enuresis has always had bed-wetting problems and has never had any extended dry periods. Typically, children with primary bed-wetting problems are less than 8 years old. A child with secondary enuresis is one who develops enuresis after having had extended dry periods. The onset of secondary enuresis is often at times of emotional distress. Primary enuresis is more likely to be genetic than secondary enuresis (Kales, Soldatos, & Kales, 1980) and is more likely to be influenced by biological factors such as a smaller bladder (Troup & Hodgson, 1971). Enuresis can occur in any stage of sleep, including nocturnal awakenings, and is most common during the first third of the night (ASDA, 1997).

Treatment for sleep enuresis includes bladder training aimed at increasing bladder capacity and control, use of the “bell and pad” system based on classical conditioning, and a combination of information, support, and reinforcement strategies. The efficacy of bladder training is about 30%, but the bell-and-pad treatment has success rates as high as 70%; with the best results have been in children older than 7 years (McClain, 1979). A common pharmacological treatment involves desmopressin, an antidiuretic hormone, which, it has been shown, reduces the number of wet nights in primary enuresis (Hansen & Jorgensen, 1997). The efficacy of desmopressin treatment may be greater for children who exhibit decreased levels of psychosocial distress (Dittmann & Wolter, 1996). Tricyclic antidepressants have relatively low success rates and high relapse rates upon withdrawal (Kales, Soldatos, & Kales, 1980).

Sleep Bruxism. Bruxism involves grinding or clenching teeth during sleep. Bruxism can occur during all stages of sleep but most commonly occurs during stage 2. As much as 90% of the population reports that they have ground their teeth some time during their lifetimes. In about 5% of them, the problem may be severe enough to require treatment (ASDA, 1997) and can lead to dental damage and temporomandibular joint (TMJ)

disorders. Severe bruxism is often associated with daytime anxiety.

A common treatment is a rubber mouth guard worn over the teeth (Lavigne & Manzini, 2000). In some cases, relaxation training or biofeedback has been effective. In a double-blind clinical trial, the administration of L-dopa, it was shown, significantly decreased the number of bruxism episodes (Lobbezoo et al., 1997).

Sudden Infant Death Syndrome (SIDS).

SIDS is characterized by sudden death during nocturnal sleep in the absence of definable pathology. Epidemiological studies have indicated that the following groups are at increased risk (ASDA, 1997): premature infants, twin or triple births, subsequent siblings of SIDS infants, infants born to substance-abusing mothers, infants who previously experienced apparent life-threatening events (ALTEs) that required mouth-to-mouth resuscitation or vigorous stimulation, infants of low socioeconomic parents, and African-American or Eskimo infants. SIDS, it is estimated, occurs in 1 to 2 per 1000 live births and is most likely to occur between the tenth and twelfth weeks of life. SIDS occurs slightly more frequently in males than females.

Polysomnographic evaluation in one group of infants who subsequently died of SIDS found three variables that differentiated SIDS victims from matched controls (Blum et al., 1988). All of the variables were related to respiratory function. More specifically, the authors found that the maximal duration of central apneas, the number of sighs followed by a central apnea, and the presence of obstructive or mixed apneas "significantly characterized the future SIDS victims." However, only 7% of those infants who had ALTEs show evidence of apnea (Ariagno, 1987). Thus, infant sleep apnea may not be the primary cause of SIDS.

Sleep Disorders Associated with Other Disorders

Sleep Disorders Associated with Mental Disorders

Schizophrenia. The majority of schizophrenics who undergo acute psychotic phases experience some sleep disturbance. It has been proposed that different sleep architectures might be useful diagnosing whether an acute psychotic episode is approaching or dissolving (Kupfer et al., 1970). Schizophrenics in the waxing phase of an acute

psychotic period have low total sleep times and very disrupted sleep. These patients took an average of 152 minutes to fall asleep. Their quantities of slow-wave sleep and REM sleep were also significantly less than those of the controls. In contrast to these findings, schizophrenics in the waning phase displayed a slight return of their sleep parameters toward those of the controls. During remission, the schizophrenics' sleep resembled the controls' sleep values.

A number of studies have found shortened REM latencies in schizophrenics (Hiatt et al., 1985; Zarcone et al., 1987) and decreases in slow-wave sleep (Feinberg et al., 1969; Hiatt et al., 1985). An exception to these findings come from studies of young schizophrenics who had never been medicated. They exhibited normal REM latencies (Ganguli et al., 1987). In contrast to the findings for REM latency, a recent study of medicated and neuroleptic-naïve, first-episode, schizophrenic patients found decreased amounts of slow-wave sleep in both groups (Keshavan et al., 1998), which may indicate that slow-wave sleep is more related to the pathophysiology of schizophrenia than REM sleep.

One puzzling observation about the sleep of schizophrenics concerns their response to experimental REM deprivation. It has been a consistent finding that acutely psychotic schizophrenics fail to exhibit REM rebound after REM deprivation (Gillin et al., 1974; Zarcone et al., 1969). One possible explanation is that hallucinations and other positive symptoms may be an expression of a REM process (Cartwright, 1978). Because acutely psychotic schizophrenics have hallucinations, they may not need as much REM during the night as nonpsychotic individuals. Another REM phenomena, dreaming, seems to be deficient in schizophrenics. Schizophrenics awakened during REM sleep often report sparse dream content. Patients have reported dreams that consisted of single objects alone without contextual cues (Dement, 1955).

The effect of antipsychotic medications on the sleep of schizophrenics remains somewhat unclear. There have been contradictory reports whether there are increases in slow-wave sleep, total sleep, and REM sleep in schizophrenics due to chlorpromazine, flenfluradol, and haloperidol (Zarcone, 1988). In a longitudinal study, schizophrenic patients, free from medication for at least two weeks, were studied at baseline, 4 weeks, and 1 year after beginning treatment (Keshavan, Reynolds, Miewald, & Montrose, 1996). At 4 weeks, sleep conti-

nity significantly improved, and REM latency showed a modest, nonsignificant increase; at the 1-year assessment, REM latency, time, and density significantly increased. It is unclear, however, whether these changes resulted from medication or a change in the illness state, or both. Slow-wave sleep did not change from baseline to the 1 year follow-up. The effects of clozapine were recently assessed in a population of long-term medication-free schizophrenics (Hinze-Selch, Mullington, Orth, Lauer, & Pollmächer, 1997). Clozapine significantly increased sleep continuity, REM density (but not REM time), and NREM sleep, particularly, stage 2 sleep, whereas stage 4 sleep significantly decreased.

Mood Disorders

Depression. Sleep problems are one of the primary symptoms of a major depressive episode (DSM-IV, 1994). It is estimated that approximately 90% of all individuals with depression will have at least a mild degree of abnormality in sleep architecture (Reynolds, 1989). Conversely, about 21% of persons who reported serious insomnia have major depression (Mellinger et al., 1985).

An extensive body of research identifies sleep EEG abnormalities of patients with major depression (see Benca et al., 1992, for a meta-analytic review of these results). These abnormalities can be grouped into three general categories. The first category, sleep continuity disturbances, includes prolonged sleep latency, increased wakefulness after sleep onset, and, most notably, early morning awakenings; all contribute to decreased sleep efficiency (see Benca, 1994). Sleep continuity disturbances lead depressed patients to complain about poor sleep and such complaints often precede the relapse of remitted depression (Perlis et al., 1997). The second category, slow-wave sleep (SWS) deficits, includes a reduction of amount and percent SWS primarily during the first non-REM period (Kupfer et al., 1986; Reynolds et al., 1985). Depressed men show a greater reduction in slow-wave sleep than depressed women (Reynolds et al., 1990). The third category, REM sleep abnormalities, includes reduced latency to the first REM episode, prolonged duration of the first REM episode, and an increased rate of rapid eye movement, also referred to as increased REM density (Vogel, 1981). This category includes the most robust findings regarding the sleep of depressed

patients. Approximately 60% of depressed outpatients (Rush et al., 1982a) have reduced REM latencies, compared with only about 9% of matched controls. Note, however, that shortened REM latency is not specific to major depression. Short REM latencies have been found in patients with narcolepsy, schizophrenia, alcoholism, and post-traumatic stress disorder (Benca, 1994).

The relationship between sleep abnormalities, particularly REM sleep abnormalities and depression, is also evidenced by the fact that REM sleep deprivation in the laboratory, as well as total sleep deprivation, often improves depressive symptoms with a time course that parallels the effects of antidepressants (King, 1977; Mendelson, 1987; Vogel, 1975). Some EEG sleep disturbances such as high REM density and low sleep efficiency are often normalized after successful treatment, whereas others, such as SWS abnormalities, remain unaffected. Normalization of sleep occurs following successful treatment regardless of modality. This includes electroconvulsive therapy (Lahmeyer et al., 1989), pharmacotherapy, and psychotherapy. Antidepressants have a suppressant effect on REM sleep (Vogel et al., 1990) and often lengthen the REM latency significantly (Roth et al., 1982). Successful psychotherapy reduces REM density but does not alter REM latencies. It has been suggested that individuals with short latency to REM sleep and with increased eye movements during REM sleep (REM density) have a better response to pharmacotherapy. In contrast, EEG sleep abnormalities do not predict response to psychotherapy regardless of the type therapy, be it individual (Buysse et al., 1992; Jarret et al., 1990) or group therapy (Corbishley et al., 1990) or interpersonal (Buysse et al., 1992) or cognitive behavioral therapy (Jarret et al., 1990) in a sample of outpatients (Thase et al., 1994) or inpatients (Thase, Simons, & Reynolds, 1993). However, a recent study that used a composite of EEG sleep parameters in a large sample of outpatients with a definite or probable endogenous subtype of depression to predict response to individual CBT (Thase, Simons, & Reynolds, 1993) found that abnormal sleep profiles and higher severity of pretreatment depression were independently associated with poorer outcome, including lower recovery rates and higher risks of recurrence.

The extensive body of research on sleep and depression has led to formulation of several theories on the etiology of depression, including mal-

function of either a REM sleep activation mechanism, a slow-wave activating and REM sleep inhibition system, some component of a circadian timing circuit, or some combination of the three. The fact that some sleep abnormalities persist beyond the active phase of the depression and may be present even before the first episode of depression indicates that sleep abnormalities may reflect a vulnerability for depression (Giles et al., 1990; Hauri et al., 1974).

Mania. In comparison to unipolar depression, there is a dearth of research on mania and sleep. Manic patients have extended periods of wakefulness, short total sleep times, long sleep latencies, and deficits in slow-wave sleep (ASDA, 1997). Manic patients also have the same shortened REM latencies and more dense REM episodes as depressed patients (Hudson et al., 1990).

Seasonal Affective Disorder (SAD). SAD is a disorder involving an annual fluctuation in mood which has been correlatively linked to seasonal fluctuations of melatonin levels and variations in the period of sunlight. SAD patients present with problems in sleep quantity, sleep quality, and circadian phase position or the timing of sleep and wake. SAD has become one of the most rapidly expanding areas in sleep research as well as in affective disorder research. Strengthening the circadian oscillation in these individuals through light therapy alleviates the sleep problems and improves mood (Rosenthal et al., 1984). Light therapy clears up both the nocturnal sleep problems and the daytime sleepiness (Terman, 1994).

Anxiety Disorders

This category includes generalized anxiety disorder, obsessive-compulsive disorder, simple and social phobias, and posttraumatic stress disorder. Sleep disturbances involve sleep onset or sleep maintenance insomnia (ASDA, 1997).

Generalized Anxiety Disorder (GAD). Patients with GAD have increased sleep latencies, diminished REM and slow-wave sleep, a higher number of transitions to light NREM sleep, increased waking during the sleep period, and decreased efficiency of sleep (Fuller, Waters, Binks, & Anderson, 1997; Reynolds, Shaw, Newton, Coble, & Kupfer, 1983). GAD patients are distinguishable from depressed patients by longer REM latencies and from psychophysiological insomniacs by persistently poor sleep efficiency.

Obsessive-Compulsive Disorder (OCD).

OCD patients have lower total sleep times, more awakenings, less NREM stage 4, and significantly shorter REM latencies than controls (Insel et al., 1982). Short REM latencies for OCD patients, similar to those seen in depressives, have been reported by some (Insel et al., 1982) but not by others (Hohagen et al., 1994).

Posttraumatic Stress Disorder (PTSD). The sleep of PTSD patients often includes terrifying nightmares. Estimates of the percentage of Vietnam veterans who suffer from nightmares have ranged from about 59–68% (DeFazio et al., 1975; van der Kolk et al., 1980). In PTSD patients, nightmares reportedly involve the same near-real-life scenes that occur over and over again, as opposed to the changing nightmare content of the chronic, non-PTSD nightmare sufferers (Hartmann, 1987). As mentioned earlier, nightmares occur frequently in normal populations (Wood & Bootzin, 1990). Thus, nightmares alone are insufficient for a diagnosis of PTSD.

Polysomnographic evaluations of the sleep of PTSD patients have revealed inconsistent and inconclusive abnormal sleep parameters. Some PTSD patients exhibit short REM latencies and high REM densities (Greenberg et al., 1972; Kauffman et al., 1987). Others exhibit increased REM latencies and less total REM time (Lavie, et al., 1979).

Panic Disorder

Panic attacks during sleep are sudden awakenings associated with intense fear. Although very similar to sleep terrors, panic attacks do not begin with a piercing scream, and they occur in stage 2 or 3, rather than stage 4 sleep. Sleep panic attacks usually occur in individuals who have daytime panic attacks. Out of a group of forty-five patients who had panic attacks, thirty-one (69%) reportedly had at least one nocturnal panic attack in their lives. Occasional or frequent sleep panic attacks were reported by fifteen (33%) of the group (Mellman & Uhde, 1989b).

Several findings emerge consistently in the literature on sleep panic attacks. Panic attack patients have increased sleep latencies, decreased sleep efficiency, and increased duration and number of body movements (Hauri et al., 1989; Mellman & Uhde, 1989a,b; Uhde et al., 1985). There is no consistent evidence of any abnormality of REM in panic attack patients.

Roy-Byrne et al. (1986) examined the effects of a night of total sleep deprivation on patients with panic disorder, along with depressed patients and normal controls. Unlike the improvement in mood and anxiety ratings evidenced in the depressed patients, the panic attack patients and controls showed no significant effects. However, when analyzing the data from the patients with panic disorder, two subgroups emerged. One group showed no change, whereas the other actually displayed an increase in next-day panic attacks and anxiety ratings. Although panic disorder and depression, it has been hypothesized, are related because both respond to antidepressants, the sleep findings indicate that they are independent disorders. Patients with nocturnal panic respond to cognitive-behavioral treatments for panic disorder (Craske & Rowe, 1997), indicating that the same principles are likely to operate in both types of panic disorder patients.

Alcoholism

Insomnia or excessive sleepiness is a common feature of alcoholism (ASDA, 1997). Alcohol often enhances early slow-wave sleep in alcoholics and decreases early REM. There is increased REM and wakefulness during the second half of the night. The acute effects of withdrawal are somewhat inconsistent. Sleep may be more fragmented soon after drinking stops, and associated increases occur in REM sleep (Johnson, 1972). In two samples of nondepressed alcoholics, shortened REM latency and increased REM percentage upon admission to an alcohol treatment program predicted relapse within a 3-month abstinence period (Gillin et al., 1994). Fragmented and reduced slow-wave sleep has been recorded in recovering alcoholics as long as 2 years after drinking ceased (Adamson & Burdick, 1973). Acute alcohol use may also precipitate or exacerbate snoring and sleep apnea (ASDA, 1997).

Sleep Disorders Associated with Neurological Disorders

A variety of neurological disorders affect sleep. For more detail, see Aldrich (2000b), Bliwise (2000b), and Lugaresi et al. (1988).

Cerebral Degenerative Disorders. Cerebral degenerative disorders encompass a group of het-

erogeneous diseases (e.g., Huntington's disease, torsion dystonia, supranuclear palsy, and multiple system atrophy) that affect one or more systems and are progressive conditions characterized by abnormal behaviors or involuntary movements, often with evidence of motor system dysfunction. Complaints of insomnia and hypersomnia are common. Sleep disturbance manifestations of these disorders include sleep fragmentation, abnormal motor activities, and disorganization of the circadian sleep-wake cycle. Polysomnography may reveal sleep fragmentation, decreased slow-wave sleep or REM sleep, disordered breathing, fragmentary myoclonus, periodic arm or leg movements, dystonic postures, and prolonged tonic contractions of one or more limb (ASDA, 1997; Chokroverty, 1996).

Dementia and Parkinsonism. Dementia refers to a loss of higher cortical functions due to a chronic, progressive degenerative disease process of the brain. Dementing illnesses include a wide variety of nonreversible conditions, including Alzheimer's disease (AD), Pick's disease, and certain forms of hydrocephalus. AD, the most common cause of dementia, accounts for as much as 70% of all cases (Bliwise, 2000b). Sleep disturbances in demented patients are very common. Their severity parallels the progression of the underlying illness, and their pathophysiology is probably related to the dementia process itself. In addition, demented patients are often treated with psychotropic medicines, and these drugs may worsen sleep disturbances and daytime symptoms. Nighttime behavior of demented patients is characterized by delirium, agitation, and sundown syndrome (ASDA, 1997). *Sundowning* is to the phenomenon of agitation strongly associated with darkness and is characterized by nocturnal wandering and confusion. Polysomnographic studies of AD patients have documented altered sleep architecture, including decreased sleep efficiency, slow-wave, and REM sleep, increased Stage 1 sleep, and an increase in the number of and duration of nocturnal awakenings (Prinz, 1995). Some patients also exhibit a fragmented 24-hour sleep-wake pattern in the form of partial or complete reversal of the sleep-wake schedule, with increased wakefulness at night and somnolence during the daytime (Chokroverty, 1996).

Parkinsonism is a group of neurological disorders characterized by resting tremor, akinesia

(reduced spontaneous movement), postural rigidity, and bradykinesia (slowness of movement). Sleep disturbance is reported by 60–90% of patients with Parkinson's disease (PD), and it tends to gradually worsen with disease progression. Insomnia is the most common complaint in these patients. The inability to get out of or turn over in bed, nocturia, painful leg cramps, back pain, limb jerks, central or obstructive sleep apnea, and medication sleep effects can all cause insomnia, sometimes with concomitant daytime sleepiness (Aldrich, 1994, ASDA, 1997; Partinen, 1997).

Characteristic polysomnographic abnormalities in PD patients include increased sleep latency, Stage 1 sleep, and the number and duration of nocturnal awakenings, as well as reduced amounts of REM and slow-wave sleep. Sleep disordered breathing (various forms of sleep apnea), REM sleep behavior disorder (RBD), and periodic limb movement disorder (PLMS) are prevalent in PD patients and can further disrupt their sleep or produce daytime sleepiness. Levodopa treatment of Parkinsonism can improve sleep disturbance due to such symptoms of the disease as rigidity or bradykinesia, but it may at the same time cause new symptoms (e.g., insomnia, vivid dreaming, nocturnal vocalizations, myoclonic movements, dyskinesias). Depression, which is a common comorbid illness in PD patients, can also contribute to sleep disturbance (Chokroverty, 1996).

Sleep-Related Epilepsy. Sleep-related epilepsy is associated with either abrupt awakenings, unexplained urinary incontinence, or abnormal muscle activity during sleep. To be considered sleep-related epilepsy, 75% or more of the seizures must occur during sleep and at least two other features must be present: automatisms, specific limb movements, or tongue biting (ASDA, 1997). Individuals suspected of this disorder usually undergo daytime EEG monitoring, nocturnal polysomnography with video monitoring, and possibly CT or MRI scanning.

Sleep-Related Headaches. Cluster or migraine headaches that occur during sleep are related to REM sleep. Breathing disturbances during sleep or alcohol ingestion may bring on cluster headaches. High levels of daytime stress, weather change, or other events may precipitate migraine headaches during sleep. Individuals typically awaken from sleep, usually late in the sleeping

period and out of a REM period, aware of the presence of the headache.

Sleep Disorders Associated with Medical Disorders

A broad range of physical illnesses affects sleep. Our discussion is selective and focuses on respiratory disorders, nocturnal cardiac ischemia, chronic pain, fibromyalgia, and AIDS.

Respiratory Disorders. Respiratory disorders that affect sleep include disorders of respiratory control, disorders of the respiratory musculature, and disease of the airways and lung parenchyma. Respiratory disorders often worsen during sleep and cause sleep disturbances. The severity of sleep disturbances correlates with the progression of the underlying pulmonary disease. Chronic obstructive pulmonary disease (COPD) and asthma are the respiratory disorders that frequently lead to sleep complaints.

COPD is characterized by a chronic reduction in airflow, with symptoms of dyspnea and cough are most common. Hypoxemia, hypoventilation, and impaired lung function are the physiological consequences. A high percentage of patients with COPD experience difficulty in initiating and maintaining sleep (Douglas, 2000). Shortness of breath in the recumbent position and frequent episodes of coughing keep COPD patients from falling asleep. Severe sleep fragmentation, again due to respiratory symptoms, often leads to a unrefreshed feeling upon awakening and to excessive daytime sleepiness. Polysomnographic features include decreased total sleep time, the amount of slow-wave and REM sleep, frequent sleep-stage changes, and increased number of arousals and awakenings. COPD patients become more hypoxemic during sleep, especially in REM sleep, than during resting wakefulness, because of hypoventilation, worsening ventilation perfusion mismatch, the loss of accessory muscles, and the medicines used to treat COPD; the xanthine derivatives particularly such as theophylline can also contribute to sleep disturbance (ASDA, 1997; Douglas, 1998).

Patients with asthma have a reversible reduction in airflow. The reduction can be abrupt and dramatic, triggering acute attacks of wheezing, shortness of breath, coughing, and chest tightness. In general, asthmatic individuals have hyperreactive airways. Exposure to allergens or irritating

stimuli produces airway obstruction, secondary to spasm of the bronchial muscles, as well as increased secretion and, if exposures are recurrent, bronchial mucus hyperplasia.

Bronchodilators, such as beta agonists (albuterol, solmeterol) or theophylline compounds ameliorate asthma symptoms but may cause increased wake time during sleep. Many asthmatics patients have symptoms at night; in studies of these patients, 61–74% report nighttime awakenings due to asthmatic attacks. Unrestorative sleep and daytime fatigue are also common complaints of asthmatics. Polysomnographic studies reveal that nocturnal asthma attacks rarely occur in slow-wave sleep and tend to cluster in the later part of the sleep period, perhaps as the bronchodilating effects of medicine taken before bed declines. Hypoxemia with attacks is rarely severe (ASDA, 1997; D'Ambrosio & Mohsenin, 1998). Compared to the sleep of controls, asthmatics patients have less total sleep time, lower sleep efficiency, and more awakenings (Montplaisir et al., 1982).

Nocturnal Cardiac Ischemia. The relationship between sleep and cardiac ischemia is controversial because the factors that precipitate nocturnal cardiac ischemia are not clear. It may occur as the result of increased myocardial oxygen demand, decreased cardiac perfusion, or increased filling of the left ventricle from lying in a recumbent position (Motta & Guilleminault, 1985).

Symptoms of nocturnal cardiac ischemia include the feeling of pressure during sleep that is often described as a "clenched fist." Pain often radiates to the left arm and upward into the neck or jaw (ASDA, 1997). These symptoms may be present during waking hours but result from activity.

The prevalence of nocturnal cardiac ischemia is unknown. However, patients with obstructive sleep apnea may experience severe oxygen desaturation and have a higher incidence of cardiac ischemia than the general population (Burack, 1984). Ischemia can also cause severe sleep fragmentation in the absence of sleep apnea (Schaffer, Koehler, Ploch, & Peter, 1997). Electrocardiographic changes that occur in the early morning hours are typically associated with REM sleep, and changes that occur at the beginning of sleep are typically associated with a fall in blood pressure and heart rate.

The presence of ischemia on an electrocardiogram is indicative of coronary artery disease. Other possible precipitating factors of nocturnal ischemia include hypertension, elevated blood

cholesterol and low-density lipoprotein, cigarette smoking, obesity, and sleep-induced hypoxemia (ASDA, 1997).

Chronic Pain. Chronic pain is a common cause of sleep complaints, especially in the elderly. Rheumatological disorders such as osteoarthritis, a degenerative joint disease, tend to be frequent causes of insomnia. During the day, the joints are kept mobile which helps to maintain flexibility and reduce pain. These joints become stiff at night and sleep may be disturbed by sudden pain when the individual moves or attempts to turn over in bed (Morgan, 1987). Adequate dosage of antiarthritic medication before bedtime can greatly alleviate the problem.

Other chronic pain conditions that may precipitate complaints of insomnia include burning foot pain from diabetes and chest and epigastric pain due to angina, reflux, esophagitis, or peptic ulcer disease. Cancer patients often exhibit more severely disturbed sleep patterns than either normals or other patients with medical conditions. Complaints of insomnia are often reported with feelings of anxiety or depression rather than pain which has led to the suggestion that antianxiety drugs may help improve sleep (Anch et al., 1988).

Fibromyalgia. Fibromyalgia (FMS) is a central nervous system disorder of unknown etiology. Its main symptom is widespread musculoskeletal pain with tenderness in at least eleven of eighteen specific anatomic sites. In addition, symptoms of fibromyalgia include fatigue and dyssomnia, unrefreshing sleep, and a higher than average prevalence of alpha sleep (Moldofsky et al., 1975; Ware, Russell, & Campos, 1986) in which an alpha EEG frequency wave occurs simultaneously with slower EEG waves. Compared with controls, fibromyalgia patients have less delta (0.5–3.5 Hz) and theta (3.5–8 Hz) and more alpha (8–12 Hz) and sigma (12–14.5 Hz) in all stages of sleep, but especially so during NREM sleep (Drewes et al., 1995).

It has been proposed that alpha sleep may cause the musculoskeletal symptoms of fibromyalgia (Moldofsky & Scarisbrick, 1976) and that it may be involved more generally in disorders that affect the immune system. Not surprisingly, there is a strong association between the severity of fibromyalgia, based on clinical examination, as well as on average daily self-rating of pain, and disturbed sleep, as indicated by lower sleep efficiencies and greater morning difficulties (Manber et al., 1998).

Acquired Immune Deficiency Disorder (AIDS). Approximately one-third of asymptomatic HIV-seropositive individuals report sleep onset or maintenance difficulties (Rothenberg et al., 1990). These differences are not attributable to those taking zidovudine (AZT) (Moeller, Wiegand, Oechsner, Krieg, Holsboer, & Emminger, 1992). Polysomnographic studies of asymptomatic individuals have often, but not always, found increased sleep fragmentation, increased amounts of slow-wave sleep, slow-wave sleep distributed throughout the night, and an alpha sleep pattern (Norman et al., 1992; Wiegand et al., 1991). Abnormal sleep architecture was evident at a 1-year follow-up (Norman, Chediak, Kiel, Gazezroglu, & Mendez, 1990).

Conclusion

As indicated throughout this chapter, understanding sleep and sleepiness is crucial to understanding all behavior, including psychopathology. Sleep is a sensitive barometer of the quality of our lives. It is affected by, and in turn affects, developmental, physiological, psychological, and socio-cultural processes. To understand sleep disorders, research must continue to be pursued as a multidisciplinary enterprise. This chapter indicates that there have been substantial advances in our understanding of the etiology and treatment of sleep disorders. This has included advances in the neurophysiology and pharmacology of sleep, our understanding of the sleep-wake circadian rhythm, and behavioral treatments for sleep disorders. But this is a field in its infancy, and we eagerly anticipate the advances still to come.

Sexual Dysfunctions

Victor J. Malatesta and Henry E. Adams

Introduction

Human sexuality is diverse and encompasses a complex and multifaceted set of biological, psychological, and sociocultural variables. An individual's sexuality includes everything ranging from one's sex organs, hormones, and basic sex drive, to sexual response, gender identity, and body image. This array of biopsychosocial factors interacts within a framework composed of individual cognition (thoughts and fantasies), behavior, and emotions that occur in response to sexual stimulation. In addition, unlike many forms of human behavior, one's sexuality and sexual activity are expressed in a relational and intimate interpersonal context. The interactive nature of human sexual behavior introduces an additional set of variables, including partner satisfaction, reproduction and (in)fertility, communication, and the ability to negotiate intimate relationships. Individual sexuality is also enmeshed with developmental and learning history, in addition to personality, mood state, and the culture in which one lives. Thus, human sexual behavior is subject to the influences of family of origin, moral and religious teachings, anxiety and power, and societal rules that govern the expression of sexuality.

Not surprisingly, the complexity of human sex-

uality poses unique challenges for the study and understanding of sexual health and normal sexual behavior. In addition, the field is challenged by an ambivalent society that is, on the one hand, preoccupied and titillated with issues of sexual expression, and—at the same time—inhibited and avoidant regarding discussion of sexuality. Tragedies associated with autoimmune disorder (AIDS) and our increased knowledge about the profound effects of sexual victimization have complicated these matters. A similar ambivalence is displayed by the academic and scientific community. On the one hand, the field is blessed with many outstanding clinical researchers and scholar-practitioners. Their work has defined this important field. At the same time, there is an unusual dearth of courses and practicums in human sexuality and sexual disorders offered by clinical psychology and psychiatry residency programs. This paucity comes at a time when issues of sexual health and sexual dysfunction have gained new importance as we enter the new millennium.

This chapter begins with a historical perspective and traces the study and treatment of sexual dysfunctions to the present. Highlighting important developments and recent trends, the chapter provides an overview of the description, diagnosis, etiology, assessment, and treatment of sexual dysfunctions. The emphasis of the chapter assumes a heterosexual orientation. However, we believe that more research on sexual minorities is needed—even while it is argued that because overlap is considerable between heterosexual and homosexual behavior and dysfunctions, general research is applicable (Sadock, 1995). For additional study, the reader is referred to Behrendt and

George (1995) and MacDonald (1998). Finally, as clinicians, we affirm the importance of a keen understanding of normal sexuality as a prerequisite for studying, evaluating, and treating sexual dysfunctions.

A Historical Perspective

Emphasizing the case study approach, Havlock Ellis (1933/1966), Richard von Krafft-Ebing (1899), and Sigmund Freud (1943) focused their pioneering work on human sexuality and on abnormal sexual behavior in particular. From the beginning of the twentieth century until the late 1960s, sexual disorders—like other forms of psychopathology—were typically understood within the context of psychoanalytic theory. From this perspective, sexual problems were viewed as “symptoms” of underlying psychopathology, originating from unresolved parent–child conflicts, basic attachment difficulties, or trauma. Consequently, sexual disorders were viewed as part of a neurotic or personality disorder. Later formulations emphasized more the interpersonal dynamics of sexual disorders. At the same time, powerful scientific and social changes were occurring.

Beginning in the 1920s and culminating in the work of Kinsey in the 1940s and 1950s, a tradition of social bookkeeping began focusing on the sexual behavior of relatively normal persons. Methodologically such studies moved away from the case study and from populations who were defined as criminal or neurotic. At the same time, general social changes were occurring that were directly affecting the rates and directions of sexual conduct in the society. The work of Alfred Kinsey charted these changes and in turn influenced public attitudes, public policy, and research interests during the 1950s and 1960s. (Gagnon, 1975, p. 111)

Kinsey’s research challenged Freudian control-repression and drive models of sexuality and legitimized sex as an area of scientific pursuit. Clinicians were already applying learning principles to the treatment of sexual problems (Lazarus, 1963; Wolpe, 1958). However, it was Masters and Johnson (1966) who revolutionized the field with the landmark volume, *Human Sexual Response*.

Masters and Johnson’s initial goal was to develop a physiological understanding of human sexual response from their extensive laboratory observational studies. Based on careful testing of 382 women and 312 men in more than 10,000 episodes of sexual activity, Masters and Johnson gathered an unprecedented array of information

about the physical processes and manifestations of sexual arousal and orgasm during various types of sexual stimulation. Their discoveries included (1) the essential similarity of male and female sexual response, (2) the nature of vaginal lubrication, (3) the notion of ejaculatory inevitability and the male refractory period, (4) the finding that women were potentially multiorgasmic, and (5) the finding of continued sexual capacity in older adults. Masters and Johnson also devised an empirical model of normal sexual behavior to describe these physiological changes.

Having developed a model of normal sexual “function,” Masters and Johnson (1970) logically extended their work to develop a treatment approach for male and female sexual “dysfunction” in their second landmark volume, *Human Sexual Inadequacy*. In contrast to intrapsychic factors, their approach emphasized learning deficits and performance anxiety in the etiology and maintenance of sexual dysfunctions. Intervention comprised a relatively brief, problem-focused and directive approach that was largely behavioral in technique. Treatment objectives consisted of (re)educating clients regarding sexuality, skill building, and alleviating performance anxiety.

Great enthusiasm was associated with Masters and Johnson’s sex therapy because of its optimistic and sexually affirmative approach. Remarkably high rates of success were being reported. Overall, their failure rate was only 20% for all sexual dysfunctions combined. Certain dysfunctions, such as premature ejaculation, were successfully treated 100% of the time. The success and enthusiasm were also fueled by important demographic and sociocultural factors, that is, the majority of men and women who sought help tended to be under 40 years of age, well educated, and members of the “60s generation.” Recall that the 1960s had ushered in an era of increased sexual freedom, experimentation, and relaxed sexual inhibitions. Women were exercising their recently found sexual rights and the freedoms afforded by the contraceptive revolution, the women’s movement, and Masters and Johnson’s work. Their scientific findings had showed that, in contrast to men, women were not restricted by a refractory period and were physiologically capable of multiple orgasms. Thus, although male sexual prowess was challenged for the first time, a brief, nonperjorative, and effective sex therapy was available.

In the wake of Masters and Johnson, Helen

Kaplan (1974) introduced her version of the “new” sex therapy that was geared more toward practitioners. Representing a blending of psychoanalytic and more contemporary behavioral approaches, her model also emphasized an initial focus on sexual symptoms. More psychological in nature, Kaplan’s model provided a therapeutic alternative if a problem-focused treatment met with “resistance” or failure. A modified psychodynamic approach then emphasized underlying intrapsychic or interpersonal factors that purportedly maintained sexual dysfunction. Thus, Kaplan’s sequential approach indicated an initial symptom-focused treatment, followed by a more dynamic intervention if the first approach failed.

Kaplan’s clinical approach aroused the enthusiasm of psychiatry and clinical psychology. Her treatment was an outpatient approach that could be applied easily in the office. In conjunction with Masters and Johnson’s scientific foundation, many clinicians began practicing sex therapy with relatively good outcome. More successfully treated problems, such as anorgasmia in women and premature ejaculation, were the prominent sexual dysfunctions presented to clinicians in the “early days” of modern sex therapy (Rosen & Leiblum, 1995a). Moreover, many of the clients of the 1970s benefitted greatly from simple education, permission-giving, and directed relaxation of negative sexual attitudes and behaviors. As a result, treatment outcome was favorable, and optimism about the efficacy of sex therapy dominated the field. Finally, the mass media communicated this optimism by providing education and self-help about a range of sexual topics.

As a result of these developments, less complex cases that early therapists saw became scarce (Schover & Leiblum, 1994). Clinical researchers were also having difficulty replicating the impressive treatment outcomes of the Masters and Johnson approach. Reviews of the clinical literature demonstrated that the majority of research in the area of sexual dysfunction consisted of clinical reports, psychometric descriptions, and poorly controlled outcome studies (e.g., Kilmann, 1978). There was also a preoccupation with treatment techniques at the expense of more basic issues such as etiology, classification, and case formulation (Malatesta & Adams, 1986, 1993). The optimism and enthusiasm that accompanied Masters and Johnson’s work abated, and even they became a focus for criticism (Zilbergeld & Evans, 1980). On

the positive side, sex research became more sophisticated and addressed a more complex interplay of physiological, behavioral, and cognitive variables (Beck & Barlow, 1984).

These changes were accompanied by the modern discovery of the concept of “sexual desire” and its more treatment-resistant manifestations (Kaplan, 1979). A disorder described as “inhibited sexual desire” was officially recognized in 1980 by the American Psychiatric Association. Although it addressed an important clinical problem, the study and treatment of sexual desire opened a Pandora’s box. Because of the biopsychosocial complexity of sexual desire, therapists struggled with issues of treatment intervention, theoretical controversy was stimulated, and a range of clinical and empirical challenges was unleashed (e.g., Schover & LoPiccolo, 1982). Sex therapy was becoming broader, less symptom-focused, and addressed necessarily a wider range of individual, relational, and developmental factors.

The 1980s also ushered in increased awareness of the important role of biological factors in sexual dysfunction (e.g., Spark, White, & Connolly, 1980). This phenomenon occurred within the context of new developments in urology, behavioral endocrinology, and penile implant surgery (Tiefer, Pedersen, & Melman, 1988). Medicine had found a new area of specialty in the era of managed care that was embraced with a “gold-rush-like enthusiasm” (Stief & Jonas, 1998). Sexual psychophysiology displayed comparable development and became a subspecialty within urology as it pertained to the differential diagnosis of erectile problems (Rosen & Beck, 1988). In addition, a greater emphasis on the sexual aspects of disease and disability occurred (Schover & Jensen, 1988). Similar emphasis was focused on the sexuality of older adults—whether partnered, single, or living within a nursing home (Malatesta, 1989). Consequently, “medicalization” of the field occurred, and some began to lament the stagnation of psychological conceptualizations of sexual dysfunctions (Schover & Leiblum, 1994). In a critical appraisal of the state of theory in sex therapy, Wiederman (1998) quoted an eminent sexual scientist on his assessment of the field:

Sex research today lives in a conceptual ghetto, theoretically poverty stricken, and lacking in consensus. It is still mired in the organic versus psychogenic dilemma, its own version of the long-obsolete nature/nurture dichotomy. For the most part, it still follows the experimental design of classical physics and

celestial mechanics, and searches for univariate cause and effect, whereas the phenomena of sex research are, virtually without exception, multivariately determined. (John Money, 1988, p. 14)

As we entered the 1990s, Money's stinging appraisal of the field gave way to the development of multivariate conceptualizations of sexual dysfunction for men and women alike (e.g., Cranston-Cuebas & Barlow, 1990; Palace, 1995).

In the 1990s the reality was also accepted that the client base for sexual dysfunctions and sex therapy had changed dramatically. Increasing focus was directed at individuals who were often older and who presented with more pervasive, chronic, and biologically influenced sexual problems (Fisher, Swingen, & O'Donohue, 1997). The medicalization of sex therapy attracted a diverse audience that was interested in pharmacological and surgical treatments for erectile disorders. Clinical psychology developed a complementary role in the multicomponent assessment of these problems (Ackerman & Carey, 1995). Some of these individuals also sought psychological help to improve their relationships. Although treatment of sexual addiction and sexual compulsivity was popularized in the 1990s, less attention was focused on issues of classification and diagnosis (Malatesta & Robinson, 1995). More importantly, confronted by the AIDS tragedy and the reality of sexual abuse, an emerging traditionalism in long-term relationships occurred. Reluctant to seek sexual gratification outside of marriage, a growing number of individuals in distressed marriages sought couples therapy to negotiate the complexities of intimate relationships (Gottman, 1999).

The 1990s also witnessed several appraisals of the field with respect to the treatment of sexual dysfunction (Hawton, 1995; Rosen & Leiblum, 1995a), women's sexuality (Andersen & Cyranski, 1995), and hypoactive sexual desire disorder (Beck, 1995). It was also concluded that only a few empirically supported treatments existed for sexual dysfunctions (Baucom, Shoham, Mueser, Daluto, & Stickle, 1998). Perhaps in a search for new impetus and bold ideas in the conceptualization of sexual dysfunction, the field revisited the psychological case study approach (Rosen & Leiblum, 1995b).

As we enter the new millennium, issues of sexual health and sexual functioning have taken on a new urgency because of at least five major developments. First, the aging "baby boom genera-

tion"—for whom sexual expression was part and parcel of the 60s and 70s—remains committed to maintaining active sexuality. Second, wide access to the Internet has caused unprecedented availability of information about sexuality (see Cooper, 1998). Again, people are better informed about a wide range of sexual matters. Third, the heightened power of women, minorities, and the disabled has called attention to the need for more sexuality research with respect to these populations. Fourth, the introduction and widespread use of sildenafil (Viagra) and similar medications has produced what may be the next "sexual revolution." In addition to providing a relatively inexpensive and effective treatment for erectile disorder, Viagra and its mass marketing have reduced the stigma associated with having a sexual dysfunction, have encouraged many men and women to seek help who might not otherwise, and have spurred needed emphasis on women's sexuality (e.g., Kaplan et al., 1999). Finally, not since the publication of the Kinsey Reports of a half-century ago have we had access to large-scale scientific information about the widespread sexual problems of men and women. This research has shown that four out of ten women and nearly one-third of men suffer from some type of sexual dysfunction (Laumann, Paik, & Rosen, 1999). In addition to raising consciousness, this work has indicated that sexual dysfunctions are a major public health problem that deserve increased study, understanding, and treatment.

Models of Sexual Response

Human sexual behavior has been viewed as the most sensitive of the biological response systems because it is functionally responsive to an array of physiological, cognitive-behavioral, and psychosocial variables (Adams, 1981). Several clinical researchers have attempted to describe this biopsychosocial complexity by developing models of sexual behavior. This section will describe the major models of sexual behavior to provide a foundation for examining the various types of sexual dysfunction. Although an understanding of the anatomical and neurophysiological underpinnings of sexual behavior represents an important prerequisite to working with the sexual disorders, this section will highlight only these components. More detailed information on these biological

aspects of sexual response is provided in Rowland (1995), Sadock (1995), and Schover and Jensen (1988).

Masters and Johnson's Sexual Response Cycle

As noted earlier, Masters and Johnson (1966, 1970) developed the first empirical model of human sexual response which paved the way for our understanding of human sexual function and dysfunction. Even today, their model of the sexual response cycle continues to provide the basis for much of our thinking about sexual function. The

model will be described in some detail. As shown in Figures 1 and 2, the four successive phases of the sexual response cycle are (a) excitement, (b) plateau, (c) orgasm, and (d) resolution. According to Masters and Johnson, the excitement phase commences in response to any form of cognitive, sensory-motor, or emotional stimulation that produces erotic feelings and sensations. In both men and women, an important physiological response to this erotic stimulation is an increase in muscle tension throughout the body (myotonia) and engorgement of the blood vessels (vasocongestion), particularly in the genital region. In men, this engorgement leads to tumescence of the penis;

Table 1. Human Sexual Response Cycle: Genital Reactions

Male	Female
<i>Excitement phase</i>	
Penile erection (3 to 8 seconds) as phase is prolonged	Vaginal lubrication (5 to 15 seconds) as phase is prolonged
Thickening, flattening, and elevation of the scrotum	Thickening of vaginal walls, flattening and elevation of labia majora as phase is prolonged
Moderate testicular elevation and size increase	Expansion of inner $\frac{2}{3}$ vaginal barrel and elevation of cervix and body of the uterus
<i>Plateau phase</i>	
Increase in penile coronal circumference and testicular tumescence ($\frac{1}{2}$ to 1 \times enlarged)	Orgasmic platform in outer $\frac{1}{3}$ of vagina
Full testicular elevation and rotation (30–35°)	Full inner $\frac{2}{3}$ vaginal expansion, uterine, and cervical elevation
Purple cast to corona of penis (inconsistent, even if orgasm is to ensue)	“Sex-skin” discoloration of labia minora (constant, if orgasm is to ensue)
Mucoid-like emission from Cowper’s gland	Mucoid-like emission from Bartholin’s gland
<i>Organism phase</i>	
Ejaculation	Pelvic response
1. Contraction of accessory organs of reproduction <ol style="list-style-type: none"> a. Vas deferens b. Seminal vesicles c. Ejaculatory duct Prostate	1. Contractions of uterus from fundus toward lower uterine segment
2. Relaxation of external bladder sphincter	2. Minimal relaxation of external cervical os
3. Contractions of penile urethra at 0.8 s intervals for 2 to 3 contractions (slowing thereafter for 2 to 4 more contractions)	3. Contraction of vagina orgasmic platform at 0.8 s intervals for 4 to 8 contractions (slowing thereafter for 2 to 4 more contractions)
4. External rectal sphincter contractions (2 to 4 contractions at 0.8 s intervals)	4. External rectal sphincter contractions (2 to 4 contractions at 0.8 s intervals) External urethral sphincter contractions (2 to 3 contractions at irregular intervals)
<i>Resolution phase</i>	
1. Refractory period with rapid loss of pelvic vasocongestion	1. Ready return to orgasm with retarded loss of pelvic vasocongestion
2. Loss of penile erection in primary (rapid) and secondary (slow) stages	2. Loss of “sex-skin” color and orgasmic platform in primary (rapid) stage Remainder of pelvic vasocongestion as secondary (slow) stage

in women, it leads to vasocongestion in the pelvis and clitoris, along with vaginal lubrication and swelling of the external genitalia (see Table 1).

As sexual stimulation continues, a number of other physiological changes occur that, in general, become more pronounced during the plateau stage

(e.g., increased heart rate, respiration, and blood pressure; testicular elevation; breast enlargement). These physiological changes associated with the excitement phase are subject to disruption by extraneous stimuli, cessation of erotic stimulation, or negative mood or cognitive states. In the normal

situation, however, sexual excitement may be regained by resuming stimulation and maintaining a conducive sexual environment.

The plateau phase is characterized by (a) an intensification of physiological and muscular changes if erotic stimuli are maintained and (b) a leveling off or plateau in these changes, indicating the high degree of sexual arousal necessary to trigger orgasm. The duration of this phase varies widely and may be particularly brief for early ejaculators or overly extended for women who experience difficulty in reaching orgasm.

The orgasmic phase represents a pervasive physiological response of the entire body in which vasocongestion and myotonia reach their maximum and are discharged through orgasm. Orgasm commences in both men and women with involuntary contractions of the internal genital organs, followed by ejaculation in the male and a wide variability of response in the female. For example, some women display the capacity for extended or multiple orgasms and can experience a number of orgasms without falling below the plateau phase. Masters and Johnson indicated that men do not share the capacity for multiple orgasms, because immediately following orgasm, the male enters a resolution or refractory period during which further orgasm is impossible. This refractory period varies considerably for men (e.g., as a function of age) and is reflected in a gradual return to preexcitement-phase levels. For the woman, this return occurs more slowly and may be altered by reinstating effective sexual stimulation. Controversy surrounds the existence of a female ejaculate and the Grafenberg spot—the vaginal site whose stimulation is associated with heightened pleasure (see Davidson, Darling, & Conway-Welch, 1989). Similarly, the strength of the circumvaginal musculature and its relationship to female orgasm reflect equivocal research findings (Trudel & Saint-Laurent, 1983).

Because their goal was to develop an objective and measurable framework, Masters and Johnson focused their model exclusively on the role of peripheral physiology in describing sexual response (e.g., genital vasocongestive processes and other autonomic changes). Thus, their work was guided by the fact that penile and vaginal vasocongestion are the only physiological responses that are specific to sexual arousal and are generally insensitive to other emotional states (Zuckerman, 1971). Consequently, however, their model has

been criticized for ignoring important cognitive and affective processes, as well as the interaction of physiological, cognitive, and affective components. On a related level, Masters and Johnson's model of sexual response has been criticized because a sexual desire phase was not included within their framework. Also implicit in their model was the male tradition of focusing on orgasm as the culmination of sexual arousal. Although they recognized the need for an objective measure of sexual outlet (i.e., orgasm), this focus has tended to overshadow other aspects of sexual response (see Tiefer, 1991).

Models Incorporating a Sexual Desire Phase

Noting the absence of a cognitive-affective-motivational dimension in the Masters and Johnson model, Lief (1977) and Kaplan (1977) independently described the need for a sexual desire-phase component to conceptualize the sexual response cycle best. Sexual desire is a multiply determined, subjective feeling state characterized by the inclination and motivation to be sexual. Lief and Kaplan indicated that in clinical practice, individuals presenting with desire-phase difficulties represented a substantial portion of patients who sought sex therapy. Whereas Lief (1977) argued for a five-state model, Kaplan conceptualized a triphasic model that consisted of three components: desire, excitement, and orgasm. Though postulating that the sexual desire phase was mediated by limbic system activation, her concept of sexual desire was more akin to the traditional idea of libido and was derived largely from a psychodynamic perspective. Consequently, neither Kaplan nor Lief offered an operationalized definition of sexual desire, and, other than anecdotal clinical data, they did not provide empirical support for their models. Nevertheless, the Kaplan (1977) triphasic model has had a great impact on the classification of sexual dysfunctions, and a growing body of research supports its importance (Beck, 1995).

Interactive Models

The basic assumption of interactive models is that the interrelationships among various dimensions of sexual arousal are critical in defining a sexual experience. These dimensions of sexual arousal include physiological, cognitive, and af-

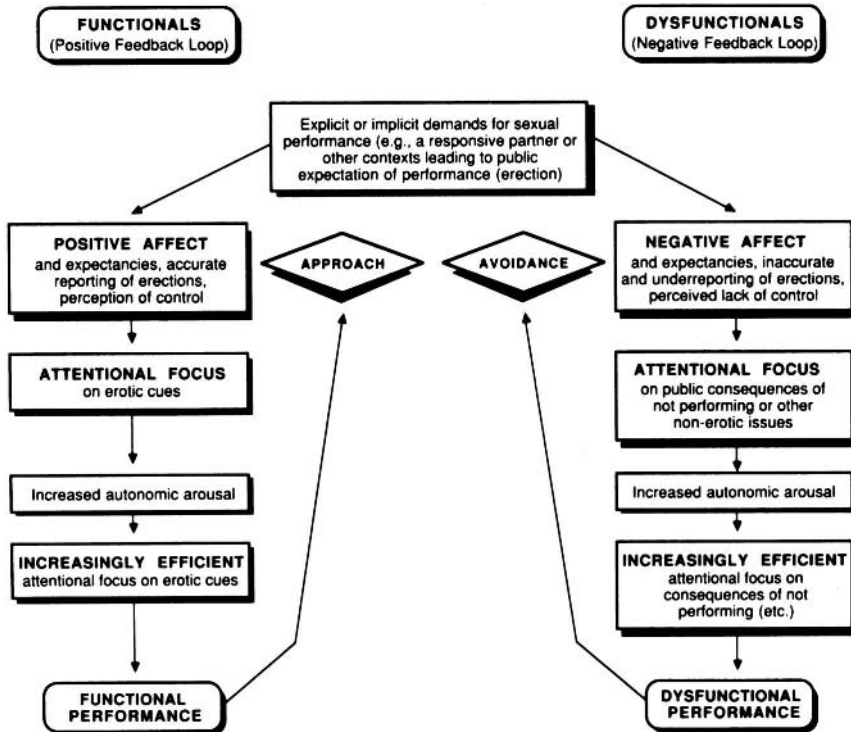

Figure 3. Barlow's "Working Model" of inhibited sexual excitement. From D. H. Barlow (1986), "Cases of Sexual Dysfunction: The Role of Anxiety and Cognitive Interference," *Journal of Consulting and Clinical Psychology*, 54, 140–148. Copyright 1986 by the American Psychological Association Reprinted by permission.

fective components. From this perspective, "sexual arousal cannot be defined adequately without highlighting the critical role of cognitive labeling and subjective experience in determining the response to a given stimulus as sexual" (Rosen & Beck, 1988, p. 28). Thus, although they maintain an emphasis on the traditional peripheral physiology of sexual response, these models (which borrow from the cognitive arousal theory of emotion) can address a range of interactive phenomena in sexual function and dysfunction. For instance, the significant rates of discordance between physiological and subjective dimensions of sexual response reported in the experimental literature highlight the need for multidimensional models of sexual behavior (Palace, 1995; Rosen & Beck, 1988).

A number of theorists have developed interactional models of sexual response (see Cranston-Cuebas & Barlow, 1990). A feature common to each of these models is the emphasis on cognitive-affective processes in mediating sexual arousal.

Special emphasis is also placed on the perception of physiological activation (or deactivation) and the processing of erotic and nonerotic cues. Barlow's (1986) model of sexual dysfunction has been developed and refined in experimental literature. As shown in Figure 3, Barlow postulated a sequence of interactive processes that leads to either functional or dysfunction sexual response. In the case of sexual dysfunction, the sexual situation is perceived by the individual as threatening and uncontrollable, and there are expectations of anxiety and performance difficulty. The individual responds emotionally to these perceptions with a negative affective evaluation. According to Barlow, at this point a critical shift in attention occurs from a focus on erotic cues (e.g., the partner) to a more internal, self-evaluative focus. The affective response also triggers autonomic arousal, which, according to experimental findings, further sharpens attentional focus. Patients at this point may become negatively distracted and have an intense and narrow focus on negative affective stimuli.

Impaired performance occurs, which eventually leads to sexual avoidance. Growing support for this model has been derived from a number of experimental studies that involved women and men, functional and dysfunction samples, and novel feedback manipulations (see Back, Brown, & Barlow, 1999; Palace, 1995). These studies suggest that low self-efficacy expectations—more than negative affect, anxiety, or low subjective arousal—may result in decreased physiological arousal.

Although Barlow's model represents an important step in developing multidimensional, interactive models of sexual response, its clinical application has not been realized. However, an exciting development regarding this model is recent work that addresses the sexual responses of functional and sexually dysfunctional women and their differential responses to distraction and performance feedback (see Elliott & O'Donohue, 1997).

DSM-IV Sexual Response Cycle

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; American Psychiatric Association [APA], 1994) continues to borrow heavily from the work of Masters and Johnson (1966, 1970) and Kaplan (1974, 1979). DSM-IV utilizes a four-stage model consisting of the following phases:

1. **Desire:** This phase consists of fantasies and thoughts about sexual activity and an interest or inclination to be sexual.
2. **Excitement:** This phase reflects both a subjective sense of pleasure and the accompanying physiological changes associated with sexual arousal. The DSM-IV excitement phase represents a combination of Masters and Johnson's excitement and plateau phases.
3. **Orgasm:** This reflects a peaking of sexual pleasure and is synonymous with the orgasmic phase described by Masters and Johnson.
4. **Resolution:** This phase reflects a sense of general relaxation, well-being, and muscular relaxation. The typical refractory period (which differs for men and women) is also included within this resolution phase.

The DSM-IV notes that "disorders of sexual response" can occur at any one or more of the four phases, although dysfunction in the resolution phase is rarely of primary clinical significance.

The DSM-IV also states that more than one sexual dysfunction may be present, reflecting the clinical reality that dysfunction at one phase (e.g., orgasm) may adversely affect functioning at another phase (e.g., desire). Thus, the sexual dysfunction classified by the DSM-IV are divided into the following categories: Sexual Desire Disorders, Sexual Arousal Disorders, Orgasmic Disorders, Sexual Pain Disorders, and Sexual Dysfunction Not Otherwise Specified. Unlike its predecessors, the DSM-IV also includes categories for Sexual Dysfunction Due to a General Medical Condition and Substance-Induced Sexual Dysfunction. These diagnoses are appropriate if the dysfunction can be attributed entirely either to a biological disorder or to the adverse effects of substance use or medication. Note that the DSM-IV uses a binary classification system to diagnose either the presence or absence of a sexual dysfunction. Although a binary system has limitations (Malatesta & Adams, 1993), other approaches to classification have not been widely accepted (e.g., Schover, Friedman, Weiler, Heiman, & LoPiccolo, 1982; Trudel, Ravart, & Matte, 1993).

For accurate diagnosis, the DSM-IV requires both an impairment in desire or objective performance and an indication that the disturbance causes "marked distress or interpersonal difficulty." Therefore, it is possible that an individual may have impairment in a phase of sexual response (e.g., desire), but not be distressed by it—personally or interpersonally. In this case, the individual would not meet full diagnostic criteria for a sexual dysfunction. Finally, the DSM-IV states that all of the sexual dysfunctions may be classified additionally as Lifelong or Acquired (i.e., developing after a period of normal functioning), Generalized or Situational (i.e., limited to certain types of stimulation, situations, or partners), and/or Due to Psychological Factors or Due to Combined Factors (i.e., psychological factors and a general medical condition).

Definition, Description, and Diagnosis

Sexual Desire Disorders. There has been an evolution in the description and classification of sexual desire disorders. Freud defined sexual desire within the concept of libido, which he viewed as an instinctive, biological urge for sexual expression. Later definitions emphasized the psychological aspects of libido as more a function of developmental and environmental influences. The modern

description of a disorder of sexual desire was offered independently by Lief (1977) and Kaplan (1977). They argued that individuals with this condition could not be diagnosed adequately by using the four categories outlined by Masters and Johnson.

Although the third edition of the DSM (DSM-III; APA, 1980) introduced a more subjective and mentalistic aspect to diagnostic models of sexual functioning (see Money, 1988), it responded to this clinical development by including, for the first time, sexual desire problems as an independent diagnostic entity. Labeled as "Inhibited Sexual Desire" in the DSM-III, this entity's definition included "persistent and pervasive inhibition of sexual desire" (APA, 1980, p. 278). Because difficulty was inherent in attempting to measure inhibited sexual desire, some diagnostic confusion and theoretical controversy resulted.

Following the publication of the DSM-III, however, sexual desire-phase disorders began to attract significant clinical and investigative attention (Rosen & Leiblum, 1987). Research studies confirmed the commonality of desire-phase disorders in clinical practice (Kilmann, Boland, Norton, Davidson, & Caid, 1986). Others wrestled with the clinical complexity in conceptualizing and treating such problems (Kaplan, 1979; Schover & LoPiccolo, 1982) and the theoretical challenge posed by desire-phase disorders (Levine, 1984, 1988; Singer & Toates, 1987). In this regard, Levine (1988) reported that sexual desire can be conceptualized as incorporating at least three critical dimensions: (1) a biological-drive component based on neuroendocrine mechanisms and evidenced by "endogenous or spontaneous manifestations of genital excitement" (p. 24); (2) a cognitive or attitudinal component that reflects the inclination or "wish" to be sexual; and (3) an affective or interpersonal component, characterized by a willingness to engage in sex. More recent conceptualizations continue this tradition by emphasizing the multidimensional nature of sexual desire and its disorders (see Beck, 1995).

The DSM-III-R (APA, 1987) elaborated on the DSM-III's initial classification of desire-phase disorders by including two distinct categories: hypoactive sexual desire disorder and sexual aversion disorder. The term "inhibited" was dropped from the DSM-III-R to avoid a more conflict-based conceptualization, in favor of the atheoretical term, "hypoactive." The DSM-IV follows the

same tradition regarding description and classification of sexual desire disorders.

Hypoactive Sexual Desire Disorder (302.71).

- A. Persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age and the context of the person's life.
- B. The disturbance causes marked distress or interpersonal difficulty.
- C. The sexual dysfunction is not better accounted for by another Axis I disorder (except another Sexual Dysfunction), and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition. (APA, 1994, p. 498)

The DSM-IV definition of hypoactive sexual desire disorder (HSDD) includes both a cognitive ("fantasies") and a more affective-motivational ("desire for sexual activity") referent. Thus, HSDD can reflect a lack of, or a deficiency in, erotic cognition, interest, and/or sexual goal-seeking behaviors (e.g., sexual initiation with a partner). The presence of sexual activity, however, does not rule out the possibility of HSDD because people may engage in sexual behavior for a number of reasons other than desire (Malatesta & Robinson, 1995).

Conversely, HSDD can also reflect a lack of sexual responsiveness to a partner's initiation. As noted by Rosen and Leiblum (1989), this distinction is influenced by gender biases, and failure to initiate is more commonly associated with male desire problems and a lack of sexual responsivity often associated with female desire disorders. We have witnessed a blurring of this distinction in recent years because of emphasis on the commonalities of women and men in the expression of sexual desire disorders.

Hypoactive sexual desire disorders can be generalized or situational. Thus, in its most extreme form, generalized HSDD would include a complete absence of erotic thoughts, fantasies, and activity. Situational HSDD may reflect problems with a specific partner or activity. The presence of a desire-phase disorder exclusively during the course of another psychiatric condition (e.g., major depression) would not warrant a diagnosis of HSDD. The diagnosis of HSDD would be made only if the loss of sexual desire persisted after the psychiatric condition was resolved.

As noted by Rosen and Leiblum (1989), the current diagnostic classification does not permit an analysis of a frequent sexual complaint pre-

sented by couples—desire discrepancies. Individual differences in sexual interest may be a source of relationship conflict, and this situation often results in a couple presenting for sex therapy. Some clinicians have reconceptualized HSDD in interactional terms (Zilbergeld & Evans, 1980), and others have argued that disparate levels of sexual interest are common and should not be formalized with a diagnosis: "... no matter how loving and caring a relationship might be, the two individuals in it are not going to have absolute synchrony in their sexual appetites any more than they would always be hungry or thirsty or sleepy at exactly the same time" (Masters et al., 1994, p. 84).

From another perspective, converging evidence supports the view that complaints of low or absent sexual desire are one of the most common sexual dysfunctions in clinical and nonclinical populations alike. Although earlier studies reflected prevalence estimates that ranged from 15–55% (see Beck, 1995), a recent comprehensive study indicated a 22% prevalence rate of low sexual desire in a large sample of normal women (Laumann, Paik, & Rosen, 1999). Large clinical studies have indicated that 65% of individuals with sexual dysfunction present with a primary diagnosis of HSDD (Segraves & Segraves, 1991).

Sexual Aversion Disorder (302.79).

A. Persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The sexual dysfunction is not better accounted for by another Axis I disorder (other than a Sexual Dysfunction). (APA, 1994, p. 500)

Sexual aversion disorder (SAD) is a relatively new diagnostic category that appeared for the first time in the DSM-III-R (APA, 1987). SAD goes beyond the simple avoidance of sexual activity to include sexual panic, sexual repugnance, and sexual phobia. Kaplan (1987) drew attention to this class of disorders with her emphasis on sexual panic states and their integrated treatment using pharmacotherapy, insight-oriented psychotherapy, and behavioral exercises. Schover and LoPiccolo (1982) conceptualized sexual avoidance as lying on a continuum, where HSDD is at the mild extreme and sexual aversions and sexual phobias are at the most severe end point. As Kaplan (1987) noted, however, some of these patients may experience normal sexual desire and interest, and can

enjoy sexual fantasy and autoerotic activity, but when confronted with an interpersonal sexual situation, they may experience aversion to partner touch or to contact with the partner's genitalia. Conversely, in some cases it may be appropriate to diagnose both HSDD and SAD in the same individual (Sadock, 1995).

Very little is known about the prevalence and etiology of SAD. Masters et al. (1994) reported that SAD involves women two to three times more frequently in its clinical presentation than men. This estimate is consistent with that of other clinical researchers (Rosen & Leiblum, 1989; Schover & LoPiccolo, 1982). As noted by Masters et al., however, it is unclear whether this actually reflects a sex difference or is a function of other factors.

Sexual Arousal Disorders. As discussed in the Models section, sexual arousal remains a complex term. On one hand it denotes a range of physiological responses to erotic stimulation and, on the other hand, it reflects an individual's cognitive and emotional reaction to these changes or lack thereof. These aspects of sexual arousal are not necessarily concordant. For example, some middle-aged male patients may present with adequate erections in response to sexual stimulation but report negative feeling and judge the experience as unpleasurable because the erection "is not hard enough." Certain female patients may react to physical sensations of sexual arousal with fears and self-statements about being out of control.

In the DSM-IV, the definition of sexual arousal disorder avoids subjective and affective criteria and focuses instead on physiological arousal. The sexual arousal disorders are divided into (1) Female Sexual Arousal Disorder, which is characterized by the absence or deficiency in vaginal lubrication-swelling in response to adequate sexual stimulation; and (2) male erectile disorder, which reflects an inability to attain and maintain an adequate erection to complete sexual activity. The diagnoses assume that the focus, intensity, and duration of sexual stimulation are adequate to maintain the vasocongestive response in the typical case. Remarkable progress has been made in the biomedical and psychophysiological evaluation of male erectile disorder (e.g., Ackerman & Carey, 1995; Melman & Gingell, 1999), but our knowledge of female sexual arousal and its disorders lags behind. Recent psychophysiological and multivariate studies are advancing our understanding of the interplay of female physiology,

emotion, and subjective response as it relates to effective as well as deficient sexual arousal in women (Andersen & Cyranowski, 1995; Elliot & O'Donohue, 1997; Laan & Everaerd, 1995; Mes-ton & Gorzalka, 1996).

Female Sexual Arousal Disorder (302.72).

A. Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The sexual dysfunction is not better accounted for by another Axis I disorder (except another Sexual Dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition. (APA, 1994, p.502)

Female sexual arousal disorder (FSAD), referred to in the DSM-III as "inhibited sexual excitement," replaces the antiquated and highly perjorative term "frigidity" once used to describe all forms of female sexual dysfunction (ranging from lack of desire and low arousal to varying degrees of orgasmic dysfunction). FSAD reflects a deficiency or absence in the vasocongestive response to sexual stimulation. This definition emphasizes physiological arousal, but it has been argued that subjective arousal may be a more salient and meaningful criterion in defining a disorder of sexual arousal for women (see Rosen & Leiblum, 1995a). In making the diagnosis, the clinician should assess this aspect and take into account important moderating factors such as the woman's age, sexual experience, and comorbid problems, including other sexual dysfunction (e.g., HSDD). Distinguishing the latter from an arousal disorder may be difficult, as is ruling out an arousal disorder from a primary orgasmic disorder (Sadock, 1995; Segraves & Segraves, 1991).

Perhaps for these reasons, earlier studies showed variability and inconsistency in the prevalence of FSAD. In their review, Spector and Carey (1990) cited community estimates of FSAD that ranged from 11–48%. An early clinical study reported that 57% of women who sought therapy experienced arousal difficulties (Frank, Anderson, & Kupfer, 1976). A recent community study found that 19–27% of women complained of difficulty with lubrication. The range depended on the age, education, marital status, and ethnicity of the woman (Laumann et al., 1999). Finally, in a gynecology clinic sample, lubrication difficulties were reported by 13.6% of women; this rose to 44.2% in

postmenopausal women (Rosen, Taylor, Leiblum, & Bachman, 1993).

Male Erectile Disorder (302.72).

A. Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The erectile dysfunction is not better accounted for by another Axis I disorder (other than a Sexual Dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition. (APA, 1994, p. 504)

Male erectile disorder (MED) is also referred to as "erectile dysfunction" and by the more generic term "impotence." Male erectile disorder reflects considerable variability among men. Some individuals experience firm erections during foreplay and/or oral sex but then detumescence on penetration. Other men achieve only a partial erection (insufficient for intromission) throughout sexual activity, whereas some will experience situational erectile difficulty under certain conditions (e.g., with a new partner). In most cases of MED due to psychological factors, there is usually minimal difficulty in attaining an erection during self-stimulation; rather, the problem seems to be restricted to attempts at intercourse. The DSM-IV definition of MED does not indicate that intercourse is necessarily part of the "sexual activity" to make the diagnosis.

The frequency of erectile disorder is strongly related to age, chronic illness, and/or other factors (e.g., use of medication). Data from the Massachusetts Male Aging Study showed that the overall incidence of mild to complete erectile difficulty was 52% in men between the ages of 40 and 70 (Feldman, Goldstein, Hatzichristou, Krane, & McKinlay, 1994). The prevalence of complete erectile difficulty during intercourse was 9.6%, which tripled from 5 to 15% between the ages of 40 and 70 for these healthy men. Focusing on a younger community sample, Spector and Carey (1990) estimated that 4–9% of men experienced erectile disorder. This estimate compares with recent figures which showed that 7–18% of men between the ages of 18 and 59 complained of trouble maintaining or achieving erection (Laumann et al., 1999).

Orgasmic Disorders. Female and male orgasmic disorder is a lack of, or marked delay in the orgasmic response following a normal excitement phase. Women and men who can experience or-

gasm with noncoital clitoral or penile stimulation but cannot achieve orgasm during intercourse (in the absence of manual stimulation) are not necessarily categorized as anorgasmic. Premature ejaculation is also classified within the orgasmic disorders, and refers to male orgasm before, on, or shortly after vaginal penetration, but before the person desires it. In making a diagnosis of an orgasmic disorder, the clinician must make judgments as to (1) the presence of a normal excitement phase, (2) the adequacy and duration of stimulation, and (3) normal situational factors that may exacerbate an orgasmic problem (e.g., premature ejaculation with a new partner).

Female Orgasmic Disorder (302.73).

A. Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of Female Orgasmic Disorder should be based on the clinician's judgment that the woman's orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The orgasmic dysfunction is not better accounted for by another Axis I disorder (except another Sexual Dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition. (APA, 1994, pp. 506–507)

Female patterns of reaching orgasm can be conceptualized as varying along a continuum that ranges from occasional difficulty in achieving climax under certain conditions to complete inability to reach orgasm through any means. By definition, however, female orgasmic disorder (FOD) is a "persistent or recurrent delay in, or absence of" orgasm despite sufficient sexual stimulation and a normal excitement phase. Thus, whereas occasional difficulties in achieving orgasm may be fairly common for most individuals, the diagnosis of FOD is typically reserved for those women who experience either significant problems in reaching climax or complete inability to experience orgasm.

Physiologically, a woman with FOD (unlike the female suffering from an excitement-phase disorder) may show vaginal lubrication and swelling and may experience subjective arousal in response to various sexual activities (e.g., foreplay and penile intromission). Similarly, in contrast to desire-phase disorders, a woman who is anorgasmic may report (at least initially) adequate sexual desire,

may seek out sexual experiences, and may report erotic thoughts and fantasies. Although FOD is by definition an orgasmic-phase disorder, it is common to find desire-phase and/or excitement-phase problems developing in women who complained initially of FOD dysfunction or vice versa.

Not surprisingly, there has been controversy regarding criteria for diagnosing FOD, and in response, clinical researchers have identified subtypes of FOD (see Andersen & Cyranowski, 1995; Fisher & Barak, 1989; Wakefield, 1987). Kaplan (1974), for instance, presented an early distinction based on "absolute" versus "situational" types of female orgasmic dysfunction. Absolute dysfunction was defined as the inability to experience orgasm under any circumstances; this definition is comparable to that of generalized orgasmic disorder. The term "preorgasmic" was also applied to this group, connoting a positive prognosis and the belief that the experience of orgasm is a learnable activity (Barbach, 1975). The ability to attain orgasm primarily under specified conditions (e.g., only through self-masturbation while alone) was referred to as situational orgasmic dysfunction. Similarly, secondary orgasmic dysfunction has been used to refer to women who are orgasmic but express concern about the frequency and circumstances of the occurrence of orgasm. Andersen and Cyranowski (1995) argued that this pattern represents a normal variation in sexual response for many women and is usually not a diagnostic entity.

FOD prevalence data derived from early community and clinic samples reflected variability that ranged from 5–20% (Spector & Carey, 1990). More recently, only 29% of women in a large nonclinical sample of women reported that they always had an orgasm with their regular partner during sex and 24% reported an inability to have orgasm (Laumann, Gagnon, Michael, & Michaels, 1994). Laumann et al. (1999) reported that 18–32% of women reported being unable to achieve orgasm during the past 12 months. Percentage differences were a function of age, education, marital status, and ethnicity.

Male Orgasmic Disorder (302.74).

A. Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase during sexual activity that the clinician, taking into account the person's age, judges to be adequate in focus, intensity, and duration. This failure to achieve orgasm is usually restricted to an inability to reach orgasm in the vagina, with orgasm possible with other types of stimulation, such as masturbation.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The orgasmic dysfunction is not better accounted for by another Axis I disorder (except another Sexual Dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition. (APA, 1994, p. 509)

Although male orgasmic disorder (MOD) represents the male counterpart of female orgasmic disorder, there are several important distinctions. First, clinically speaking, MOD is a relatively rare disorder, compared to the commonality of FOD. Spector and Carey (1990) reported that MOD was the least common male sexual dysfunction whose occurrence is less than 4–10% in the general population. Laumann et al. (1999) reported that 7–11% of men between the ages of 18 and 59 complained of inability to achieve orgasm during the past year. Although MOD may be relatively more common in the general population, individuals who have such difficulties are not likely to come into treatment. It has been noted that the major reason these individuals do seek treatment is because of partner demands for impregnation through intravaginal ejaculation (Apfelbaum, 1989). Thus, a second contrast with FOD is that a major focus of MOD is the male's inability to experience vaginal or coital orgasm. For women, more flexibility is afforded in describing FOD, in that lack of coital orgasm may not be an indication of a disorder. Third, though a biomedical condition may be associated with MOD (Rosen, 1991), this appears less commonly for FOD. Finally, MOD has been called inhibited male orgasm (APA, 1987) and "retarded or delayed ejaculation" which suggests a slowness to ejaculate during intercourse. In psychogenic cases, however, the clinical research suggests that such individuals cannot usually experience orgasm with a partner and may reflect psychopathology (Sadock, 1995).

For these reasons, Apfelbaum (1989) reconceptualized MOD and introduced the term "partner anorgasmia" to call attention to the fact that the primary difficulty in the male who has MOD is reaching any kind of orgasm with any partner. Autoerotic activities, such as masturbation, may be unimpaired. Thus, Apfelbaum argued that MOD may represent one end of a continuum that ranges from those who strongly prefer stimulation by a partner to those who, like the individual with MOD, are more responsive to their own stimulation. There also is, however, a small group of men

who (like the women with primary orgasmic dysfunction) have difficulty reaching orgasm under any conditions. Thus, clinical researchers have presented case studies that have spanned a continuum of male orgasmic dysfunction—ranging from total lifelong inability to experience orgasm by any means to ejaculation that is restricted to highly circumscribed situations and methods (Munjack & Kanno, 1979; Sadock, 1995).

Premature Ejaculation (302.75).

A. Persistent or recurrent ejaculation with minimal sexual stimulation or before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty or the sexual partner or situation, and recent frequency of sexual activity. (APA, 1994, p. 511)

B. The disturbance causes marked distress or interpersonal difficulty.

C. The premature ejaculation is not due exclusively to the direct effects of a substance (e.g., withdrawal from opiates).

Although premature ejaculation is the most prevalent male sexual dysfunction (Laumann et al., 1999; Spector & Carey, 1990), the concept of premature ejaculation (PE) is deceptively simple and subject to misconception. The term "early ejaculation" was introduced a decade ago (McCarthy, 1989) to provide a less perjorative term and to focus description on the role of orgasmic control. However, efforts to generate a precise clinical definition have illuminated the complexity of PE (Metz et al., 1997; St. Lawrence & Madakasira, 1992). Some have argued that PE may not be considered a dysfunction except in extreme cases (Wincze & Carey, 1991), and others have stated that PE is potentially debilitating and often is a precursor to other dysfunctions (McCarthy, 1989).

Part of the definitional difficulty is related to the fact that, for many individuals, premature ejaculation is defined as a problem on the basis of the partner's response. In other words, the latency of male ejaculation is usually viewed within the context of the partner's sexual response cycle. Thus, if the man's early ejaculation consistently limits his partner's sexual satisfaction, a problem has been defined. For some couples, however, abbreviated ejaculatory latencies may not restrict or prevent a partner's satisfaction; this is particularly the case if the woman's excitement phase has been extended through foreplay and/or other sexual behaviors (e.g., cunnilingus) and if she finds these activities highly pleasurable and arousing.

In spite of these difficulties, premature ejaculation has been defined arbitrarily as the inability of the male to control ejaculation for a length of time sufficient to satisfy his partner in at least 50% of their coital encounters, provided there is no female sexual dysfunction evident (Masters & Johnson, 1970). In contrast, Kaplan (1974) focused greater attention on the male's self-regulation or pacing of his excitement phase by defining prematurity as the absence of voluntary control over the ejaculatory reflex. Finally, Masters et al. (1994) state, "While experts have long debated over the precise definition of premature ejaculation, almost every man with this problem knows he's got it: Splitting fine semantic hairs doesn't add much to our understanding" (p. 102).

In the light of the previous discussion, the DSM-IV definition of premature ejaculation emphasizes both temporal and self-evaluative criteria. This definition provides enough flexibility to address normative differences in ejaculatory control associated with age, context (e.g., with a new partner, or following sexual abstinence), and primary versus secondary or situational PE (Cooper, Cernovsky, & Colussi, 1993; Spiess, Geer, & O'Donohue, 1984). Finally, in past decades, it was believed that men with more education displayed greater concerns about partner satisfaction and thus greater concern about PE. Recent data, however, show that men of varying educational backgrounds and ethnicity express similar concerns about climaxing "too early" (Laumann et al., 1999). Contrary to clinical lore, older men expressed as much concern about PE as younger men.

Sexual Pain Disorders. Dyspareunia is recurrent and persistent pain during intercourse in either women or men. In men, it is relatively rare (Bancroft, 1989; Sadock, 1995). In women, it is a highly prevalent condition that occurs at 10–21% in community samples and particularly in younger women (Laumann et al., 1999); Rosen, Taylor, Leiblum, & Bachman, 1993). Dyspareunia is a common presenting complaint in gynecologic clinics but is less frequently encountered in mental health settings. Female dyspareunia may be related to biomedical problems (e.g., anatomical defect, infection, surgical scar tissue). In other cases, female dyspareunia may reflect insufficient lubrication or postmenopausal hormonal insufficiency, which affects both vaginal lubrication and the elasticity of the vaginal lining (Masters et al., 1994; Meana & Binik, 1994). If the dyspareunia is

caused exclusively by a biological disorder, then the appropriate diagnosis would be Dyspareunia Due to a Medical Condition. Psychological and/or relational factors may be implicated in many cases of dyspareunia (Lazarus, 1989; Sadock, 1995). Vaginismus—an involuntary spasm of the vaginal musculature that interferes with coitus—may be more often associated with psychological variables (Wincze & Carey, 1991), even though biomedical factors may be implicated in the genesis of this disorder. For instance, a medical condition that produces pain during intercourse may precipitate conditioning of vaginal musculature and result in vaginismus, even after the physical cause has been resolved (Kolodny et al., 1979). Similarly, even in its less severe forms, vaginismus often exacerbates dyspareunia because a woman tenses her circumvaginal muscles in anticipation of painful intercourse (Carey & Gordon, 1995; Tollison & Adams, 1979). In either case, however, sexual pain disorders may exist to a far greater degree than reported because individuals with these disorders may avoid sexual activity and/or intimate relationships.

Dyspareunia (302.76).

- A. Recurrent or persistent genital pain associated with sexual intercourse in either a male or a female.
- B. The disturbance causes marked distress or interpersonal difficulty.
- C. The disturbance is not caused exclusively by Vaginismus or lack of lubrication, is not better accounted for by another Axis I disorder (except another Sexual Dysfunction), and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition. (APA, 1994, p. 513)

Dyspareunia may be expressed by a variety of pain phenomena that range from postcoital vaginal irritation to severe discomfort with intromission and penile thrusting. Persistent dyspareunia may lead to other sexual dysfunctions, such as vaginismus, desire-, and/or excitement-phase disorders. Dyspareunia in men, though rare, is often associated with a medical condition and may be expressed as a postejaculatory pain disorder (Sadock, 1995).

Vaginismus (306.51).

- A. Recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse.
- B. The disturbance causes marked distress or interpersonal difficulty.
- C. The disturbance is not better accounted for by another Axis I disorder (e.g., Somatization Disorder) and is not due exclu-

sively to the direct physiological effects of a general medical condition. (APA, 1994, p. 515)

Vaginismus can range from severe cases where penile insertion into the vagina is impossible because of the spasm, constriction, and consequent pain, to situations where intercourse is possible but only with considerable discomfort. Partial and situational vaginismus may also occur, but these individuals are not inclined generally to seek treatment (Leiblum et al., 1989; Masters et al., 1994). In the generalized type of vaginismus, the woman may be unable to tolerate tampon or finger insertion or pelvic examination (which may need to be performed under general anesthesia). In some cases, a significant phobic element (e.g., fear of penetration by a foreign body) may occur, and sexual encounters are avoided. The presence of a clear avoidance of pain or vaginal penetration *per se* distinguishes vaginismus from a sexual aversion disorder.

Vaginismus can result in desire- or excitement-phase difficulties. However, it may be more common to find that this condition does not interfere with sexual responsiveness, arousal, and orgasmic capability (Kolodny et al., 1979; Masters et al., 1994). In fact, oral-genital sex and other noncoital sexual activities may be quite pleasurable and sexually satisfying to these women. This may be one reason many of these women do not seek treatment. Leiblum et al. (1989) state that in these cases, "often, it is the desire to have children that ultimately propels the couple to seek assistance" (p. 114). At the same time, women presenting with either vaginismus or dyspareunia should be assessed for prior sexual trauma, even though research is inconclusive (Carey & Gordon, 1995).

Etiology of Sexual Dysfunction

A multivariate perspective is crucial in appreciating the causal complexity and variability of problems in sexuality. Why does one woman with a history of childhood sexual abuse suffer from desire-phase difficulties and avoid all sexual encounters, whereas a second woman with a similar history is sexually active but complains of orgasmic difficulties and a general lack of pleasure? Similarly, why is obsessive anxiety associated with premature ejaculation in one man and with erectile dysfunction in another? Why is a third person able to perform without difficulty even though he displays greater anxiety than the first

two men? To understand the causes of sexual dysfunction and appreciate that sexual function occurs in the face of psychological adversity (McCarthy, 1998; Sarrell & Masters, 1982) is a complex issue that is only beginning to be unraveled. This section begins with a clinical model of etiological factors in sexual dysfunction.

A Clinical Model of Etiology

During the last 20 years, an important development in the field has been the recognition that sexual dysfunctions in general are caused by a unique interplay of biological, psychological, and interpersonal factors. In the area of erectile disorder, for instance, etiological emphasis has been placed upon vascular, hormonal, and neurological variables (Melman & Gingell, 1999), as well as cognitive-affective and information-processing factors (Bach et al., 1999). Conceptualization of premature ejaculation—which focused initially upon a hypersensitivity to penile stimulation—has proven more complicated (Grenier & Byers, 1995; Rowland, Cooper, Slob, & Houtsmuller, 1997). Female desire-phase difficulties have emphasized hormonal and relational-marital factors (Beck, 1995), whereas sexual trauma has been associated with a range of sexual problems in many women and men (Bartoi & Kinder, 1998; Backer, 1989; Laumann et al., 1999).

Wincze and Barlow's (1997) "Balancing Scale" is an initial approach to conceptualization of these etiological factors. The Balancing Scale shown in Figure 4 is useful as a clinical heuristic and teaching tool for clients. In the left column, the figure lists nine positive psychological factors and nine positive physical factors. In general, these positive factors have been associated with intact sexual functioning and overall sexual enjoyment. In the right column, the Scale also lists nine negative psychological and nine negative physical factors that have been associated with an increased likelihood of sexual dysfunction and distress. However, it is the number of negative risk factors that will "tilt the balance" toward development of a sexual dysfunction. In addition, it is also assumed that the interaction and individual processing of many of these factors are critical in determining whether they lead to sexual dysfunction. For example, an individual who possesses a flexible attitude toward sex (positive psychological factor) may be better able to cope with and actively manage the negative sexual side effects of antihypertensive

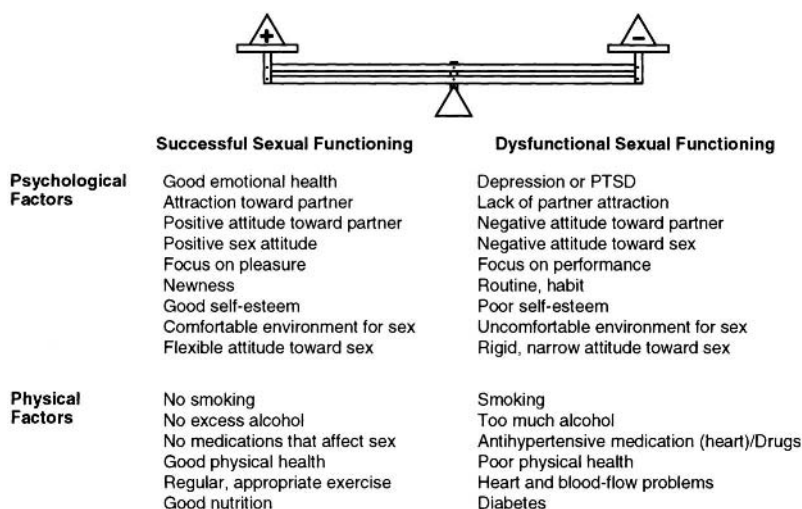

Figure 4. Wincze and Barlow's Balancing Scale: Positive and negative factors that affect sexual functioning. From *Enhancing Sexuality: A Problem-Solving Approach* Copyright 1997 by Graywind Publications. Reproduced by permission of publisher, The Psychological Corporation. All rights reserved.

medication (negative physical factor). Similarly, an isolated episode of erectile failure associated with excessive alcohol intake (negative physical factor) may pose minimal difficulty to an emotionally healthy individual (positive psychological factor), but it represents a traumatic event that leads to future erectile problems for an anxious individual who is cognitively focused on his performance (negative psychological factor).

Thus, the mere presence of a negative etiological factor may not necessarily result in sexual dysfunction. Instead, the interaction of an environmental event, biological integrity, interpersonal support, and individual psychological makeup will determine whether a sexual dysfunction develops in a given individual. Although a relatively simple model, the Balancing Scale reflects the multivariate process of conceptualizing etiological factors in sexual dysfunction. Moreover, it is similar to the medical approach of identifying an individual's behavioral and biological "risk" factors versus "health" factors to determine the likelihood of developing medical disorders related to life-style such as heart disease.

Biological Risk Factors

Disease and Illness. Sexual dysfunctions are often related to biomedical illness, which may operate by differential interaction of physical and

secondary factors. These problems range from a predominant physical causation (as in the case of prostate or cervical cancer) to a medical etiology with indirect but significant psychological sequelae. For example, for 50% of female gynecologic cancer survivors, posttreatment sexual difficulties do not resolve—even though improvement occurs in other life areas, including mood and social adjustment (see Andersen, Andersen, & deProse, 1989). Sexual problems have included arousal difficulties, orgasmic disorder, and dyspareunia (Andersen, 1985). For these women, research has shown that a psychological factor, "sexual self-schema," accounts for variance comparable to that of two physical factors (the extent of cancer treatment and menopausal symptoms) in predicting current sexual behavior and responsiveness (Andersen, Woods, & Copeland, 1997).

Although any major organ-system dysfunction (renal, pulmonary, cardiac, or hepatic) may cause sexual dysfunction, psychological factors may aggravate the case, for example, where transient and remitting sexual disturbance is an early disease symptom (e.g., in diabetes). In these cases, the onset of illness-induced sexual dysfunction may be characterized by etiological uncertainty and misattribution. In other cases (as in the postcoronary male), the sexual situation often reflects misinformation, anxiety, and fear of the "coital coronary." As an adjunctive problem, certain surgical

procedures and classes of medication can also exert negative influences on sexual interest and functioning (Galyer, Conaglen, Hare, & Conaglen, 1999).

During the last decade, clinical researchers have directed greater investigative attention to the sexual needs and problems of women and men who suffer from chronic illness and physically disabling conditions. In the past, disability status often carried the stigma of asexuality. Moreover, less attention was focused on the sexual lives of women with disability. Today, a number of clinical researchers active in this area display a sophistication in psychological issues related to illness and sexuality and also keen understanding of the medical, physiological, and pharmacological variables within this complex area (e.g., Andersen et al., 1997; McCormick, 1996; Schover & Jensen, 1988). Work has addressed the spectrum of disease and illness that ranges from life-threatening crises (e.g., cardiovascular disease, cancer, end-stage renal disease) to insidious illnesses (e.g., diabetes, chronic obstructive pulmonary disease). Similar studies have addressed sexual and relationship dysfunction in multiple sclerosis patients (McCabe et al., 1996; Schover, Thomas, Lakin, Montague, & Fischer, 1988) and sexual rehabilitation in cancer patients (Schover, Evans, & von Eschenbach, 1987). Others have focused on sex problems and therapy issues for patients with spinal cord injury (Whipple, Gerdes, & Komisaruk, 1996). Diabetes and sexual dysfunction in men and women is an active area of research (Jensen, 1986; Lipshultz & Kim, 1999; Prather, 1988; Weinhardt & Carey, 1996). Finally, studies are addressing the unique sexual problems of women with chronic pain, interstitial cystitis, and types of spinal cord injury (Schlesinger, 1996; Spiski, Alexander, & Rosen, 1999; Webster, 1996).

For additional study of the topic of physical illness/chronic disease and sexuality, see Table 2, which presents a brief listing of relevant literature (see also the journal *Sexuality and Disability*).

Aging. The later years, once synonymous with impairment and eventual loss of sexual desire and activity, now reflect more accurately both a variability and stability in sexual expression (Adams & Turner, 1985; Butler & Lewis, 1993; Fisher, Swingen, & O'Donohue, 1997; Malatesta, 1989). Many studies that address older adult sexuality use cross-sectional designs that confound the effects of age and cohort. Consequently, these studies

present a deceptively pessimistic picture that shows a precipitous "age-related" decline in sexual desire and activity. In reality, cross-sectional studies only tell us about age differences (i.e., differences between age groups) while telling us little about age changes (i.e., changes in the same age group during a period of time). Longitudinal data have shown that although advancing age *per se* may be related to quantitative but not qualitative changes in sexual activity (George & Weiler, 1981; Pfeiffer, 1977), a host of variables that accompanies aging may exert significantly adverse effects on sexual behavior and interest: (1) physical debility; (2) chronic disease; (3) increased use of medication; (4) age-related emotional problems; (5) interpersonal logistics (e.g., widowhood, lack of privacy, nursing home); (6) societal, family, and personal expectations; and (7) a previous life-style of low sexual activity (Butler & Lewis, 1993; Malatesta, Chambless, Pollack, & Cantor, 1988; Martin, 1981; Weizman & Hart, 1987).

For healthy women, aging is not associated with decreased sexual desire or a decreased capacity for orgasm (Masters & Johnson, 1966). The most frequently encountered problems (atrophy of the va-

ginal mucosa and decreased vaginal lubrication) usually become apparent with postmenopausal hormone deficiencies and may cause dyspareunia, which is treatable by vaginal lubricating agents and/or estrogen replacement therapy (Masters et al., 1994; Sherwin, 1991).

The normal pattern of sexual aging in older men is qualitatively different from that in women. In contrast to the female aging process, there is usually not as dramatic a decrease in sex-steroid hormone levels, although a gradual reduction in the circulating levels of testosterone is usually evident after age 60 (see Butler & Lewis, 1993; Masters et al., 1994). Considerable variability exists, but male aging is typically associated with (1) increased latency to erection, (2) greater need for longer tactile stimulation to produce erection, (3) mild but noticeable changes in penile tumescence, (4) decreased ejaculatory intensity and decreased urgency to reach orgasm, and (5) an increased refractory period (Butler & Lewis, 1993; Masters & Johnson, 1966). Not surprisingly, these age-related sexual changes may be misinterpreted by both the uninformed male and his partner, who may then attribute his "difficulties" to loss of masculinity or partner attractiveness, or to any number of variables. Clearly, the availability of age-relevant sexual information is crucial for handling these sexual alterations associated with aging.

It is important to emphasize that individual sexual patterns established early in life tend to be maintained in middle and old age and that complicating factors such as physical illness, partner availability, and societal expectations are the greatest causes of sexual problems among older adults. The issue of prolonged celibacy or sexual abstinence as a cause of sexual problems in older adults remains a controversial and generally unsubstantiated finding (Schover & Jensen, 1988). It has been argued and generally assumed that extended periods of sexual abstinence may exert a "physiological handicap" for the elderly who wish to resume sexual activity at a later time. There are minimal data to substantiate this claim, and this belief may represent another myth associated with sexuality and older adults.

The sexual problems of older adults may not significantly differ from those of younger individuals, but greater sensitivity must be paid to the impact of biological and psychological factors (Fisher, Swingen, & O'Donohue, 1997; Leiblum

& Seagraves, 1989). Any therapeutic intervention should reflect a respect for the continuity of one's sexual life-style and a readiness to explore alternative methods of meeting the sexual and affectional needs of older adults who remain interested in their sexuality but who are disabled, without partners, or live within a restricted environment (Malatesta, 1989).

Pharmacological Influences. Multiple studies show that a vast array of drugs can interfere with any phase of sexual response. A number of sources provide comprehensive information on drug actions with specific reference to sexual side effects (Ashton, Hamer, & Rosen, 1997; Gitlin, 1994; Sadock, 1995). Work has also addressed the sexual side effects of psychotropic drugs on women (see Crenshaw & Goldberg, 1996; Jani & Wise, 1988; Riley & Riley, 1993; Seagraves, 1988).

Some of the more popular medications associated with sexual dysfunction are (1) selective serotonin re-uptake inhibitors (SSRIs); (2) heterocyclic antidepressants (e.g., anticholinergic agents) and monoamine oxidase inhibitors (MAOIs); (3) dopamine-blocking agents (e.g., haloperidol and the phenothiazines); (4) antihypertensive drugs (e.g., beta-blockers and diuretics); (5) antiandrogenic compounds (e.g., estrogen and progesterone); and (6) narcotics and sedative hypnotics, which decrease CNS cortical activity.

Alcohol, another CNS depressant, has received attention in studies that address its effects on sexual functioning among individuals who display either moderate or addictive drinking patterns (Crowe & George, 1989; Rosen, 1991; Schover & Jensen, 1988; Wilsnack, 1991). It has been shown empirically that acute alcohol intoxication in non-alcoholic samples of men and women affects sexual arousal (Briddell & Wilson, 1976; Wilson & Lawson, 1978) and orgasm (Malatesta, Pollack, Crotty, & Peacock, 1982; Malatesta, Pollack, Wilbanks, & Adams, 1979). Other studies have addressed the detrimental effects of alcohol intoxication and cognitive distractors on male sexual arousal (Wilson, Niaura, & Adler, 1985).

Similar findings have been reported for male alcohol abusers (Wilson, Lawson, & Abrams, 1978), and sexual detriments tend to last well after alcohol intake stops (Schiavi, 1990). A study of 116 male alcoholic inpatients revealed that at least one sexual problem was reported by 75% of the sample: erectile dysfunction in 42%, premature ejaculation in 43%, low sexual desire in 46%, and

delayed orgasm in 23% (Fahrner, 1987). Female alcoholics report a range of dysfunctions, including heightened premenstrual dysphoria, reduced sexual desire and arousal, anorgasmia, dyspareunia, and vaginismus (Wilsnack, 1984, 1991). Moreover, heavy drinking may block ovulation and cause other hormonal abnormalities in some healthy women (Mendelson & Mello, 1988).

A range of complex and interactive etiological factors may account for the disruptive effects of chronic alcohol abuse and alcoholism on sexual function (Goldman & Roehrich, 1991; Wilsnack, 1980). These include (1) the acute depressant effects of alcohol on sexual response, (2) the disruption of gonadal hormone metabolism secondary to liver damage, (3) reduced sexual sensation as a result of alcohol-induced neuropathy, (4) organic brain damage that causes impairment of both interpersonal and sexual interest, and (5) concomitant medical and psychological problems associated with alcoholism (e.g., hypertension, psychopathology).

Psychosocial Risk Factors

Our knowledge of the complex role of psychosocial risk factors reflects a range of data sources, including clinical impression, observational studies, correlational designs with clinical and nonclinical samples, and more formal experimental research. There are inherent difficulties in studying psychological causes of sexual dysfunction. Moreover, compared with many areas, there is a dearth in funding opportunities for basic sex research. As a consequence, there has been less emphasis on hypothesis testing, theory research, and more rigorous experimental methods. Still, the contribution of laboratory research, including theory-driven approaches, cannot be underestimated (e.g., Bach et al., 1999; Palace, 1995; Rowland, 1999).

Predisposing Factors. Based upon their extensive clinical observation, Masters and Johnson (1970) indicated that a rigid religious orthodoxy was the greatest single cause of sexual dysfunction. Obviously a complex issue (Davidson, Darling, & Norton, 1995; Rundel, 1998), negative sexual learning that involves religious themes has been associated with the range of sexual dysfunctions, including low sexual desire (LoPiccolo & Friedman, 1988), arousal and orgasmic problems (Kaplan, 1974; Masters et al., 1994), and vaginismus (Silverstein, 1989). "In these cases, it is

not the religious teachings per se that are the problem, but the often-associated family attitudes that are imparted to the child that sex is dirty and sinful" (Masters et al., 1994, pp. 140–141). Similarly, it is assumed that an early childhood sexual environment characterized by negative attitudes and misinformation is not conducive to healthy sexual learning; instead, it can be expected to result in sexual inhibitions, fears, and negative attitudes about sexual expression. Deficits in sexual knowledge or experience may be expected to exert a similar influence, as would early-learned negative sexual sanctions (Leight, 1990).

Sexual trauma has been consistently related to the development of sexual dysfunction in both women and men (Bartoi & Kinder, 1998; Becker & Kaplan, 1991; Laumann et al., 1999). Note, however, that "Sexual trauma is a multicausal, multidimensional phenomenon with variable outcomes and vast individual differences" (McCarthy, 1998, p. 91). Traumatic experiences such as sexual abuse/assault, incest, and other illicit sexual activity have been associated with a range of difficulties, including intimacy and trust issues, sexual avoidance, arousal disorders, and negative conditioning, including dyspareunia. In a retrospective study of 372 sexual assault survivors, Becker and her colleagues reported that 58% of these women experienced sexual dysfunctions, compared to 17% of a control group without a history of sexual assault (see Becker & Kaplan, 1991). The most common sexual dysfunctions involved fear of sex, arousal dysfunctions, and desire problems. Several authors have noted that women who have a history of incest may present with vaginismus as part of their sexual dysfunction (LoPiccolo & Stock, 1987; Carey & Gordon, 1995). Finally, male victims of adult-child contact are three times as likely to experience erectile dysfunction and twice as likely to experience low sexual desire and premature ejaculation (Laumann et al., 1999).

Although empirical data are lacking, early negative conditioning events have been associated with sexual dysfunction (Masters et al., 1994; Tollison & Adams, 1979). In particular, one explanation of premature ejaculation has focused on the conditioning of rapid orgasm engendered by early sexual experiences (Ruff & St. Lawrence, 1985). These experiences might include, for example, masturbation, intercourse with prostitutes who encourage rapid ejaculation, and intercourse in semi-

private situations where a related fear of detection is conducive to rapid orgasm. Fear of pregnancy and fear of detection represent important anxiety-conditioning factors to female sexual dysfunction, and vaginismus can be a reactive or self-protective conditioning event secondary to traumatic sexual experiences or other unwanted sexual contacts (see Carey & Gordon, 1995).

Relationship difficulties are obviously an important risk factor in the development of various sexual dysfunctions, including desire, arousal, and orgasmic disorders. Conflict, intimacy and control problems, stress, and poor communication and technique have been noted most frequently (see Beck, 1995; LoPiccolo & Friedman, 1988; Morokoff & Gilliland, 1993; Rosen & Leiblum, 1995a). Unresolved partner differences in sexual desire may also be precursors of a couple's sexual problems (Zilbergeld & Ellison, 1980). Sexual boredom or habituation, though sometimes reflecting a couple's lack of creativity and innovation, often predates sexual dysfunction in the middle and later years (Butler & Lewis, 1993). Finally, there is need for clinical research to address the unique stresses and challenges associated with couples who are coping with infertility and its effects on individual and couple sexuality (Lasker & Borg, 1995).

Precipitating and Maintaining Factors.

Precipitating factors have a close temporal relationship to the onset of sexual dysfunction and are assumed to have instigated it. Maintaining factors, in contrast, perpetuate dysfunctional activity. In many cases, a discrete precipitating factor cannot be identified, but an array of variables, including stress and emotional problems (Laumann et al., 1999), have been hypothesized to precipitate sexual failure, distress, and avoidance. Predisposing factors discussed before may also function as precipitating and/or maintaining factors. Early formulations, relying on data suggesting that penile erection and vaginal lubrication/swelling are predominantly parasympathetic functions, emphasized increased sympathetic nervous activity as one construct to explain sexual failure in men and women (Masters & Johnson, 1970; Wolpe, 1982). There are any number of variables that increase sympathetic activity that could be relevant to sexual dysfunction. Negative mood states, especially anxiety, were implicated in this process. In particular, anxiety arising from performance demands, perceived inadequacy of sexual performance, or

fear of performance failure was believed to be the most important precipitating (as well as maintaining) factor in sexual dysfunction (Kaplan, 1974; Masters & Johnson, 1970).

Because sexual arousal is mediated by both parasympathetic and sympathetic activation (see Rowland, 1995), anxiety *per se* is inadequate to explain the range of clinical phenomena in sexual dysfunctions. Beck and Barlow (1984) described a number of very different studies showing that elevated anxiety can actually increase sexual response under certain conditions. A growing number of studies also illustrates the complex relationships among anxiety and mood state, cognitive factors, and affective response in mediating sexual arousal and dysfunction (see Bach et al., 1999; Meston & Gorzalka, 1996; Palace, 1995). These studies show that sexually dysfunctional and sexually functional men and women respond quite differently to anxiety, distraction, and performance-related feedback (Mitchell, DiBartolo, Brown, & Barlow, 1998).

Although sexual dysfunction may represent a common final outcome of a sexual problem, the critical issue is this: Almost everyone has had at least one sexual episode that has resulted in distress and/or failure. Why do some people develop sexual dysfunction as a result, whereas others do not? If one responds to an initial failure with alarm and distress and attempts to cognitively "check" oneself in the next encounter, another failure is more likely. Masters and Johnson (1970) described this cognitive response as "spectatoring," that is, an individual's self-monitoring of sexual response during an encounter that reduces sexual pleasure, interferes with attention and response to more relevant sexual cues, and heightens anxiety level when the desired response is not achieved. This experience is likely to condition and solidify the dysfunctional pattern (Masters & Johnson, 1970). Experimental studies described earlier help to articulate this process. In addition, research has shown that sexually functional men tend to ignore or do not attend to declines in physiological arousal (Mitchell et al., 1998). These studies imply that if one can maintain a positive sexual self-efficacy in the face of impaired performance, then sexual dysfunction is less likely to develop (Bach et al., 1999). This has been described as "resistance to the dysfunctional mentality" (see Barlow, Chorpita, & Turovsky, 1996). Relatedly, based on experimental studies, it has been suggested that

for sexually dysfunctional women, attempts to increase autonomic responsivity (perhaps through physical activity) may facilitate genital response and positive sexual learning and promote more rapid extinction of conditioned negative response patterns (Palace, 1995).

The Role of Psychopathology. Traditionally, psychopathology has been associated with sexual problems. Early psychoanalytic thinkers, for instance, equated female orgasmic dysfunction with psychological maladjustment (Fenichel, 1945), and even Freud referred to his early work as a sexual theory of neuroses. To date, however, a direct cause and effect relationship between psychopathology and sexual dysfunction has been difficult to establish. Still, even with the limited data available from clinical and correlational studies, two important conclusions can be drawn: (1) Many individuals (as well as their partners) who seek treatment for sexual dysfunction have diagnosable psychiatric disorders and (2) many individuals who seek treatment for psychiatric problems also display significant sexual dysfunction or distress (Derogatis, Meyer, & King, 1981; Rosenheim & Neuman, 1981; Schreiner-Engel & Schiavi, 1986; Sadock, 1995).

Psychopathology may be a cause, a consequence, or a concomitant of sexual dysfunction. In the first case, psychopathology, it can be hypothesized, operates as a predisposing, precipitating, and/or maintaining factor. For instance, work has addressed the conceptual relationship between panic disorder and sexual dysfunction (Sbrocco, Weisberg, Barlow, & Carter, 1997). Other studies have focused on the role of obsessive-compulsive disorder in relation to the degree of sexual distress and dysfunction (e.g., Freund & Steketee, 1989; Staebler, Pollard, & Merkel, 1993). Studies have also addressed the well-known association between depression and diminished sexual desire (Schreiner-Engel & Schiavi, 1986). In this case, however, it is unclear whether depression is exerting its influence on sexual desire via biochemical substrates, lowered self-esteem, loss of pleasure and sensual awareness, or other undisclosed variables. Note that sexual desire and arousal problems are a common response to depression, and other sexual dysfunctions occur considerably less often (Masters et al., 1994). Finally, the challenge of untangling etiological factors is exemplified in the association between eating disorders and sexual dysfunction (Renshaw, 1990; Wiederman,

1996). The etiology of sexual dysfunction in individuals with eating disorders includes biomedical factors, possible sexual abuse history, body-image distortion, maturational fears, and sexual phobia (Werlinger, King, Clark, Pera, & Wincze, 1997).

Comprehensive Assessment of Sexual Dysfunction

The assessment of sexual dysfunction, particularly the investigation of its psychophysiological correlates, continues to develop (Ackerman & Carey, 1995; Rowland, 1999). The assessment of sexual dysfunction should include biobehavioral, cognitive, and interpersonal components, even though the nature of the relationships among these components is not yet fully understood.

Sexual Assessment

The hallmarks of adequate sexual assessment can be classified into three major areas. First, the assessment of sexual dysfunction requires systematic investigation across three components of response: verbal or self-report (cognitive-subjective), behavioral indexes, and physiological measurement. This tripartite assessment approach is sensitive to the intricacies of sexual response and provides important data regarding response congruences and discrepancies that are of value in hypothesis testing and treatment planning.

Second, sexual assessment should attend to four distinct but ultimately related systems of sexuality: (1) biological/medical/health status; (2) the phases of sexual response (e.g., desire, arousal, orgasm); (3) individual psychological makeup, including personality, developmental liabilities, mood-state variables, and psychopathology; and (4) interpersonal issues, relationship status, and partner variables. Although each of these systems is important to an individual's sexuality, different system combinations will predominate in a given case.

Third, comprehensive assessment involves two essential processes that should be used in all cases: preintervention assessment (the composite of procedures to arrive at a final formulation and treatment plan) and continuous assessment (the ongoing monitoring of selected components and systems throughout the treatment and follow-up phases). This continuous assessment is a constant check on

the accuracy of one's formulation, provides a system of feedback for treatment progress, and offers a method of outcome evaluation.

Self-Report Techniques

Clinical Interview. The interview remains the most common and useful assessment technique for obtaining relevant data and for developing an initial problem formulation. This format can be optimized by imposing a systematic (but sensitive) interview strategy that, in addition to relevant assessment areas, considers the level of sexual knowledge and the comfort of the couple in talking about their sexual habits and beliefs. The clinical interview represents the first important step in conducting a sexual assessment. This first formal contact with the patient will determine whether sufficient data are available to proceed with an objective assessment and whether the clinician has engendered sufficient trust, professional respect, and therapeutic hope to allow the patient or couple to participate actively in an assessment process. Clinical interviewing for sexual problems is a highly sensitive area that demands judgment, flexibility, and common sense.

In addition to the goal of problem specification and analysis, the aims of the initial interview are (1) to establish a therapeutic alliance that emphasizes comfortable communication between patient and therapist about sexual matters in particular; (2) to generate hypotheses about the development and maintenance of the sexual disorder; (3) to address factors that would make sexual assessment inappropriate at this time (e.g., medical problems, other psychopathology, severe marital conflict); (4) to arrive at a tentative formulation about the case; and (5) to develop a plan for the more formalized, objective assessment of the individual and his or her partner.

Specific guidelines and formats for sexual interviewing can be found in Carey and Gordon (1995), Sadock (1995), and Wincze and Barlow (1997). Catania (1999) provides a state-of-the-art review of sexual assessment, including issues related to reporting bias. Similarly, several semistructured interviews are available for either broad-based or problem-focused sexual assessment (see Ackerman & Carey, 1995; Derogatis, 1997).

Self-Administered Questionnaires and Inventories. Pencil-and-paper assessment tools that provide more detailed and somewhat more

objective data continue to be developed. These instruments play an important role in sexual assessment and treatment evaluation, particularly in view of the expense and specific difficulties in obtaining valid and reliable physiological measures. The variety and range of questionnaires and inventories are too numerous to discuss separately, but the *Handbook of sexuality-related measures* provides a complete listing and analysis of scales and inventories for various areas of sexuality (Davis, Yarber, Bauserman, Schreer, & Davis, 1998). Many of these instruments have been subjected to psychometric analysis and test development procedures. Table 3 provides a brief listing of current scales and the areas of sexuality that they assess. Some provide an individual profile analysis of various aspects of sexual function and dysfunction (Derogatis, 1978, 1997), whereas others focus on sexual preferences and specific patient populations (Brockway & Steger, 1980; Purnine, Carey, & Jorgensen, 1996; White, 1982). Although all suffer the weaknesses and threats to validity that are common to most self-report instruments, their judicious use offers a range of information sometimes unavailable in the standard interview, allows quantifying the assessment data, and some instruments provide a method of continuous assessment of pre-post-therapy changes.

Self-Monitoring and Other Recording Techniques. Self-monitoring is a well-known behaviorally oriented technique (Bornstein, Hamilton, & Bornstein, 1986). Writing methods and other recording techniques can be used in both assessment and treatment (e.g., Apfelbaum, 1995). Within the area of sexual dysfunction, the typical format requires the couple to record individually and sometimes to evaluate their intimate and sexual activity, including the level of sexual desire and arousal, affectional behaviors, sexual initiation responses, quality and frequency of orgasmic experience, pleasure, and perceived partner satisfaction. Cognitive, emotional, or more qualitative data may also be collected. Besides providing a level of external validity, the flexibility of these procedures permits specific hypothesis testing, as well as a quantifiable means of measuring treatment progress. Conte (1986) describes the most popular sexually oriented self-monitoring procedures, and Apfelbaum (1995) provides an interesting example of writing assignments within the context of couple treatment for low sexual desire.

Table 3. Questionnaires and Inventories Used in Sexual Assessment

Assessment area	Questionnaire
Sexual knowledge and attitudes	Sexual Knowledge Inventory (Casselman & Durham, 1979); Aging Sexuality Knowledge/Attitude Scale (White, 1982); Sexual Opinion Inventory (Gilbert & Gamache, 1984); Sexual Attitudes Scale (Hendrick & Hendrick, 1987)
Sexual arousal, anxiety, and preferences	Sexual Arousability Inventory—Expanded Version (SAI-E; Chambless & Lifshitz, 1984); Sex Anxiety Inventory (Janda & O'Grady, 1980); Sexual Aversion Scale (Katz, Gipson, Kearl, & Kirskovick, 1989); Inventory of Dyadic Heterosexual Preferences (Purnine, Carey, & Jorgensen, 1996); Intimacy Scale (Waring & Reddon, 1983)
Sexual dysfunction and satisfaction	Derogatis Interview for Sexual Functioning—Self-Report (Derogatis, 1997); Derogatis Sexual Functioning Inventory (Derogatis, 1978); Marital Satisfaction Inventory—Revised (Snyder, 1997); Sexual Dysfunction Scale (McCabe, 1997); Inventory of Sexual Satisfaction (Rust & Golombok, 1986); Pinney Sexual Satisfaction Inventory (Pinney, Gerrard, & Denny, 1987); Sexual Interaction Inventory (LoPiccolo & Steger, 1974); Index of Sexual Satisfaction (Hudson, Harrison, & Crosscup, 1981)

Direct Behavioral Observation

In the light of the serious ethical and legal problems associated with the direct observation of a patient's sexual activity, such measures do not represent a viable clinical assessment option. Although the pioneering work of Masters and Johnson (1966) illustrates an exception to this rule, others received much negative criticism for their questionable assessment practices (Hartmann & Fithian, 1974). The use of sexual surrogates, initiated but later abandoned by Masters and Johnson, is similarly frowned upon (Apfelbaum, 1977) and fraught with potential legal, moral, and interpersonal tangles. However, the direct observation of nonsexual but related behavior and interaction patterns (e.g., communication skills, expression of intimacy) can provide important assessment data that may lend indirect support to hypothesized sexual problem areas (see Larson, Anderson, Holman, & Niemann, 1998; McCabe, 1997; Purnine & Carey, 1997).

Biomedical and Psychophysiological Methods

Biomedical Assessment. From multiple perspectives (ethical, evaluative, and therapeutic), a case of sexual dysfunction is outside the domain of the mental health professional until biomedical factors have been addressed by medical personnel. The medical workup represents an essential prerequisite for formal psychological assessment of

sexual dysfunction and also reflects the need for a working relationship with a specialist physician (urologist, gynecologist) (see Perelman, 1994). Moreover, the biomedical evaluation has become increasingly important as the issue of sexuality has interfaced to a greater extent with those of advancing age, illness and disability, medication and drug use, and our increased biological understanding of arousal disorders (Laan & Everaerd, 1995; Melman & Gingell, 1999). This emphasis has mirrored a growing sophistication in the biomedical assessment of erectile dysfunction and the availability of "urology-based evaluation centers" that specialize in the comprehensive assessment and multidisciplinary treatment of these disorders (Tiefer & Melman, 1989).

The medical data base is typically derived from four subareas of assessment: (1) a thorough medical and health history; (2) physical examination; (3) laboratory evaluation; and where indicated, (4) specialized clinical laboratory testing. These procedures have been outlined and described by a number of clinicians (Kolodny et al., 1979; Schover & Jensen, 1988; Tiefer & Melman, 1989). It is also recommended that each partner undergo the complete medical workup, including endocrine testing (e.g., plasma testosterone, serum estrogens, pituitary function) (see Sadock, 1995). Specialized laboratory evaluations have focused on penile response assessments, including vascular testing (e.g., penile arterial pressure, doppler sonography and cavernosography, or penile venous outflow),

neurological testing (e.g., nerve conductivity), and nocturnal penile tumescence/rigidity testing (see Rowland & Slob, 1995).

Psychophysiological Assessment. Although focused initially on basic sex research, quantitative measurement of the psychophysiological aspects of arousal and orgasm is an increasingly active domain of sexual assessment. This complex area continues to receive considerable investigative attention, and several methodological and nontechnical reviews have appeared in the literature (Ackerman & Carey, 1995; Rosen & Beck, 1988; Rowland, 1999). Psychophysiological assessment of female sexual dysfunction continues to lag behind, even though promising developments have occurred (Andersen & Cyranowski, 1995; Laan & Everaerd, 1995; Rosen & Beck, 1988).

There is also a growing understanding that a simple dichotomy between biogenic and psychogenic arousal disorders is artificial, misleading, and inadequate in addressing actual clinical cases. This view has been replaced by a biopsychosocial approach that incorporates a multivariate perspective. In addition, there is greater clarity that male arousal disorders result from the culmination of various interacting vascular, hormonal, neurobehavioral, cognitive-affective, and life-style factors (National Institutes of Health, 1993). Therefore, to delineate etiology, "state of the science assessment" requires input from several disciplines (see Ackerman & Carey, 1995). Clinical psychophysiology has developed an important role in this process.

The most commonly used psychophysiological procedure in diagnosing erectile disorder is nocturnal penile testing (NPT) during the sleep cycle. NPT is based upon the rationale that naturally occurring REM-related erectile responses will be exhibited during sleep, particularly because interfering psychological phenomena (e.g., performance demands, interpersonal and emotional conflict) should be inoperative at that time. Those cases with a substantial organic basis typically exhibit impaired or absent erections. Typically, two to three consecutive nights of NPT assessment are required. This evaluation also includes regular sleep-laboratory evaluation to document REM periods and sleep architecture. A less costly but more experimental procedure is that of NPT monitoring during naps (Gordon & Carey, 1995). If portable NPT monitors, "snap gauges," and stamp-ring

testing (which do not verify sleep stages) are used, they should be viewed only as screening devices (Rosen & Beck, 1988). One exception is the "RigiScan Diagnostic Monitor," a computerized device that measures erectile rigidity, tumescence, and duration throughout the sleep cycle (Levine & Carroll, 1994). It is a popular alternative to sleep-laboratory NPT. Related developments include comparing these NPT procedures with visual sexual stimulation and/or with vasoactive penile injections (see Ackerman & Carey, 1995). Overall, however, NPT is best regarded as one component in the comprehensive assessment of erectile dysfunction.

Case Formulation

An important goal of assessment is development of an individual and/or couple "case formulation" (Meyer & Turkat, 1979). Sometimes confused with diagnosis and functional analysis, the case formulation is an attempt to identify and describe the major biological, psychological, and interpersonal components in a case. The formulation should (1) explain the relationship of all of the patient's or couple's problems (sexual and otherwise) to one another, (2) delineate why and how these problems developed and are maintained, and (3) provide specific predictions of the patient's and couple's behavior in the treatment process (Carey, Flasher, Maisto, & Turkat, 1984; Meyer & Turkat, 1979). In essence, the case formulation, based on integrating assessment and historical data, should posit a discrete explanation statement or hypothesis that can be tested clinically and that will then govern the treatment selection, planning, and the treatment process. Difficulties such as noncompliance, symptom fluctuation and relapse, and barriers to a collaborative therapist-patient relationship are anticipated, and one hopes minimized, by relying on this formulation (AuBuchon & Malatesta, 1998). Even though good clinicians from varying orientations formulate their cases at least on an intuitive level (see Rosen & Leiblum, 1995b; Perry, Cooper, & Michels, 1987), it is good clinical practice and a fruitful clinical discipline to actually record one's case formulation in a written format. Examples of cognitive and behavioral formulations can be found in Bruch and Bond (1998), Persons (1989), and Turkat (1985). Psychodynamic, systems, and ego analytic case formulations are discussed in Rosen and Leiblum (1995b).

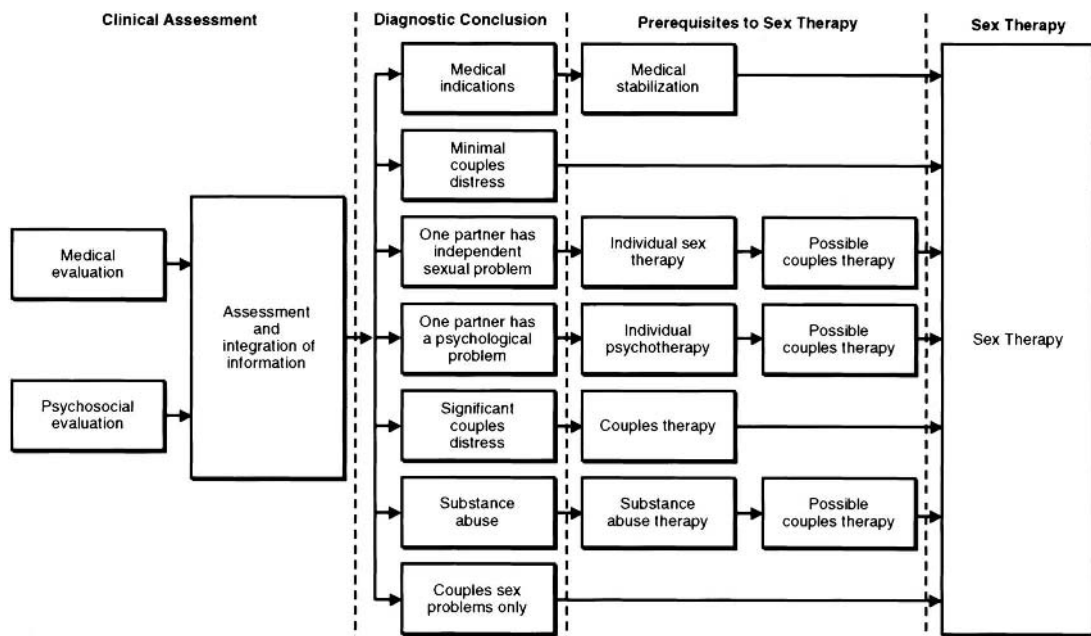

Figure 5. A flow chart depicting “Seven Critical Pathways” or sequences of clinical events based on assessment, diagnosis, and case formulation. From *Enhancing Sexuality: A Problem-Solving Approach*. Copyright 1997 by Graywind Publications. Reproduced by permission of publisher, The Psychological Corporation. All rights reserved.

The case formulation is used in two major ways: (1) to guide treatment selection and/or (2) to orchestrate and pace the process of psychological treatment. With respect to general treatment selection, Wincze and Barlow (1997) offer a useful flow chart, described as “Seven Critical Pathways,” which outlines different sequences of clinical events that depend on diagnosis and case formulation. As shown in Figure 5, the flow chart assumes that—in addition to sexual assessment findings—the clinician has detailed assessment data regarding the medical status of the patient and his or her partner, the quality of the couple’s relationship, and a psychological understanding of the client and his or her partner. As illustrated, the treatment pathways will differ as a function of (1) whether a medical basis for the problem is identified, (2) the presence or absence of substance abuse, (3) the degree of concomitant individual psychopathology, and (4) the degree of couple distress.

In the second situation, the case formulation is used to guide, pace, and organize psychological treatment, which eventually, may include sex therapy *per se*. In this way, the formulation assists the

clinician in focusing first on more central or keystone problem areas, as well as anticipating resistance and potential areas of noncompliance. For example, the formulation in the case of an anxious woman who displays primary orgasmic disorder in addition to other problem areas (e.g., high anxiety about self-disclosure and avoidance of nonsexual intimacy) might indicate a general fear of relaxing personal control. This general fear may relate to a developmental history showing rigid and perfectionistic parents who discouraged and punished even minor displays of relaxing personal control (e.g., laughing, sharing personal information). In this case, then, the patient would be overwhelmed by and resist behavioral prescriptions for masturbation training to promote orgasmic responding. Instead, therapeutic emphasis might need to focus first upon (1) the therapist–patient relationship, helping the individual to begin to trust and relax personal control within that context and (2) ways to encourage and teach the individual to relax personal control in other nonsexual situations (e.g., dancing, receiving massage, relaxation training). Only then might this individual be ready

for sex therapy *per se* (see AuBuchon & Malatesta, 1998; Bruch & Bond, 1998).

Other case formulations will span the range of etiologies. At one end of the continuum, a primary biological formulation for a case of secondary erectile disorder in a severely diabetic male with peripheral neuropathology who has been non-responsive to oral and penile injection pharmacotherapy might necessitate penile implantation and couples sex therapy of a primarily educational and supportive nature. At the other end of the continuum, a case of low sexual desire in an individual who survived childhood sexual trauma might require initial treatment for posttraumatic stress disorder and/or a more exploratory psychotherapy within the context of a trusting therapeutic relationship (Golden, 1988). This particular treatment sequence, however, may not be indicated in another case of childhood sexual trauma (McCarthy, 1998). The process of case formulation within the area of sexual dysfunction is still within its infancy. The work of Rosen and Leiblum (1995b) provides examples of this important clinical skill.

Treatment of Sexual Dysfunction

Overview

As a semantic label, sex therapy is a general term for a variously defined group of educational, behavioral, cognitive, and other psychotherapeutic procedures for (1) improving sexual knowledge, communication, and sexual attitudes; (2) decreasing inhibitions, fears, and skill deficits associated with sexual activity; (3) improving the range of sexual response, including sexual desire, arousal, and orgasm, as well as the biobehavioral, cognitive, and affective components of this experience; and (4) enhancing sexual satisfaction, pleasure, and general intimacy in both the patient and his or her partner.

In actuality, sex therapy encompasses a variety of psychotherapeutic methods and procedures ranging from more directive approaches to skill-building and couples therapy. In fact, there has been a general blending and integration of sex therapy procedures with marital therapy techniques (Baucom et al., 1998; Weeks & Hof, 1987). Although the multidetermined nature of human sexuality, however, affords therapeutic contributions from a number of disciplines and approaches, it

also makes it impossible to encompass sex therapy under a single theoretical umbrella. As a consequence, the sex-therapy literature reveals a multiplicity of labels for similar therapeutic activities and a scientific orientation that ranges from atheoretical to multitheoretical (Rosen & Leiblum, 1995a,b). A “mixed model pragmatic approach” is currently popular (Segraves, 1998), and the move toward empirically supported treatments has helped to delineate the most effective interventions for sexual dysfunction (Baucom et al., 1998). This section provides a brief overview of the most common sex-therapy interventions.

General Components of Sex Therapy

Education. The first component of sex therapy is providing accurate and sensitive information about individual and couple sexuality. With few exceptions, an effective sex-therapy plan should ascertain that the presenting couple or individual adequately understands human sexual response, especially with regard to the presenting complaint. It is not uncommon to find well-educated men and women who are misinformed about a variety of sexual issues—including, for example, age changes in sexual function, gender differences in sexual arousal patterns, and the competing influences of drugs, mood states, and couples conflict on sexual desire and responsiveness. Education also helps to challenge negative beliefs about sex and sexuality and may represent a starting point for cognitive interventions (Carey & Gordon, 1995).

Psychoeducation also helps to prepare the couple for active participation in the treatment process. Providing sexual information may also function as an initial step in attitude change, in permission giving (e.g., for sexual experimentation), and in helping the individual or couple to understand the problem. Therefore, psychoeducation is limited only by the therapist’s creativity and the resources available and may reflect any format combination, including books (Heiman & LoPiccolo, 1988; McCarthy & McCarthy, 1998; van Lankveld, 1998), shared readings, and films (see Winks & Semans, 1997). Finally, note that education is a component of each of the empirically supported interventions described by Baucom et al. (1998).

Communication, Intimacy, and Relationship Skills Training. In the past, issues of communication and intimacy were often underemphasized in sex-therapy literature. In actuality,

Masters and Johnson's (1970) treatment approach emphasized interventions that improved couple communication and nongenital physical intimacy. The commonality of desire disorders also necessitated a greater therapeutic focus on communication and other relationship issues. Thus, because the strength of the relationship is ultimately tied to the couple's motivation to participate actively in treatment, most sex-therapy programs routinely include systematic attention to issues of communication, intimacy, and general relationship skills (Baucom et al., 1998; Beck, 1995; Heiman, 1986; Rosen & Leiblum, 1995a,b).

Built on the education component of sex therapy, communication skills and relationship therapy ranges from training in assertiveness and problem solving to negotiation and conflict management skills. More fundamentally, from the beginning of assessment and throughout the treatment process, "the therapist should serve as a model of good communication by active listening, display of empathy, asking clients to express themselves clearly, and other such social and communication skills" (Carey & Gordon, 1995, p. 191). Where necessary, interventions may extend to more general relationship issues (e.g., life-style, power and control). Finally, training in general intimacy skills may be indicated where individuals and/or couples are focused excessively on genital sexual expression at the expense of other kinds of intimacy (Malatesta, 1989).

Structured Behavioral Activities. Popularized by Masters and Johnson (1970), the prescription of a systematized plan of structured sexual activities remains an integral feature of sex therapy. Much as a desensitization hierarchy does, the activities typically represent a graduated series of sexual tasks that may begin with individual body-awareness exercises or masturbation, progress to mutual nongenital touching, and finally culminate in partner-guided sexual intercourse. The term *sensate focus* was used by Masters and Johnson (1970) to describe a set of behavioral exercises designed to help a couple develop sensual awareness and focus on sexual sensations, rather than sexual performance. The goal in this case may be to improve body image and response, to minimize and control anxieties and distractions associated with sexual activity, and to help the couple gradually to shape and redevelop their sexual relationship. This is why, for example, a ban on attempting intercourse and genital touching may be suggested

to some couples who present with sexual dysfunction. This approach allows a couple to begin focusing on and enjoying other aspects of sexuality that are often ignored (e.g., sensual communication, nongenital touch, and massage) without anxiously wondering whether or not erection or lubrication—and thus intercourse—is forthcoming.

In other cases, the initial behavioral prescription may involve graduated masturbation training to facilitate orgasmic responding or to improve ejaculatory control (Baucom et al., 1998; LoPiccolo & Stock, 1986; Masters et al., 1994). Interventions may be individual, partner-assisted, or couples-based. In cases of sexual aversion, phobia, and sexual pain disorders, the structured behavioral exercises may most closely resemble a traditional desensitization or *in vivo* exposure and mastery hierarchy (see Wincze & Barlow, 1997).

Another aspect of behavioral prescriptions concerns the extent to which couples can (1) disengage from extraneous stimuli, such as work or children; (2) promote an interesting and creative atmosphere for sexual expression; and (3) focus on individual and partner sexuality. In some cases, activity scheduling is needed to encourage "intimacy time" when the partners are not fatigued or preoccupied with other matters. Environmental issues may also reflect ways to help couples expand and enhance their repertoire of sexual stimuli, including exposure to sensitive erotica (Robinson, Manthei, Scheltema, Rich, & Koznar, 1999).

Biomedical Treatments. Although biomedical approaches are not necessarily under the guise of sex therapy *per se*, they have acquired an important role in treating sexual dysfunctions that reflect either a primary organic or mixed etiology. Pharmacotherapy and surgical interventions have been two major treatments. Oral pharmacotherapy for sexual dysfunctions has developed dramatically and has focused primarily on treating erectile disorders (Marks, Duda, Dorey, Macairan, & Santos, 1999), premature ejaculation (Kim & Seo, 1998), and mixed female sexual dysfunctions (Kaplan et al., 1999). Before the development of oral medications such as Viagra, the self-injection of vasoactive substances (e.g., papaverine and phentolamine) directly into the intracavernous area of the penis to induce erection was heralded as a breakthrough in treating men with organic, mixed, and even chronic psychogenic erectile disorder (Kiely, Williams, & Goldie, 1987). Whether this therapy

was administered by the patient or a physician, however, it has significant problems (Lehmann, Casella, Blochlinger, & Gasser, 1999). Treatment dropout rate may range up to 60%, side effects may be significant (e.g., prolonged erection, liver function abnormalities), success is variable, and self-injection poses a formidable challenge for the patient (e.g., injections need to be self-administered before sex; Althof et al., 1989; Sexton, Benedict, & Jarow, 1998). Recent work includes study of alternative delivery systems for the vasoactive substance (Segraves, 1998).

A range of SSRI and heterocyclic antidepressant medications has been investigated in treating sexual dysfunction (Riley & Riley, 1993; Strassberg, Brazao, Rowland, Tan, & Slob, 1999). In addition, androgen-replacement and estrogen-replacement therapies are increasingly helpful to postmenopausal women, and there is increasing agreement that androgens play a key role in female sexuality (Davis, 1998).

Surgical treatments of erectile dysfunction represent a reasonable alternative when pharmacotherapy fails (Shabsigh, 1998). This treatment usually involves surgical implantation of one of three types of penile prostheses: (1) the semirigid, which results in the penis being permanently erect, (2) the adjustable, which also causes a permanent erection but allows for the penis to be placed in different positions for sexual intercourse, and (3) the inflatable, which contains an implanted pump for controlling the erection by inflating a storage reservoir located in the penis. Although patients may derive benefit from these surgical treatments (Sexton et al., 1998; Tiefer, Pederson, & Melman, 1988), much of the evaluative research has employed global measures of patient satisfaction and has not addressed partner satisfaction and psychosocial adjustment (see Lehmann et al., 1999). In this regard, psychosocial factors may interfere with successful postoperative adjustment, and these procedures have potentially serious side effects (Kaufman, Kaufman, & Borges, 1998).

Taken together, developments in biomedical treatment provide sex therapists with unprecedented opportunities for educating women and men about the importance of psychosocial factors in evaluating and treating sexual dysfunction (Perelman, 1998). In addition, much work needs to be done to determine (1) predictors of success for medical treatments, (2) the interactive and sequential roles of biological and psychosocial interven-

tions, and (3) the positive and negative "psychosocial side effects" of pharmacological treatments (Segraves, 1998; Wise, 1999).

Summary and Concluding Comments

Sexual dysfunctions have been recognized as a major public health problem that deserves increased study, evaluation, and intervention. Developments in biological understanding and treating sexual dysfunction have spurred what may be the next sexual revolution by attracting a huge and more diverse population of men and women who seek help for sexual problems. Changes in age demographics have contributed to this diversity because older adults, who are more likely to be coping with chronic health problems and taking medication, are presenting with more complex and multifaceted sexual dysfunctions. In addition, the increased focus on the sexuality of women and physically challenged individuals must remain a priority. Similar attention must be devoted to the unique sexual needs and problems associated with ethnicity and homosexuality.

To meet these challenges, a range of important developments has occurred in the field of sexual dysfunction. Multivariate approaches hold promise for the future, and assessment of sexuality, including psychophysiological methods, will continue to represent an important clinical function. Increased understanding of psychosocial etiology and developments in empirically supported treatments of sexual dysfunction will help to maintain the importance of psychosocial interventions. On the other hand, because there has been a "marked decline in the number of studies evaluating psychological, as opposed to medical or surgical approaches to treatment" (Rosen & Leiblum, 1995a, p. 885), some have questioned if sex therapy research has "withered on the vine" (Hawton, 1992). Funding for psychosocial outcome research will continue to be a challenge, but developments in biomedical treatment and increased focus on relationship interventions offer sex therapists a range of new opportunities in basic and clinical sex research. Thus, sex therapists have a responsibility to contribute to the vitality of the field. Sex therapists also have a responsibility to respect the continuity of their patients' sexual life-styles and to be ready to explore methods of meeting the

sexual needs of diverse individuals and couples. Finally, sex therapists have an ethical and professional responsibility to maintain firm knowledge of basic and clinical research in sexuality and an empirical openness to scrutinize and alter their treatments where appropriate.

Sexual Deviation: Paraphilias

**Richard D. McAnulty, Henry E. Adams,
and Joel Dillon**

Introduction

Sexuality has always been viewed as a force that must be tightly controlled and regulated. Sexual behavior has been considered a legitimate topic of scientific inquiry only for the past 50 years, beginning with Alfred Kinsey's landmark surveys (Bullough, 1998). Before that time, sexuality and its problems were to be regulated by the church, the government, or medicine. Accordingly, sexual behavior that deviated from the established norm, however it was defined at the time, was declared sinful, criminal, or sick. Deviant behavior, then, called for penitence, punishment, or a cure. This historical heritage still influences our thinking about sexual deviation. Do persons with sexual deviation suffer from an evil nature, a criminal/psychopathic disposition, or a mental illness?

We do not presume to answer such a question because, like most questions relating to sexual behavior, it hinges on personal values and beliefs. There are currently no universal and objective criteria for evaluating the adaptive value of sexual attitudes and practices. Outside of sexual homicide, no sexual behavior is universally deemed dysfunctional. Although most definitions of sex-

ual disorders emphasize that the associated patterns of sexual arousal deviate from normative patterns (hence the term *sexual deviations*), there are presently no clear criteria for defining normal sexual arousal or behavior. Definitions of what is entailed under the heading of "normal" vary over time and across cultures. Sexual norms change, as illustrated by the shift in professional and societal attitudes toward homosexuality. Whereas homosexuality was classified as a sexual deviation in the 2nd ed. of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II; American Psychiatric Association [APA], 1968), it has been omitted from the most recent versions of the official psychiatric nomenclature (APA, 1987, 1994). The rationale for excluding homosexuality from the category of sexual deviation category was apparently the lack of evidence that homosexuality *per se* is a harmful dysfunction (Wakefield, 1992). Curiously, the same line of reasoning has not been applied to other "disorders" such as fetishism and consensual sadomasochism. We agree with Laws and O'Donohue (1997) that such conditions are not inherently harmful and their inclusion in this category reflects an inconsistency in classification.

The topic of sexual deviation has the distinction of being one of the most controversial in clinical psychology and related fields. Few disorders elicit as much curiosity and outrage as sexual deviations, or *paraphilias*, as they are officially known (APA, 1994). Numerous cases of sexual offenses and the ensuing sensational media coverage have rekindled the public's fascination and alarm. Studies of victims (Koss, Gidycz, & Wisniewski,

1987) and perpetrators (Abel et al., 1987) reveal that the prevalence of sexual offending is higher than previously believed. Finally, international computer network services that have sexually explicit sites, chat rooms, and special interest groups have brought sexual deviation out of the closet and into cultural awareness. Themes of sexual deviation are evident in several mainstream films, and they are regular features in televised talk shows and documentaries.

Unfortunately, there remains a great amount of undocumented information and often misinformation about paraphiliac disorders. More than ever before, there is a need for sound research on sexual deviation. There are many unanswered questions about the features, etiologies, and effective treatments of the DSM-IV paraphilias. As we reviewed the research literature to update this chapter, we were surprised and disappointed that few advances have occurred in our understanding of most sexual deviations. Most research in the area has concerned nonconsenting paraphiliacs, namely, child molesters and rapists. The attention to these problems is clearly warranted, but we still have much to learn about other paraphilias that may be even more prevalent. Additionally, these other sexual deviations may sometimes be associated with sexual violence and coercion, which renders them equally legitimate and important topics of study.

The objective of this chapter is to provide an overview of paraphiliac disorders. This presentation begins with a discussion of issues related to classifying and assessing these disorders. The empirical literature pertinent to specific paraphilias is subsequently presented with an overview of etiological theories. Treatment strategies will be briefly covered, followed by a summary of legal and professional issues.

Definitions and Classification

The diagnostic criteria of paraphilias have changed considerably during the past 30 years. In the original DSM (APA, 1952), these disorders were subsumed under the heading of "sociopathic personality disturbance." The following edition of the official psychiatric nomenclature, the DSM-II (APA, 1968), defined sexual deviations as a type of personality disorder, though they were no longer classified under sociopathic personality disorders. Specific subtypes (e.g., pedophilia, fetishism) were introduced in the DSM-II. In both early clas-

sification schemes, the diagnosis was based on inferred personality dynamics, in accord with the prevailing psychoanalytic formulations of these disorders.

Historically, psychoanalytic writers favored the term *perversions* (Freud, 1953; Stoller, 1975a), but this term has been relegated to the vernacular in recent years. Sexual deviations were renamed *paraphilias* and were classified in a separate category of *psychosexual disorders*, along with sexual dysfunctions, in the 3rd ed. of the DSM (APA, 1980). This revision paralleled the shift toward an atheoretical nosology. The term *paraphilia* was borrowed from Karpman (1954) and was adopted because it was more descriptive (specifying the aberration, *para-*, to which the person is attracted, *-philia*) than previous labels. The new classification schemes, including the DSM-III-R and DSM-IV (APA, 1987, 1994), do not assume that the deviant sexual interests necessarily pervade the individual's entire range of interpersonal functioning or personality. The defining features of the disorder may be limited to the individual's sexual behavior and causes minimal impairment in other areas of functioning. A noteworthy change in the DSM-III-R from the previous edition is the removal of the criterion specifying that the given paraphilia is the *preferred* or *exclusive* means of attaining sexual pleasure. Therefore, individuals may prefer "normal" heterosexual intercourse but receive paraphiliac diagnoses if they have fantasized about or actually exposed their genitals in public on occasion during the previous 6 months (or longer).

According to the DSM-IV, paraphilias entail arousal that often interferes with "the capacity for reciprocal, affectionate sexual activity" (APA, 1994, p. 524). The preferred sexual stimulus is typically highly specific, and it may be necessary for sexual functioning and, thus, may become a major focus in the individual's life. The diagnosis requires that individuals have acted on their deviant urges or are distressed by them and that the pattern of arousal is evident for a minimum of 6 months. In this nosology, paraphilias are characterized by intense, recurring sexual urges and fantasies related to (1) nonhuman objects (e.g., womens' undergarments), (2) suffering or humiliation of oneself or one's partner in a manner that is not merely simulated (e.g., bondage), or (3) children or other nonconsenting partners. Paraphilias are almost exclusively seen in males. The specific types of paraphilias are listed in Table 1.

Table 1. DSM-IV Paraphilias

Disorder	Sexual fantasies, urges, and/or activities
Exhibitionism	Exposing to an unsuspecting stranger
Fetishism	Use of a nonliving object (not limited to cross-dressing)
Frotteurism	Touching or rubbing against a nonconsenting person
Pedophilia	Sexual activity with a prepubescent child
Sexual masochism	Being humiliated, beaten, bound, or otherwise made to suffer
Sexual sadism	Inflicting psychological or physical suffering
Transvestic fetishism	Cross-dressing
Voyeurism	Observing an unsuspecting person is who disrobing or having sex
Paraphilia Not Otherwise Specified	
Telephone scatologia	Making obscene phone calls
Necrophilia	Sexual activity with corpses
Partialism	Exclusive sexual focus on part of the body
Zoophilia	Bestiality or sex with animals
Coprophilia	Sexual arousal to feces
Klismaphilia	Sexual arousal to enemas
Urophilia	Sexual arousal to urine

Gender identity disorders, formerly known as *transsexualism*, are no longer classified as sexual disorders. For historical reasons, these disorders are included in the same section as sexual dysfunctions and paraphilias in the DSM-IV. The essential feature of gender identity disorder involves incongruence between one's biological sex and gender identity (the individual's subjective experience of his or her sex), combined with persistent discomfort with one's biological sex. Consistent with the DSM-IV, we provide an overview of gender identity disorder in this chapter.

Issues in Classifications

Though the DSM-III-R and DSM-IV classification schemes represent significant improvements over previous nosologies, they are not uniformly

accepted by experts on paraphilia. For example, Money (1984, 1986) argued that there are more than thirty subtypes of paraphilias; the majority of them would be classified as "paraphilia not otherwise specified" in the DSM-IV. Other criticisms involve the lack of information provided by some diagnostic labels and the false impression of homogeneity implied by diagnostic categories.

Several other controversies exist in the classification of paraphilias. As previously mentioned, homosexuality is no longer classified as a sexual deviation, although some specialized books continue to include sections on homosexuality (e.g., McConaghy, 1993). As evident in Table 1, the paraphilia category includes a heterogeneous group of conditions. We question the validity of including such disparate conditions as fetishism and pedophilia in the same category. Although both are socially unacceptable to most people, pedophilia involves nonconsenting and harmful sexual behavior, whereas fetishism is usually victimless (unless the person steals the fetish from an unsuspecting person). We believe that the etiologies of these conditions are also very different. These are empirical questions that merit attention and scrutiny.

An important distinction should be made between sexual behavior and preference. Sexual activity is not always indicative of sexual preference; some homosexual males may engage in heterosexual intercourse, although they clearly prefer male sexual partners (and may resort to homosexual fantasy during encounters with females). As previously noted, sexual preference is no longer required as a diagnostic criterion for paraphilia. Sexual preferences, values, and behavior may be incongruent, as evidenced by the observation that some paraphiliacs find their erotic interests despicable. Yet, they regularly engage in these "immoral" acts. Hence, overt sexual behavior is not perfectly correlated with sexual preference or arousal. Subjective distress over erotic preferences, however, is clearly not a sufficient criterion for defining paraphiliac arousal (i.e., some paraphiliacs resent interference by social agencies and view their behavior as enjoyable and normal). This view is recognized in the DSM-IV because subjective distress is not a requisite for a diagnosis of paraphilia.

Other issues center on such questions as whether rape is a sexual offense or exclusively an act of aggression. Though some feminists have emphasized the aggressive component of rape, there is

clearly a sexual element in at least some forms of rape. The term *rape* is at best ambiguous because the legal and political aspects of this concept have hindered a neutral, scientific definition of this behavior. The vast majority of researchers and clinicians who work with rapists tend to classify rape as a paraphilia (Freund, 1990; Laws & O'Donohue, 1997). Abel and Rouleau (1990) also criticized the exclusion of rape from the DSM because they believe that rapists display "recurrent, repetitive, and compulsive urges and fantasies to commit rapes" (p. 18), thereby qualifying it as a paraphilia.

Another issue pertains to the relationship between incest and pedophilia. There are some significant differences between these categories; for example, in pedophilia, a prepubertal partner is often involved, which may not be the case in incest. Finally, controversy continues to exist over the occurrence of multiple deviations. Although a number of authorities argue that the presence of multiple paraphilias in one person is not uncommon (e.g., Abel et al., 1987; Langevin, 1983), such a view is not unanimously accepted. Money (1984) argued that it is rare "for a person to have more than one paraphilia, or to change from one to another" (p. 166). Based on clinical experience, McConaghy (1993) also concluded that most paraphiliacs have a single preferred deviation, although they may occasionally experiment with others. This issue remains unresolved. Furthermore, the belief that all or most paraphiliacs progress from minor disorders (such as exposing their genitals) to major disorders (such as child molestation or rape) is not well documented and is controversial. These issues will be addressed in more detail in the discussions of the specific disorders.

Assessment of Paraphiliac Disorders

Although a detailed overview of assessment strategies with this population is beyond the scope of this discussion, a brief summary is essential. Assessment, or measurement, is the technological implementation of a classification system (Adams & Haber, 1984). In paraphilia, there are four major areas to be assessed: (1) sexual arousal (to deviant and normal stimuli); (2) heterosexual skills, including sexual knowledge, experience, and cogni-

tive distortions; (3) heterosocial skills (e.g., dating skills, assertiveness); and (4) gender identity and behavior. A comprehensive evaluation of these areas is essential for classification, treatment selection, and implementation (Malatesta & Adams, 1986; McAnulty & Adams, 1992). Assessment results should facilitate the determination of the person's ability to engage in reciprocal affectionate activity with a partner and the nature of sexual urges, fantasies, and erotic preferences.

The most common methods include interviews, questionnaires and other self-report measures, and penile plethysmography. Though useful information may be obtained via self-report measures, these methods suffer from a number of problems. Self-report measures are notoriously sensitive to the patient's response set, biases, and motivation. As has been widely documented, paraphiliacs frequently tend to minimize, and even deny, their deviant sexual interests and behaviors (Haywood & Grossman, 1994; Rosen & Kopel, 1977). Second, such instruments as the Minnesota Multiphasic Personality Inventory (MMPI) are notoriously insensitive to the vagaries of paraphilias (Erickson, Luxenberg, Walbek, & Seely, 1987; McAnulty, Adams, & Wright, 1994). Other psychometric tests for evaluating paraphiliacs such as the Clarke Sexual History Questionnaire (Paitich, Langevin, Freeman, Mann, & Handy, 1977) and the Multiphasic Sex Inventory (Nichols & Mollinder, 1984) are available but all are transparent and prone to response biases such as social desirability.

Among the various measures of sexual arousal, penile plethysmography (entailing the direct measurement of erectile responses to explicit sexual stimuli), is the most useful (Barbaree & Seto, 1997; Freund & Blanchard, 1989; Rosen & Beck, 1988). As applied to the measurement of deviant sexual arousal, the procedure entails exposing the person to a variety of deviant and nondeviant stimuli to assess sexual responsiveness to these cues. The technique has been used successfully to differentiate heterosexual arousal from homosexuality (Freund, 1963; Tollison, Adams, & Tollison, 1979), pedophilia (Abel, Becker, Murphy, & Flanagan, 1981; Avery-Clark & Laws, 1984), and rape (Quinsey, Chaplin, & Upfold, 1984). For a discussion of the applications and limitations of penile plethysmography, the reader is referred to Murphy and Barbaree (1994) and O'Donohue and Letourneau (1992).

The Abel Screening Test for Sexual Deviation (Abel, Lawry, Karlstrom, Osborn, & Gillespie, 1994) consists of a visual reaction time (VRT) and a subjective rating of sexual interest in a series of slides of both black and white adult males and females, adolescent males and females, very young males and females (2 to 4 years old), young males and females (ages 8 to 10 years), and various types of sexual activities. An Abel Questionnaire that inquires about various types of sexual history items is usually given in conjunction with the Abel Screen. This questionnaire also has a Social Desirability scale, a cognition distortion scale that measures the individual's attempt to justify child sexual abuse, a risk of recidivism scale and a scale for determining the type of deviant sexual activities that the individual admits. The Abel Screen is a comprehensive, cognitive measure of objective (reaction time) and subjective (ratings) sexual interest and preferences, compared to the physiological measure of sexual arousal obtained by the penile plethysmograph. It has several advantages compared to the penile plethysmograph. First, the people shown in the slides are clothed, eliminating concerns about showing pornography to the patient, although nude slides would probably increase its discriminant validity (Wright & Adams, 1991). Second, it does not have invalid protocols if administered properly, compared to the penile plethysmograph where a significant number of patients show "flat lines" or no response. Further, it has been shown that it has good reliability and validity similar to the penile plethysmograph (Abel, Huffman, Warberg, & Holland, 1998). It is a very useful tool, but more research is needed. When used with the penile plethysmograph (they provide similar results), clinicians' confidence in their opinions is greatly enhanced because cognitive and physiological measures indicate similar conclusions.

Characteristics of Paraphilias

The term "sexual deviation" conjures many images that are largely without empirical support. The existing literature suggests that paraphiliac disorders consist of a fairly heterogeneous group with respect to psychosocial adjustment, sexual history, erotic preference, criminal charges, and scores on psychometric tests. The empirical data for some subtypes of this disorder are limited,

whereas significant progress in understanding others has been accomplished. This is largely attributable to the fact that most paraphiliacs come to the attention of clinicians only when coerced by the family or the courts. Furthermore, some types of these disorders are apparently quite rare. Hence, many generalizations about these paraphilias are tentative and need further investigation.

Exhibitionism

The diagnostic criteria of *exhibitionism* in the DSM-IV consist of recurrent, intense urges and fantasies of genital exposure that are enacted or are subjectively distressing. The urges and fantasies center on exposing oneself to an unsuspecting female for sexual excitement. Exhibitionism, or "indecent exposure," it is estimated, accounts for one-third of all sexual offenses in England, Wales, Canada, and the United States (Rooth, 1973; Smukler & Schiebel, 1975). Community and college student surveys reveal that 32–44% of women have been victims of exhibitionists (Cox & MacMahon, 1978; Gittelson, Eacott, & Mehta, 1978). Exposers typically have a large number of victims. Abel et al. (1987) found that their sample of 142 exhibitionists reported having a mean of 514 victims (median: 34); thus, a relatively small number of offenders may account for many victims.

The exhibitionist often experiences an erection and may masturbate during exposure, although this is not always the case. Contrary to popular belief, exhibitionists do not typically seek to shock or frighten their victims. Most exposers report that they hope the victim will derive enjoyment and sexual arousal from the sight of the exposed penis (Lang, Langevin, Checkley, & Pugh, 1987; Langevin et al., 1979). The desire for sexual intercourse with the victim apparently plays a secondary role because less than one-third of exposers claim that they desire sexual relations with the victim (Langevin et al., 1979). In terms of the nature of the act, Abel, Levis, and Clancy (1970) noted that the individual tends to engage in a relatively prolonged sequence of behaviors including (1) reviewing stimulating memories from previous exposures, (2) going to the site of exposure, (3) locating a victim, (4) mentally rehearsing and anticipating the act, (5) exposing himself, and (6) masturbating or achieving orgasm passively in some cases. Most exposers tend to have preferred settings for exposing (e.g., libraries, bus stations)

that may relate to the availability of potential victims and decreased chances of being apprehended.

In their review of the characteristics of exhibitionists, Blair and Lanyon (1981) reported that the age of onset is usually in the early to mid-twenties, although it is commonly assumed that the activity begins in adolescence. One study found that the deviant sexual interest developed before age eighteen in half of the cases (Abel & Rouleau, 1990). The onset is correlated with interpersonal difficulties and is related to a variety of situations. Exhibitionistic behavior declines after age forty, suggesting a "burn out" process like that documented in psychopathic men (Hare, 1998). This decline, however, does not occur in every case, and the authors (R. M. and H. A.) have treated exhibitionists who had exposed well into their sixties. By definition, exhibitionism is limited to males. A few cases of female exhibitionism have been reported; most involve women who are retarded or mentally ill (Hollender, Brown, & Roback, 1977). Females who engage in genital exposure as nude models or striptease should not be labeled exhibitionists because their behavior is not associated with sexual arousal. As Skipper and McCaghy (1970) noted, these women appear nude for financial rather than sexual reasons (McAnulty, Satterwhite, & Gullick, 1995). Therefore, striptease and topless dancers would not have sexual urges and fantasies of exposing themselves to strangers.

One-half to two-thirds of exposers are married, although marital and sexual adjustment is marginal. Intelligence, educational level, and vocational interests do not differentiate them from the general population (Murphy, 1997). In terms of criminal history, including sexual and nonsexual offenses, exhibitionists have a greater than average number of convictions. The majority of them (72%) are for sexual offenses. Blair and Lanyon (1981) stated that most studies were consistent in reporting that exhibitionists suffered from inferiority feelings and were viewed as timid and unassertive, socially inept, and had problems expressing hostility. Other studies (e.g., Langevin et al., 1979), however, have found that exposers are unremarkable in terms of personality functioning. Gender identity is typically masculine, and narcissistic features may be noted in some cases (Lang et al., 1987; Langevin, 1983).

The sexual history of exhibitionists is characterized by a reliance on masturbation during ado-

lescence and adulthood. This is apparently more common in unmarried exposers (Blair & Lanyon, 1981). Sexual dysfunctions such as erectile failure and premature ejaculation are reportedly uncommon (Lang et al., 1987). Although some authors believe that the presence of other sexual deviations is uncommon, several studies reveal that exhibitionism may be associated with voyeurism (Langevin, 1983; Langevin et al., 1979; Rooth, 1973); 50% of the exposers studied by Lang et al. (1987) had been voyeurs, as were 32% of the 241 exhibitionists described by Freund (1990). Exhibitionism may also be associated with frotteurism and obscene telephone calling (Freund & Watson, 1993). Lang et al. (1987) found that 41% of their sample of exposers had engaged in transvestic fetishism. It has been reported that exposers frequently choose children as victims, and it is estimated that between one-fifth and one-third of victims are female children (MacDonald, 1973; Mohr, Turner, & Jerry, 1964). This observation has led some to postulate a relationship between exposing and pedophilia (e.g. Rooth, 1973). However, studies using penile measures of arousal reveal that exhibitionists respond most to adult females and respond minimally to children (Langevin et al., 1979). Furthermore, in pedophilia, the victim is usually known to the offender, close bodily proximity and physical contact are sought, and the incident tends to occur in a private rather than a public setting. The choice of prepubertal victims by some exhibitionists may relate to the fact that children are less likely to report the incident to the police; hence, they are safer victims. We should note, however, that men who expose predominantly to children and adolescents may actually be pedophiles.

A number of theories of exhibitionism have been formulated. The biological theories postulate an association between epilepsy, especially excess neural discharges in the limbic system, and exposing; however, there is little or no support for this view (Blair & Lanyon, 1981). The psychoanalytic explanations have centered on the concepts of castration anxiety and oedipal conflicts. According to Fenichel (1945), for the exposer, the victims' reactions are reassurances against castration fears. Other psychoanalytic themes include sadistic impulses directed at women and masochistic needs to be caught and punished. As Kline (1987) noted, "it is disappointing to find that the often elaborate and fantastical psychoanalytic theories

of sexual deviance are so lacking in objective support" (p. 173).

Behavioral models of exhibitionism emphasize the importance of conditioning experiences. McGuire, Carlisle, and Young (1965) suggested that deviant sexual behavior is often based on one-trial learning from crucial, often incidental, sexual experiences. These experiences are subsequently incorporated into masturbatory fantasy; the pairing of these fantasies with orgasm strengthens their sexually arousing properties. Several case studies provide some support for this view. In two cases reported by McGuire et al. (1965), the male was surprised by an attractive female while urinating in a semipublic place. The encounter was subsequently included in masturbatory fantasies, which thereafter inclined the males to repeat the act. In support of this theory, Zechnich (1971) noted a striking amount of nudity among family members in the history of exhibitionists. More recently, Marshall, Eccles, and Barbaree (1991) hypothesized that assertiveness deficits, problems with adult intimacy, and perfectionism are characteristic of exhibitionists. These predictions await independent replication.

Voyeurism

The essential feature of *voyeurism* is a pattern of repeatedly observing an unsuspecting person who is nude, disrobing, or engaged in sexual activity (APA, 1994). By definition, "peeping" is done to attain sexual gratification, and no sexual activity with the unsuspecting victim is sought. The sample of voyeurs studied by Abel et al. (1987) reported a mean of 430 victims (median: 8.5). As is the case for exposing, the sexual act does not typically involve physical contact with the victim. Sagarin (1973) and Yalom (1960) emphasized the importance of the lack of victim consent, which distinguishes voyeurism from viewing pornography and striptease acts. Gebhard, Gagnon, Pomeroy, and Christenson (1965) stressed the importance of distinguishing between individuals who take advantage of an opportunity to observe a person disrobing, thereby exhibiting poor judgment, from the peeper, who repeatedly seeks such situations.

Empirical literature on voyeurism is extremely limited. Langevin, Paitich, and Russon (1985b) found no exclusive cases of voyeurism in a sample of more than 600 paraphiliacs. Voyeurism was associated with a number of other paraphilias but

never existed as an exclusive sexual deviation. In fact, Langevin (Langevin, 1983; Langevin, Paitich, & Russon, 1985b) questions the existence of voyeurism as a discrete clinical entity. The dearth of clinical evidence for the disorder may stem from the covert nature of voyeuristic activity, as opposed to exhibitionism. One study of male college students found that 42% had engaged in voyeuristic behaviors (Templeman & Stinnett, 1991). Abel (1989) reported that 13% of adults who sought treatment at his clinic for sexual deviation were voyeurs. Voyeurism, it has been found, coexists with several other paraphilias, including frotteurism, pedophilia, and exhibitionism (Abel & Rouleau, 1990; Langevin, Paitich, & Russon, 1985b; Rooth, 1973; Yalom, 1960). According to Abel and Rouleau (1990), one-third of the voyeurs they studied had committed rape. The belief that peepers are prone to violence, including rape, has received mixed support; some individuals who are accused of voyeurism and rape are probably more accurately described as rapists who engaged in surveillance of their prospective victims.

As a group, peepers frequently report disturbed relationships with their parents during their development and are less likely to identify with either parent than normal and other deviant groups (Langevin, Paitich, & Russon, 1985b). Their early home environment is described as hostile and emotionally distant. In terms of sexual history and functioning, contrary to expectations, voyeurs tend to have a greater than average amount of sexual experiences with adult females. Approximately one-third to one-half are married, but these men often have heterosexual fears and deficits (Kaplan & Krueger, 1997).

According to psychoanalytic theory, a voyeur seeks to observe a woman's "castrated" genitals while reassuring himself through masturbation that he has a penis (Meyer, 1995). The late psychoanalyst Robert Stoller (1975a) proposed that voyeurism, like all paraphilias, stemmed from unconscious hostility. Paraphiliacs attempt to harm or humiliate their victims in retaliation for their own feelings of having been humiliated. Overall, voyeurism remains one of the least studied sexual deviations.

Pedophilia

According to the DSM-IV, *pedophilia* (literally, *love of children*) consists of (1) recurrent and in-

tense sexual urges and fantasies that involve sexual activity with a prepubertal child (usually 13 years old or younger) and (2) an age discrepancy of at least 5 years. To receive the diagnosis, the person must be at least 16, and it is specified that a relationship between an older adolescent and a 12- to 13-year-old would not qualify as pedophilia (APA, 1994). Although the terms "pedophile" and "child molester" are often used interchangeably, we believe that there are important differences (see also, Barbaree & Seto, 1997). Pedophilia is reserved for those individuals who evidence a marked preference for children. Child molestation may be motivated by the unavailability of an adult partner (Freund, McKnight, Langevin, & Cibiri, 1972), due to cognitive deficits such as mental retardation or dementia, or due to disinhibitory influences such as substance dependence or psychopathy (Dorr, 1998). In other words, pedophilia is but one of several possible motives behind child molestation. Such a distinction in terms is not simply a matter of semantics but has important implications for treatment selection.

An important aspect of the current nosology is the provision for specifying preferred victim gender (male, female, or both), relationship to the victim (incestuous vs. nonincestuous), and whether the pattern is exclusive (i.e., the pedophile is attracted only to children) or nonexclusive. The distinction between homosexual, bisexual, and heterosexual pedophilia is well established (Langevin, 1983; Lanyon, 1986). Heterosexual pedophilia is more common than the homosexual variant, whereas the bisexual subtype is uncommon. Homosexual pedophiles, however, tend to have a larger number of victims than heterosexual pedophiles. For example, Abel et al. (1987) found that their sample of heterosexual child molesters (nonincestuous) reported an average of 20 victims, compared to 150 for homosexual pedophiles (nonincestuous). Incestuous offenders in the same study (Abel et al., 1987) admitted to an average of 1.8 female victims and 1.7 male victims. As with nonincestuous child molestation, most incestuous pedophiles chose female victims. In contrast to homosexual pedophilia, heterosexual child molesters are more likely to be married (Langevin, Hucker, Handy et al., 1985). Contrary to popular belief, pedophiles are not "dirty old men"; as most incarcerated pedophiles are in their mid-twenties to mid-thirties (Groth & Birnbaum, 1978; Langevin, Hucker, Handy et al., 1985). By defini-

tion, the victims in both groups are prepubertal; the average victim's age is approximately 10 years (Groth & Birnbaum, 1978). Approximately 25% of victims are less than 6 years of age, another 25% are between 6 and 10 years old, and roughly 50% are between 11 and 13 years of age (Erickson, Walbek, & Seely, 1988).

The type of sexual activity with the victim ranges from fondling to oral-genital contact and actual penetration (Erickson et al., 1988). Among heterosexual pedophiles, fondling of the victim is by far most common (54%), although vaginal contact (41.5%) and cunnilingus (19%) are not rare. For homosexual offenders, fondling of the victim is also most common (43%), followed by the performance of fellatio on the victim (41%). Anal contact in the latter group occurs in one-third of cases. In cases involving younger children, actual anal or vaginal penetration is uncommon; contact usually entails rubbing the penis against the orifice or between the thighs (Erickson et al., 1988; Langevin, Hucker, Handy et al., 1985). In cases of intrafamilial incest, there tends to be a progression from masturbation and fondling to actual attempts at intercourse over time. Aggressive and sadistic sexual activity occurs in less than 20% of cases (Groth & Birnbaum, 1978). Methods of obtaining victim compliance include enticement via bribery, seduction, appeal to curiosity, and intimidation and threats in some cases. The majority of pedophiles is at least acquainted with their victims. Incestuous pedophiles commonly molest biological, adoptive, or stepchildren, whereas the victims of nonincestuous offenders may include neighbors, relatives, and acquaintances.

With respect to criminal histories, a significant proportion of pedophiles has prior criminal convictions for sexual and nonsexual offenses; however, they tend to display fewer antisocial features than rapists (Bard et al., 1987). Of possible etiological significance is the finding that more than 50% of child molesters report having been the victim of sexual abuse during childhood (Bard et al., 1987). Pedophiles typically have facilitating cognitions regarding sexual contact with children (Hanson, Gizzarelli, & Scott, 1994; Ward, Hudson, Johnston, & Marshall, 1997). Specifically, they tend to believe in beneficial effects for the child from adult sexual contacts, assume less responsibility on the adult's part, and perceive greater child complicity in the sexual activity than rapists and normal subjects (Stermac & Segal, 1989).

A useful typology of pedophiles is the distinction between preferential and situational pedophilia (Lanyon, 1986). This typology is similar to the exclusive-versus-nonexclusive dichotomy of the DSM-IV and to the fixated-versus-regressed classification proposed by Cohen, Seghorn, and Calmas (1969) and Groth and Birnbaum (1978). *Preferential* or *fixated* pedophiles are primarily interested in children as sexual partners and tend to be unmarried. Homosexual pedophiles are usually preferential molesters. Their sexual experiences with adults tend to be very limited; they commonly have experienced lifelong difficulties in relating to adults, and their sexual development is described as fixated. Most encounters with children are premeditated rather than impulsive. These individuals tend to be more comfortable socially and sexually with children. The *situational* or *regressed* pedophiles tend primarily to be heterosexual child molesters. Incestuous offenders would generally be classified as situational offenders. These individuals are more likely to be married and to have more extensive sexual experience with adult partners than preferential pedophiles. A common pattern is an apparently normal development with adequate social and heterosexual skills. As the person enters adulthood, however, his social, occupational, and marital adjustment become tenuous and marginal. The pedophilic acts are typically precipitated by direct confrontation with a female or a threat to the person's masculinity. These individuals' sexual encounters with children are more impulsive, usually with older but prepubescent females, and tend to occur intermittently rather than continuously (Lanyon, 1986). A major question is whether these individuals have always had some sexual arousal to children as well as to adults. It is important to note that some degree of heterogeneity is evident within both of these categories (Fischer & McDonald, 1998).

A final category includes the *aggressive* pedophile (Cohen et al., 1969) or sadistic child molester. Boys are typically the preferred victims, and the sexual activity is clearly vicious and cruel. Sexual activity may include the mutilation of the victim's genitalia and insertion of foreign objects into bodily orifices. In some cases, forcible anal intercourse (with resultant rectal lacerations) may occur. Avery-Clark and Laws (1984) identified a group of aggressive pedophiles who were equally aroused by depictions of consenting intercourse with a child and graphic descriptions of aggressive

assault of a child. Penile measures of arousal suggested that these pedophiles were sexually aroused or at least not sexually inhibited by sexual aggression and violence directed at children. Although these individuals are fairly rare, the results of their deviant sexual arousal are tragic; these offenders may be involved in serial molestation and murder of boys.

As a group, pedophiles have been characterized as shy, unassertive, and passive (Langevin, 1983). Additionally, they have been described as introverted and socially withdrawn (Bard et al., 1987; Langevin, Hucker, Ben-Aron, Purins, & Hook, 1985). However, no single personality profile is consistently observed among pedophiles (Levin & Stava, 1987; Okami & Goldberg, 1992). Pedophiles tend to be concerned with negative evaluations by females, to view themselves as unassertive, and to hold very conservative stereotypes of women (Overholser & Beck, 1986). In interactions with adult females, they rate their performance more poorly than rapists (Segal & Marshall, 1985). In terms of additional diagnoses, pedophiles most frequently receive a personality disorder diagnosis (Langevin, Hucker, Handy et al., 1985). Depending on the sample and measures used, 8–30% of child molesters meet the diagnostic criteria for antisocial personality disorder and/or psychopathy (Quinsey, Harris, & Rice, 1995; Serin, Malcolm, Khanna, & Barbaree, 1994; for a review, see Dorr, 1998). Alcohol abuse is one of the most commonly reported problems among child molesters (Marshall, 1997). Paradoxically, some pedophiles are moralistic, conservative individuals in other aspects of their lives (Marshall & McKnight, 1975).

The sexual arousal of pedophiles has been extensively studied with penile plethysmography. As a group, nonincestuous child molesters exhibit as much or more penile erection in response to stimuli involving children than to stimuli involving adults (Freund, 1967; Marshall, Barbaree, & Butt, 1988; Quinsey, Steinman, Bergersen, & Holmes, 1975). These findings are consistent with the notion of an erotic preference for prepubertal partners. Incestuous pedophiles, however, tend to be more like nonoffenders in measured sexual preference (Marshall, Barbaree, & Christophe, 1986; Quinsey, Chaplin, & Carrigan, 1979). Some incest offenders respond most to adult females, which has led some authors (e.g., Quinsey, 1977) to speculate about nonsexual motives in incest. Barbaree

and Marshall (1989) discovered five separate sexual preference profiles among child molesters. Two profiles were indicative of pedophilic arousal, one suggested a normal adult heterosexual orientation, one revealed a preference for adolescents, and the last involved indiscriminate arousal. In sum, child molesters, including pedophiles, represent a heterogeneous group with respect to psychopathology, personality style, and sexual preference.

Psychoanalytic theories emphasize that pedophiles choose children as partners because they elicit less castration anxiety than adults (Fenichel, 1945). Others have hypothesized an aversion to adult females and an association with homosexuality. The experimental evidence, however, does not support these theoretical views (Langevin, 1983; Langevin, Hucker, Ben-Aron et al., 1985). The behavioral or social learning theories stress the importance of early conditioning, direct reinforcement, or modeling experiences, such as the presence of sexual abuse in the offender's past or an initial or early sexual experience with a younger child (McGuire et al., 1965). The single most popular factor theory of pedophilia is the "abused-abuser hypothesis" which postulates that individuals who were sexually abused in childhood are predisposed to developing pedophilia. As Garland and Dougher (1990) commented, despite the popularity of this view, there is surprisingly little empirical support. There are at least three theoretical problems with this hypothesis: (1) most victims of child sexual abuse are females, but the vast majority of pedophiles is male; (2) fewer than half of all child molesters have personal histories of sexual victimization by an adult in childhood (Garland & Dougher, 1990; Weeks & Widom, 1998), and (3) some pedophiles allege having been sexually abused in childhood as a ploy to reduce their perceived responsibility for their sexual offenses (Freund, Watson, & Dickey, 1990). Thus, the majority of individuals who were sexually molested as children do *not* develop pedophilia (Hansen & Slater, 1988).

Araji and Finkelhor (1985) advanced a four-factor model of pedophilia. According to them, pedophilia may be understood in terms of (1) *emotional congruence*, or the emotional need to relate to children (e.g., faulty development, inadequacy); (2) *blockage*, or the inability to attain alternative sources of gratification (e.g., skills deficits, heterosexual fears); (3) *disinhibition*, the failure to be

deterred from socially disapproved sexual behavior (e.g., alcoholism, sociopathy); and (4) *sexual arousal* to prepubertal partners. Araji and Finkelhor (1985) noted that most existing theories of pedophilia include one or more of these factors. This proposed model is promising because it stresses the multidetermined aspect of the disorder, but empirical tests are needed.

In their review of incest, Dixen and Jenkins (1981) outlined five factors that appear important in initiating incest:

1. The occurrence of incest in either parent's family.
2. Unsatisfactory marital sexual relationships in which the wife is sexually inaccessible to the husband.
3. Frequent absence of the mother, especially in the evening.
4. Any condition that reduces impulse control, such as alcoholism, sociopathy, or subnormal intelligence.
5. The oldest daughter having been coerced into adult responsibilities, with a role-reversal between mother and daughter.

Psychoanalytic theories of incest state that the victim experiences oral deprivation in the preoedipal stage; the incestuous relationship occurs as a revenge against the mother and as a form of oral gratification. Several other theories stress the importance of a dysfunctional family system. In such views, incest represents a maladaptive attempt to maintain family homeostasis (Dixen & Jenkins, 1981; see Long, 1995).

One of the newest and most elaborate multifactorial theories of sexual offending was proposed by Marshall and colleagues (Marshall, 1989; Marshall, Hudson, & Hodgkinson, 1993). In this formulation, a lack of intimacy in adulthood and the resulting experience of loneliness predispose some individuals to sexually aggressive behavior (Garlick, Marshall, & Thornton, 1996; Seidman, Marshall, Hudson, & Robertson, 1994). This deficiency in adult intimacy may interact with sociocultural influences, precocious sexualization, conditioning events, and biological factors in the development and maintenance of deviant sexuality (Marshall & Eccles, 1993). According to the model, the developmental history of sex offenders renders them vulnerable to various influences and events; this proposed developmental vulnerability is attributed to inadequate parent-child attachment early

in life (Smallbone & Dadds, 1998; Weeks & Widom, 1998). Consequently, the child lacks the skills and self-confidence necessary to master the challenges in the transition to adolescence. The vulnerable male experiences pubertal development and emerging sexual urges and feels socially inept, especially with female peers. Thus, the individual is believed to be especially susceptible to nondemanding and nonthreatening sexual scripts (Marshall & Eccles, 1993). Examples of nonthreatening scripts for a socially incompetent male might include child molestation, voyeurism, and fetishism. Likewise, for a male who fears intimacy, nonconsenting sexual activity, including rape, may be less threatening. These individuals may also be attracted to cultural messages that perpetuate gender role stereotypes, such as the view that males are naturally aggressive and women are inherently passive. It is further postulated that if the individual incorporates these nonthreatening and distorted fantasies into masturbating practices, this may strengthen the conditioning process (McGuire et al., 1965). Any disinhibiting influences, including drug abuse and brain damage, may further increase the risk of enacting any existing deviant urges.

Sexual Sadism and Sexual Masochism

Sexual sadism, as defined in the DSM-IV, consists of sexual urges and fantasies centering on the actual (not simulated) infliction of psychological and physical suffering on a victim. The victims' involvement in these activities may range from fully consenting (in the case of a sadomasochistic relationship) to a complete lack of consent (as might occur in sadistic rape). The sadistic fantasies and acts may range from verbal humiliation to bondage, forceful restraint, spanking, and in extreme cases, torture, mutilation, and killing. *Sexual masochism* entails recurrent sexual urges and fantasies of being actually humiliated, beaten, bound, or made to suffer. An extreme form of masochism is known as "asphyxiophilia" or "autoerotic strangulation," which entails derivation of sexual pleasure and intensification of orgasm via oxygen deprivation (Garos, 1994). Although apparently rare, the latter condition is sometimes publicized after the person's escape mechanism from the self-strangulation contraption fails (Resnik, 1972). In such cases, the dead individual is found by an unsuspecting spouse or relative,

and the incident may be erroneously explained as suicide.

The majority of sadists and masochists are heterosexual, although both disorders occur among homosexuals (Gosselin, 1987; Kamel, 1980). Although many sadists and masochists tend to favor their respective roles, some role reversal does occur, suggesting that these disorders may coexist in some cases (Gosselin, 1987). Masochism is believed to be one of the few paraphilias found in women (Levitt, Moser, & Jamison, 1994). In the vast majority of instances, sadomasochistic sexual interactions are consensual (Stoller, 1991). Gosselin (1987) described the "sadomasochistic contract" which governs the sexual scripts of sadists and their masochistic partners. With few exceptions, sadists do not derive pleasure from inflicting more harm than is desired by their partners (Gosselin & Wilson, 1984). In fact, most sadists seek a partner who is sexually excited by suffering or humiliation rather than one who would not enjoy these practices (Gosselin, 1987; McConaghy, 1993). Masochists have very specific preferences for the type of pain or humiliation they seek; as Stoller commented, "no sadomasochists like all kinds of pain" (1991, p. 16). According to Weinberg (1995), control rather than pain is at the core of sadomasochism. Thus, most sadists and masochists are interested in consensual sexual activities that include elements of mental or physical control, and some individuals alternate between giving and receiving the suffering or humiliation (Stoller, 1991).

According to Gosselin (1987), who has extensively studied sadomasochism, three aspects are characteristic:

Beatings that may vary drastically in intensity and duration (up to 200 strokes in some cases). The stereotypical whip is reportedly seldom used because of difficulties in controlling its impact.

Bondage that is ritualistic and often associated with beatings. Common forms include mouth gags, hoods, blindfolds, immobilization, and rope or leather restraints, sometimes to the point of partial asphyxiation.

Humiliation that may range from bootlicking and crawling to the use of urine, feces, and enemas.

Sexual sadism is distinct from psychopathy by virtue of the fact that sadists are highly sensitive to their partners' emotions and delight in controlling

their display (Gosselin, 1987). Furthermore, in sadomasochistic relationships, the sexual encounters are governed by explicit rules and agreements about the boundaries of acceptable behavior. Although empirical data are limited, sadomasochism (or S & M) is not rare, as evidenced by the availability of S & M handbooks (e.g., Masters' and Mistresses' Handbooks), magazines, clubs, on-line computer sites, and societies.

Rape is not included in the DSM-III-R nosology for two apparent reasons: (1) Many rapists are not considered paraphiliacs, and (2) there was concern that paraphiliac rape might be used as a legal defense to avoid prosecution. Curiously, this latter line of reasoning was not applied to pedophilia or other paraphilias. According to the DSM-III-R, approximately 10% of rapists meet diagnostic criteria for sexual sadism. Sadistic rapists and lust murderers who seek nonconsenting victims meet the DSM-IV criteria for *severe* sadism. However, we have serious reservations about grouping such extreme and rare individuals in the same category as couples who enjoy consenting sadomasochistic interactions.

Among the various classification schemes of rapists (e.g., Rada, 1978), several subtypes have been consistently proposed. According to Knight and colleagues (Knight & Prentky, 1990; Knight, Rosenberg, & Schneider, 1985; Prentky, Knight, & Rosenberg, 1987), the following subtypes have some empirical support:

1. *Opportunistic* rapists use force to obtain victim compliance. For these individuals, rape is just one aspect of a predatory life-style. According to Rada (1978), 30–40% of rapists fall into this category. The majority of these individuals have antisocial and/or psychopathic personalities.
2. *Pervasively angry* rapists evidence undifferentiated anger and tend to be very aggressive. This is a very uncommon type of rapist (Barbaree, Seto, Serin, Amos, & Preston, 1994).
3. *Vindictive* rapists are primarily motivated by aggression; rape is an expression of rage and anger that is specifically directed at women. The rape is intended to punish and degrade the victim.
4. *Sexual sadistic* rapists evidence sexual-aggressive erotic fantasies. The infliction of pain and suffering is sexually arousing for these individuals who meet the DSM-IV criteria for severe sexual sadism.

5. *Sexual nonsadistic* rapists are those for whom aggression is instrumental in securing sexual compliance, and the rape is associated with nonsadistic sexual fantasies.

According to Prentky et al. (1987), victim injury varies across rapist types, although it is often difficult to determine the true intent of a perpetrator: Was the aggression solely instrumental or gratuitous? The authors noted that the dimensions of social competence and life-style impulsivity may further enhance the classification of rapists. Blader and Marshall (1989) noted that sadistic rapists consistently evidence an erotic preference for nonconsenting and aggressive sexual activity with women, as documented by tumescence studies of rapists. The other subtypes may appear normal on tumescence measures of arousal by responding most to consensual sexual activity but may fail to inhibit arousal to a partner's resistance or suffering (as in the case of normal males). In most other respects, incarcerated rapists resemble the general inmate population in criminal history, psychosocial adjustment, comorbidity, and social competence (Polaschek, Ward, & Hudson, 1997).

The phenomenon of *acquaintance* or *date rape* has been a topic of interest in recent years. Estimates of the prevalence of date rape range from 5–54% of female college students (Koss, 1989). According to Muehlenhard and Linton (1987), the following risk factors for date rape have been identified:

1. The male initiates and takes a dominant role in the date.
2. Miscommunication regarding sex.
3. Heavy alcohol or drug use.
4. Going to a secluded area, or "parking."
5. Male acceptance of traditional gender roles, interpersonal violence, antagonism toward relationships, and rape myths.

Malamuth and colleagues (1989, 1993) found that several variables, including hostility toward women, antisocial features, and sexual arousal to rape cues, were predictive of the propensity of male college students to engage in forceful sexual activity. According to them, two separate pathways, hostile masculinity and sexual promiscuity, lead to sexual aggression. It remains unclear how these persons who commit acquaintance rape fit into the classification scheme of rapists. It seems likely that some of these individuals who engage in date rape may progress into a recurrent pattern

of opportunistic or sexual nonsadistic rape. More research is needed to understand males who perpetrate date and other types of rape. Particularly significant is the role of force and victim suffering in instigating or failing to inhibit sexual arousal. Cues indicative of a victim's suffering and fear do not inhibit sexual arousal in sexually coercive male college students (Lohr, Adams, & Davis, 1997).

Frotteurism

Previously classified as an "atypical paraphilia," frotteurism (from the French *frotter*, "to rub") remains a full-fledged category in the DSM-IV. The criteria for frotteurism include intense urges, fantasies, or behaviors centering on touching and rubbing (frottage) against a nonconsenting female. The criteria emphasize that the act of rubbing, rather than the coercive element, is the arousing stimulus. Experts on paraphilia tend to distinguish frotteurism from "toucherism" (arousal by touching a stranger's body), although the DSM-IV makes no such distinction. Individuals who engage in frottage typically engage in this activity by boarding crowded public transportation vehicles and positioning themselves next to an attractive female. The individual takes advantage of the proximity afforded by the crowding and swaying of the vehicle to rub his genitals against the victim's thighs, buttocks, or crotch. The individual typically fantasizes that he is having a consenting sexual encounter with the victim. The frequent stops of subways and buses allow escape should the victim become aware of the activity and protest.

There are very few accounts of frotteurism in the clinical literature; either the condition is uncommon or, more likely, frotteurs are rarely seen in clinical settings. In their large-scale study of paraphilias, Abel et al. (1987) examined sixty-two self-proclaimed frotteurs. The mean number of victims was 901 (median: 29.5). After exhibitionists, frotteurs accounted for the greatest percentage (18.1%) of total paraphiliac acts in the sample of 561 admitted paraphiliacs. Freund (1990) reported that 61% of the 119 frotteurs he studied had also engaged in exhibitionism. More than 30% admitted to voyeuristic acts, and 22% admitted to having raped a woman.

Money (1986) claims that the impersonal nature of the sexual contact is essential to the frotteur. Others argue that frotteuristic patterns can be seen

as a distortion of the normal sexual or erotic tactile interaction phase (Freund & Watson, 1993). According to Langevin (1983), frotteurism can be classified as a form of sexual aggression on the basis of the lack of consent that characterizes the sexual activity.

Fetishism

In the DSM-IV, the essential features of fetishism include intense sexual urges, fantasies, or behaviors that involve the use of nonliving objects; these items may be used with a partner who wears the item during sexual activity to facilitate the fetishist's sexual arousal. It is specified that female clothing items used for cross-dressing purposes are criteria for transvestic fetishism rather than simple fetishism. Docter (1988) differentiated fetishism from fetishistic transvestism on the basis of the extent of cross-dressing and gender identity: fetishists occasionally wear the fetish but do not seek to appear as women, and gender identity is masculine. Blanchard (1991) argued that specific features of female clothing items may differentiate fetishism from transvestic fetishism: In the former, the preferred item (e.g., panties) has been previously worn by a female instead of being purchased new in a store. In some cases, the fetish is necessary for sexual arousal, and erectile failure may occur in its absence (Gosselin & Wilson, 1984). Arousal to a specific nonsexual body part (e.g., feet or hair) was previously labeled fetishism, although the preferred term among experts in the area is "partialism." In the DSM-IV, partialism is categorized as a Paraphilia Not Otherwise Specified. The separation of partialism and fetishism has generated some debate because the majority of researchers believes that these conditions are related (Bancroft, 1989; De Silva, 1993).

In their study of fetishists, Chalkley and Powell (1983) found that approximately 60% preferred clothing items (e.g., panties, stockings, raincoats), 23% were aroused by rubber items, 15% chose footwear, and 15% preferred body parts (i.e., partialism), whereas the remainder was excited by stimuli ranging from leather to nylon garments. In this sample, 44% preferred to wear the item, 23% enjoyed seeing the item worn by another person, and 37.5% regularly stole the preferred fetish. According to McConaghy (1993), fetishists most commonly receive professional attention only after being apprehended for theft.

According to Money (1984, 1986), fetishes may

be categorized according to texture, such as silk or nylon, or smell, usually associated body parts (as with soiled undergarments). Rubber and leather combine both texture and smell. Bancroft (1989) suggested that virtually all fetishes are directly or symbolically associated with the body. Weinberg, Williams, and Calhan (1994) investigated the fetishistic preference and sexual behavior of 262 homosexual or bisexual males who expressed sexual interest in male feet or footwear. Participants were recruited through an organization for foot fetishists. Sixty percent of the respondents found clean feet sexually arousing, followed by boots (52%), shoes (49%), sneakers (47%), and smelly socks (45%). Other fetishistic objects were sexually arousing; almost half of the respondents were also aroused by clothes and leather. In addition, the respondents expressed great specificity in their shoe fetishes: wing-tips, penny loafers, etc. Almost three-fourths of the respondents said they were very particular in the type of footwear that aroused them, and 60% were equally specific in the type of feet they found sexually arousing. For the reasons that the respondents were aroused by feet and footwear, 50% made a direct reference to sensual aspects of the fetish object (taste, touch, smell etc.), 30% emphasized symbolic themes, and 20% were unable to explain their attraction. When asked about the importance of the fetish object in their sexual fantasies, 83% of the respondents masturbated at least once a week while fantasizing about feet or footwear. Finally, a third of the respondents was currently involved in an intimate relationship, and almost 80% of these reported engaging in "foot play" with their partners. Furthermore, nearly 60% evaluated foot/footwear activities as an important part of their sex lives with their steady partners.

In a large-scale study of fetishists, transvestites, and sadomasochists, Wilson and Gosselin (1980) found significant overlap among sexual fantasies and activities. Eighty-eight percent of their fetishists, it was found, engaged in sadomasochism and/or transvestism. In terms of personality functioning, all three groups were described as introverted, shy, mildly anxious, and depressed. Weinberg, Williams, and Calhan (1995), however, found that fewer than one in four men in their nonclinical sample of foot fetishists endorsed psychological problems. This finding suggests that clinical samples of fetishists may not be representative of the larger population of fetishists. Approximately 60–

70% of the participants in Wilson and Gosselin's (1980) survey had steady sex partners, and the modal age for all groups was around 40–50 years. In their cross-sectional survey in the United States, Janus and Janus (1993) found that 11% of men and 6% of women had personal experiences with fetishes. The authors did not specify the extent of the women's involvement, but it appears that it involved having a male partner with a fetishistic preference. This finding would be consistent with reports that this paraphilia is rare in women.

Epstein (1969) argued that the etiology of fetishism involves increased orgasmic excitability, which he viewed as indicative of cerebral pathophysiology. According to this theory, fetishism is associated with epilepsy and temporal lobe dysfunction (Langevin, 1983); however, this claim has not been substantiated by others (e.g., Landsdell, 1971). Pesta (1993), using classic Freudian theory, considered early childhood events and trauma as developing factors in adult fetishism. Most psychodynamic formulations of fetishism postulate that it stems from castration anxiety and the fantasy of the phallic woman (Bak, 1968). The fetish symbolizes the penis from this perspective.

A classic study by Rachman (1966) illustrated a conditioning paradigm for acquiring fetishistic arousal. In a laboratory setting, photographs of women's boots were paired with slides of nude adult females. After a number of conditioning trials, the participants (seven psychology graduate students), it was found, exhibited increased erectile responses to the boots alone. Furthermore, some generalization to other types of women's shoes was reported. Although the conditioning model received support, a number of questions remain unanswered: What predisposes an individual to develop this pattern of arousal? Why do some evidence this type of sexual response (apparently an uncommon condition in clinical settings), whereas others do not? Are those former students still "turned on" by women's boots?

Transvestic Fetishism

The term *transvestic fetishism* replaces the former DSM-III category of *transvestism*. The diagnostic criteria for transvestic fetishism in the DSM-IV include (1) for at least 6 months, recurrent sexual urges, fantasies, or behaviors in a heterosexual male that involve cross-dressing; (2) the urges have been enacted or are subjectively dis-

trressing; and (3) the person does not meet the criteria for a gender identity disorder. Thus, the diagnosis precludes conditions in which a homosexual male (a "drag queen") cross-dresses, as well as disorders that involve a subjective sense of discomfort and incongruence between one's biological sex and gender identity, such as in transsexualism. An important differentiation between these disorders is that cross-dressing is sexually arousing in transvestic fetishism but not in the other conditions (Docter, 1988). According to Docter (1988), there are five essential characteristics that identify transvestic fetishism: heterosexual orientation, sexual arousal to cross-dressing, the cross-dressing is periodic, no desire for surgical or hormonal gender reassignment, and gender identity is masculine except when cross-dressed. In cases where the sexual arousal in response to cross-dressing declines over time, the diagnosis may be revised to a gender identity disorder. Some evidence suggests that a number of transvestites eventually develop transsexualism (see Blanchard, 1993; Langevin, 1985).

Some sadomasochists also cross-dress (Wilson & Gosselin, 1980); however, it is unclear if this is associated with fetishistic arousal or with humiliation rituals. Langevin, Paitich, and Russon (1985a) found, surprisingly, that up to one-fourth of the rapists they studied engaged in cross-dressing. In transvestism, gender identity is masculine, although many report experiencing a feminine side while cross-dressed. Therefore, it appears that cross-dressing entails a fairly heterogeneous group of individuals. As defined by the DSM-IV, the fetishistic component in a heterosexual male is essential.

In a replication study of Prince and Bentler's (1972) classic survey of 504 transvestites, Docter and Prince (1997) investigated various demographic, sexual, and cross-gender variables among 1032 self-defined periodic cross-dressers. With few exceptions, the second survey findings closely mirrored those of the first survey. As expected, the vast majority of respondents (87% to 89%) was heterosexual although nearly one-third in both samples had some prior homosexual experience. The initiation of cross-dressing began before the age of ten for 54–66% of respondents. In both samples, nearly two-thirds of the transvestites were married, and the vast majority also had children. The majority of wives was aware of their husbands' cross-dressing; the most common reac-

tion was ambivalence; fewer than one-third was accepting. Most cross-dressers preferred to cross-dress in full costume (85–93%). Nearly three-fourths of transvestites had appeared in a public setting while cross-dressed, but only one-quarter reported going to highly visible or crowded places such as public transportation, restaurants, or shopping centers where they might be recognized. With regard to the participants' "view of self when cross-dressed," 80% reported that cross-dressing represented an "expression of a different part of myself." Nearly 75% of respondents agreed that cross-dressing elicited sexual arousal at least occasionally.

According to Fenichel (1945), transvestism incorporates the homosexual's identification with the mother with the fetishist's denial that the female has no penis. Castration anxiety and the oedipal complex have figured prominently in psychoanalytic interpretations of transvestism (Wise & Meyer, 1980). Learning theories emphasize the importance of conditioning experiences in the development of the disorder. For example, being cross-dressed as a child (e.g., "petticoat punishment") or praised for feminine appearance may reinforce these behaviors; incorporating these activities and fantasies into masturbatory activity may further strengthen the sexually arousing properties of cross-dressing (McGuire et al., 1965).

Money (1974) proposed that the disorder develops as a product of "postnatal programming." According to him, gender role is developed by identification with the same-sex parent and is reinforced by the complementary actions of the opposite-sex parental figure. Transvestism, in Money's view, arises because of faulty identification and inappropriate family reinforcement phenomena. Interestingly, boys who display cross-gender (i.e., effeminate) behaviors tend to develop into adult homosexuals instead of transvestites or transsexuals. Zucker and Blanchard (1997) noted that mother-son conflict, characterized by anger, hostility, and rejection, is characteristic of the childhood of most transvestites. Hostility toward females may play a role in the development of transvestic fetishism.

Gender Identity Disorder

Gender identity disorder is characterized by incongruence between the individual's biological sex and gender identity. Gender identity distur-

bance, or *gender dysphoria*, is relatively rare and is usually evident during childhood. The DSM-IV criteria for gender identity disorder, or *transsexualism* as it was formerly known, include (1) strong and cross-gender identification (not merely a desire for any cultural advantage of being the other sex), (2) persistent discomfort with one's sex or a sense of inappropriateness in the gender role of that sex, and (3) the absence of any physical intersex condition such as androgen insensitivity syndrome. The disorder involves a preoccupation with getting rid of primary and secondary sex characteristics and/or the conviction that the person was born the wrong sex. The primary goal for transsexuals is to pass successfully in society as a member of the other sex on a full-time basis (Pauly, 1990). Children with gender identity disorder frequently voice their desire to be the other sex, may cross-dress, and prefer playing with peers of the other sex. They typically identify with the other sex gender role. Children and adolescents with gender identity disorder have deficits in same-sex skills and in peer interactions (Bradley & Zucker, 1997). Gender identity disorder is more prevalent among males.

Sexual orientation may be asexual, heterosexual, homosexual, or unspecified. In biological female transsexuals, only the homosexual subtype has been reported (Zucker & Bradley, 1995). These individuals describe themselves as males trapped in women's bodies, and they are erotically attracted to females. In males, heterosexual transsexualism consists of the subjective conviction of being a female, and attraction is to females. Conversely, homosexual transsexualism in males also involves a feminine gender identity and sexual preference for males (Zucker & Bradley 1995). The confusion in terminology may be clarified if one understands that the specified sexual orientation refers to the individual's *biological* partner preference: a homosexual transsexual prefers a partner of the same biological gender, whereas the heterosexual variant involves a preference for an opposite-sex partner. Homosexual transsexualism is considered the most common form of the disorder in males and is the exclusive type in females (Blanchard, 1989, 1990). In one study of the sexual orientation of gender dysphoric patients, one of seventy-two females was attracted to men (Blanchard, Clemmensen, & Steiner, 1987).

The distinction between transvestism and male transsexualism is based on several differences: (1) Transvestites cross-dress for purposes of sexual

excitement, whereas transsexuals' cross-dressing is associated with gender dysphoria; (2) transsexuals, in contrast to transvestites, desire to rid themselves of their masculine anatomy; and (3) transsexualism is associated with feminine gender identity. Congruent with the male transsexuals' belief that they are not genuine males, they reportedly tend to avoid using their penises during sexual encounters (Langevin, 1985).

In their study of homosexual transsexual males who requested sex-reassignment surgery, Freund, Langevin, Zajac, Steiner, and Zajac (1974) found that a major goal for the sex-change operation was the ability to attract heterosexual male partners. During sexual intercourse with another male, homosexual transsexuals tend to fantasize that they are a female engaged in sexual activity with a male. Male transsexuals have a more pronounced feminine gender identity than nontranssexual homosexuals, and there is minimal overlap between these groups (Freund, Nagler, Langevin, Zajac, & Steiner, 1974). Although homosexual transsexuals are attracted to members of the same biological gender, they resent being labeled "gay" because they perceive themselves as women; hence, their attraction to males is seen as equivalent to heterosexuality.

Some transsexuals assume a cross-gender role by cross-dressing permanently and establishing themselves as members of the opposite sex in the community. In some cases, homosexual transsexuals may initiate hormone intake (estrogens for males and testosterone for females) to acquire some cross-gender secondary sex characteristics. In a biological male, regular estrogen intake leads to a redistribution of body fat, a reduction in facial and body hair, and mild to moderate breast enlargement (Steiner, 1985). A percentage of transsexuals will seek sex reassignment surgery (some extreme cases of autocastration have been reported in transsexuals). Surgical sex reassignment is generally more effective for males than for females. The creation of an artificial penis is difficult and often unsatisfactory (see Steiner, 1985). For males, surgery entails removing the penis and testes and creating a vagina and breast augmentation. In his review of the literature on reassignment surgery outcome, Blanchard (1985a) concluded that the majority of transsexuals who have undergone surgery are satisfied with the outcome, although the level of satisfaction is variable. The level of postsurgical adjustment is highly correlated with presurgical adjustment and the effective-

ness of the operation (Kuiper & Cohen-Kettenis, 1988). Transsexuals who present evidence of co-existing psychopathology are less likely to benefit from surgical sex reassignment (Bodlund & Kullgren, 1996; Midence & Hargreaves, 1997). Additionally, female-to-male transsexuals tend to have more favorable outcomes than male-to-female counterparts. Postsurgical complications, such as excessive scarring and collapse of the neovagina, also influence the individual's satisfaction with the procedure (Ross & Need, 1989). Regarding the relationship of orgasm to sexual and general satisfaction in postsurgical transsexuals, Lief and Hubschman (1993) found a decrease in orgasmic capacity in male-to-female patients and an increase in female-to-male patients. However, despite the decrease in the ability to experience orgasm in male-to-female patients, satisfaction with the quality of sexual activity and general satisfaction with the results of surgery were high in both groups of patients. Although the majority of transsexuals is satisfied with the outcome of sex reassignment surgery, prospective candidates must be carefully evaluated because up to 10% later regret undergoing the procedure. Additionally, a few cases experience severe distress and commit suicide (Pauly, 1990). Therefore, postoperative psychotherapy may be advisable (Rehman, Lazer, Benet, Schaefer, & Melman, 1999).

Clinicians and researchers in gender dysphoria have recognized that this disorder is far more complex than previously assumed (Bradley et al., 1991; Pauly, 1990). There is no scientific consensus on the determinants of gender dysphoria. From their review, Bradley and Zucker (1997) concluded that prenatal exposure to maternal sex hormones is probably implicated in the etiology of this disorder (see Money, 1974; Pillard & Weinrich, 1987). Hoenic (1985) noted that hormonal and antigen abnormalities, cerebral dysfunction, and genetic factors were likely to be important in the etiology of gender dysphoric behavior. However, other researchers contend that there is insufficient evidence of a biological determinant of this disorder (Coleman, Gooren, & Ross, 1989; Gooren, 1987). Stoller (1975b) proposed that psychoanalytic formulations can be applied to this disorder and that oedipal complex and castration fears play key roles. Green (1974, 1987) argued that environmental factors are critical in determining gender dysphoria. According to him, as children, male transsexuals tend to be treated as girls in dress, are overprotected by the mother, prefer female friends,

and experience an absence of male role models. Pauly (1974, 1990) emphasized family dynamics in the etiology of gender identity disorder. In support of these views, Bradley and Zucker (1997) observed that many of the mothers of boys with gender identity disorder had experienced major disappointment over not having a girl. Consequently, such parents are less likely to discourage gender nonconformity, and they may actually reinforce such behavior in their children.

Paraphilia Not Otherwise Specified

Paraphiliac disorders that do not meet criteria for any of the specific sexual deviations previously discussed are classified as paraphilia not otherwise specified (NOS). The DSM-IV provides a list of seven paraphilia NOS, although this listing is by no means all-inclusive (for a review, see Milner & Dopke, 1997). The empirical data on these disorders are limited and consist mostly of descriptive case studies:

1. *Telephone scatologia* or lewdness entails sexual arousal associated with exposing a victim to obscene language over the telephone. The condition may be functionally related to exhibitionism, where auditory exposure is the equivalent of visual exposure. The individual may masturbate while talking to the victim; in support of this view, Alford, Webster, and Sanders (1980) demonstrated that obscene phone calling and genital exposure were functionally related in one subject. Heavy breathing may also be a type of voyeurism, where listening is similar to looking. Approximately one-third of female college students and 11% of male have received obscene phone calls (Matek, 1988; Murray & Beran, 1968).
2. *Necrophilia* involves sexual activity with a corpse. Access to a morgue or funeral parlor is essential for a person with this erotic preference (Money, 1986). In some extreme cases, necrophilia may be linked with severe sexual sadism; in such cases, the individual may murder the victim for sexual access (Rosman & Resnick, 1989). Access to a non-resistant and nonrejecting sexual partner is a prime motive of necrophiliacs.
3. *Partialism* is considered by many experts to be a form of fetishism. By definition, it consists of exclusive arousal to a specific body

- part, usually not associated with sexual activity. This may include feet, hair, or legs.
4. *Zoophilia* entails sexual arousal in response to animals. The preferred animal is often one to which the person has been exposed during childhood, such as a household pet or farm animal. Although some males raised on a farm may experiment in sexual activity with livestock, this probably does not constitute a paraphilia unless intense urges and fantasies are involved and the pattern is repetitive. There are, however, cases of males who describe a lifelong sexual attraction to an animal.
 5. *Coprophilia* involves the derivation of sexual excitement from feces. This pattern of arousal may be incorporated in sadomasochistic rituals in some cases. There are few empirical findings on this disorder which is rarely seen in clinical settings.
 6. *Urophilia* is the equivalent of coprophilia with urine. It usually consists of a desire to be urinated upon by a partner; vernacular terms for this activity include "water sports" and "golden showers." Like coprophilia, this paraphilia may be associated with sadomasochistic practices.
 7. *Klismaphilia* involves sexual arousal associated with administering or receiving enemas. It may be an adjunct to rubber fetishism or sadomasochism. Although homosexual males may use enemas before anal intercourse, this does not entail klismaphilia because it is a sanitary rather than erotic practice. The majority of practitioners are heterosexual men (Arndt, 1991).

Treatment of Paraphilias

A multitude of interventions for modifying deviant sexual arousal have been proposed over the years. In the majority of cases, however, the effectiveness of these treatments has not been established. Group and insight-oriented psychotherapies, for example, are commonly used with sex offenders despite the absence of evidence for their effectiveness.

Two general approaches to modifying deviant sexual arousal have been empirically evaluated: pharmacological approaches and cognitive behavior therapy. The pharmacological approaches entail administering agents that reduce or eliminate

the individual's sex drive. Dubbed "chemical castration," it has been shown that the use of anti-androgen drugs (medroxyprogesterone acetate and cyproterone acetate) lowers sexual urges, fantasies, and behaviors in sex offenders (Gijs & Gooren, 1996; Money, 1987; Robinson & Valcour, 1995). Although these treatments do not alter the offenders' deviant sexual interests, they generally reduce rates of both normal and deviant sexual behavior. Hall (1995) concluded that pharmacological approaches reduce recidivism rates although they have not been shown superior to cognitive behavioral approaches. A number of problems are associated with pharmacological approaches, including noncompliance, side effects (such as weight gain, testicular atrophy, and hypertension), and high relapse rates upon discontinuation. Furthermore, the long-term effects of these medications remain unknown. More recently, anecdotal reports and case studies suggest that selective serotonin re-uptake inhibitors (SSRIs) may be promising agents for selectively lowering deviant sexual urges. Galli and colleagues (1998), for example, reported successfully treating a male with multiple paraphilias by using fluoxetine (Prozac). Abouesh and Clayton (1999) administered another SSRI, Paroxetine, to a voyeur and an exhibitionist and reported reductions in paraphiliac urges. However, pharmacological interventions are not a panacea, and they should only be used in combination with other interventions as part of a multicomponent treatment plan.

Cognitive behavioral interventions are designed to decrease deviant sexual arousal, to eliminate facilitating cognitive distortions, and to build skills that will facilitate the formation of normal intimate relationships. Additionally, relapse prevention has become an integral component of treatment (Laws, 1989). A problem inherent in many treatment outcome studies is the lack of adequate follow-up data. It has been documented that recidivism rates increase over time; therefore, extended follow-up periods are necessary (Furby, Weinrott, & Blackshaw, 1989). Contrary to popular belief, not all sex offenders relapse. A recent review suggests that sex offender recidivism rates are near 55%, which is comparable to recidivism rates for nonsexual criminals (Heilbrun, Nezu, Keeney, Chung, & Wasserman, 1998). Hall (1995) concluded that pharmacological and cognitive behavioral treatments produced a 30% decrease in recidivism.

Early cognitive behavioral treatments relied on

aversive conditioning. A study by Quinsey and colleagues (1980) supports the effectiveness of electrical aversion in reducing pedophilic arousal. Other studies, however, have produced equivocal results (Rice, Quinsey, & Harris, 1991). Olfactory aversion is a variation that is less controversial; aversive odors can be self-administered in the natural environment by motivated clients. Another procedure, known as masturbatory satiation, requires prolonged masturbation to deviant fantasy to pair paraphiliac fantasy with boredom (Laws & Marshall, 1991). Maletzky described the use of covert sensitization with large samples of paraphiliacs, and his reported success rates are impressive (Maletzky, 1991). Vicarious sensitization is a variation that involves exposing offenders via films to aversive consequences for deviant sexual behavior (see Maltezky, 1997). Cognitive interventions are designed to challenge and modify distorted beliefs relevant to deviant urges and practices. Additionally, cognitive interventions may be used for empathy training. The strategies of relapse prevention entail (1) teaching individuals to recognize high risk situations; (2) learning strategies to avoid these situations that may lead to relapse; and (3) teaching coping strategies, such as assertiveness training and anger management, that will help lower relapse risk (Pithers, 1990). Accountability and supervision are common components of relapse prevention.

Although cognitive behavioral treatments reduce recidivism rates among sex offenders (Hall, 1995; Heilbrun et al., 1998), the exact mechanism by which they achieve such change remains unclear. Their efficacy seems to involve more than a simple conditioning process, and therefore, a self-control model may be more accurate in explaining the effectiveness of cognitive behavioral and pharmacological interventions for paraphilias. Along these lines, the relapse prevention model of change emphasizes self-management rather than a cure.

Professional, Legal, and Research Issues

The assessment and treatment of paraphiliacs poses unique ethical, legal, and professional issues. Because most paraphiliacs enter treatment under coercion, their motivation to change is typically low. Therefore, the validity of their self-reports is questionable. In summary, this population is considered difficult and challenging.

Increasingly, clinicians are serving as expert witnesses in the courtroom and other legal situations (e.g., parole hearings) in cases involving sex crimes. This role places the professional in a relatively foreign situation, namely, in an adversarial process. It imperative that clinicians be aware of the limits of their expertise (Blau, 1985). All findings presented in this context must be data-based, which requires a thorough knowledge of the properties (including the limitations) of assessment instruments. Additionally, expert consultants must possess a comprehensive understanding of the research findings, theories, and issues pertaining to sexual deviations. The expert witness must understand that any information presented in court may be entered in evidence (Weiner, 1985). As experts, clinicians must maintain a neutral and objective stand, which may be challenging in view of the reprehensible nature of some paraphiliac practices.

Clinicians are increasingly being asked to provide a risk assessment, a prediction of an individual's likelihood of perpetrating future offenses. Overall, psychometric instruments have limited predictive validity in this respect. Static factors such as criminal history are moderately effective predictors. Dynamic predictors such as deviant sexual arousal and psychopathy may also be useful (Hanson, 1998; Hanson & Bussiere, 1996; Quinsey, Harris, & Rice, 1995). Risk assessment is a critical process that requires aggressive empirical investigation. The consequences of inaccurate risk assessment can be costly to the offenders who may face unnecessarily prolonged incarceration and to society in terms of sexual victimization. Clinicians and researchers bear a heavy responsibility in keeping abreast of developments in this area.

Therapists in every state are required to report evidence of sexual abuse. Mandatory reporting represents one exception to confidentiality and privileged communication, which may drastically alter the therapeutic relationship. Clinicians involved in the assessment, treatment, or research of paraphilias need a thorough understanding of state and local laws in these matters.

Because of the continuing misinformation about sexual deviation among the public and professionals alike, there is a critical need for sound clinical research. There is an urgent need for treatment outcome research, prospective studies of risk factors in paraphilia, and controlled descriptive studies using homogeneous samples. Although

major advances in our understanding of paraphilias have occurred in the past several decades, many unanswered questions remain.

Psychobiology of Health and Disease

Phillip J. Brantley and Steven C. Ames

Introduction

For centuries, philosophers and scientists have remained interested in psychological processes believed to influence health. As early as the fifth century B.C., Hippocrates posited that the workings of the brain were related to bodily processes and illness (Pattishall, 1989; Watson & Evans, 1991). Although his theory of bodily humors was later falsified, his notion that health can be realized by maintaining a balance with the physical world is consistent with contemporary theories.

Interest in psychological factors and illness waned when the seventeenth-century philosopher Rene Descartes popularized the concept of mind and body as distinct entities with entirely different governing principles. Cartesian dualism had a lasting impact on science such that interest in psychological factors as determinants of health did not resurface as a prominent area of investigation until the nineteenth century and the advent of psychoanalytic theory (Levy, 1989; Pattishall, 1989).

Psychosomatic medicine developed as a result of this renewed interest in the influence of psycho-

logical processes on health and was initially concerned with psychoanalytic explanations of personality and the subsequent development of particular types of disease. Early psychoanalytically based psychosomatic theories considered that particular diseases result from unconsciously displaced expressions of conflict and age regression to early childhood. Childhood was viewed as a time when emotions are expressed as bodily activities. Such thinking gave rise to “specificity theories” of illness. Collectively, these theories attempted to explain physical illness in terms of common features of individuals who experience a particular illness. Although specificity theories persist, they are currently considered less credible due to equivocal research findings (Levy, 1989; Suls & Rittenhouse, 1987).

Since the 1950s, investigators have emphasized psychological factors such as the impact of stress common to nearly all diseases. In particular, the approaches formulated by Selye (1956, 1976) and Holmes and Rahe (1967), which propose how stressful life events impact health and illness, have remained influential. Current research is focusing on the association of life stress and physiological processes believed to underlie diseases. Health behavior is another common psychological factor in illness. Empirical support has been found for a strong association between common high-risk health behaviors (e.g., smoking sedentary lifestyle, poor diet) and a variety of diseases. Determining how high-risk behaviors are acquired and maintained will hopefully provide insight into

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

ways that these behaviors can be reduced. Further, as a result of the growing influence of behavioral psychology since the 1950s and the advent of the medical behavioral science model (i.e., psychobiological model), researchers continue to remain interested in the role that learning plays in the expression of physical illness.

This chapter will review psychobiological models of health and disease. Initially, the reader will be introduced to early specificity theories and modern advancements of these theories. Second, the impact of stress on illness will be examined. Third, the nature of chronic illness will be explored, and chronic pain syndromes will be discussed from a psychobiological perspective. Fourth, the acquisition of illness behavior and failure to change high-risk health behavior will be discussed in the context of behavior models. Throughout the chapter, a psychobiological approach will be emphasized to highlight the biological mechanisms by which behavioral factors influence health outcome.

Specificity Theories of Illness

Early psychodynamic formulations of “specificity theory” can be traced to Dunbar’s (1935) use of the term “personality profile” to refer to the personality traits of individuals who experience the same physical ailments. Alexander (1950) later expanded upon this work and became an influential proponent of specificity theory by proposing that underlying unconscious conflicts predisposed an individual to illness. Alexander’s theory rested on the notion that persons with particular personality profiles, specific underlying unconscious conflicts, and preexisting organ vulnerability had an increased likelihood of developing a specific illness when situations arose that activated the conflict. Alexander believed that this conflict then led to autonomic, neural, or hormonal activation that caused the physiological changes associated with the disease.

Somewhat later, Alexander and his colleagues (Alexander, French, & Pollack, 1968) proposed that seven distinct types of illness existed that, it was hypothesized, result from particular identifiable unconscious conflicts. However, Alexander’s theory emphasized that the underlying unconscious conflicts could occur within a wide variety of individuals with different personalities. The seven psychosomatic diseases included bronchial asthma, essential hypertension, neurodermatitis,

peptic ulcer, rheumatoid arthritis, thyroid toxicosis, and ulcerative colitis.

For example, Alexander and his colleagues posited that bronchial asthma resulted from conflicts that were associated with attachment to a mother figure. A child’s attempts to gain the mother figure’s attention by crying aroused anxiety associated with the potential for maternal rejection. Thus, Alexander and his colleagues proposed that “asthmatic attacks could be understood as an inhibition of the expiratory act for communication, either by crying or confession” (Alexander et al., 1968, p. 12). Similarly, conflicts associated with neurodermatitis were believed to include unconscious themes of exhibitionism, guilt, masochism, and a strong desire for affection. Alexander and colleagues commented that neurodermatitis is “precipitated after the patient achieves some form of exhibitionistic victory. The victory arouses guilt and creates a need for suffering in the precise part of the body that is involved in the exhibitionistic success” (Alexander et al., 1968, p. 14).

As noted earlier, specificity theory has been considered less credible in recent years. Research that examined Alexander’s (1950) unconscious conflict hypothesis has proven inconsistent. Research conducted in the 1950s and 1960s concluded that Alexander’s approach offered little explanatory or predictive power in understanding the role of personality variables in physical disease (Suls & Rittenhouse, 1987). However, the hypothesis that underlying conflicts play a role in physical illness and specificity theories in general remained influential in clinical practice and psychosomatic research in the 1940s and 1950s. Although interest in the specificity theories of illness declined after the 1950s, the lasting influence of these theories can be seen by their impact on the 2nd ed. of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association [APA], 1968).

The 1980s saw renewed interest in the personality–health relationship. Researchers attempted to address the limitations of earlier work by trying to define personality variables more precisely and to examine the biomechanical mechanisms that linked psychological variables to disease (Holroyd & Coyne, 1987). Interest in the relationship of personality variables and health in the 1990s has largely focused on the Type A behavior pattern and its relationship to coronary artery disease. Research focusing on the relationship between personality variables and health has merged with

research that examines the relationship between stress and illness. This merging of trait and more behavioral approaches arises from efforts to develop more comprehensive and meaningful explanations of the way psychological factors affect physical processes. This merger of approaches is well characterized by the current state of the Type A behavior pattern literature.

Type A Behavior Pattern (TABP)

Most of the research that has focused on the relationship between personality and coronary heart disease (CHD) has centered around TABP. The TABP was described by Rosenman (1986) as a behavior pattern consisting of competitive striving for achievement, time urgency, impatience, aggressiveness, and easily aroused hostility. It is worth noting that TABP does not simply refer to individuals who are considered to have very high levels of involvement in their jobs (Shapiro, 1996). Glass (1977) asserted that a strong desire to control the environment was inherent in individuals with TABP, and Rosenman (1986) argued that those with TABP exhibit limited insight into their disorder. Related to these hypotheses, it is interesting to note that much earlier in the century, Alexander (1939) proposed a hypothesis suggesting that excessive and inhibited hostile impulses were central to developing cardiovascular disease (i.e., essential hypertension).

Based on the results of the Western Collaborative Group Study (Rosenman et al., 1975) and the Framington Heart Study (Haynes, Feinlieb, & Kannel, 1980), it was found that TABP is associated with the incidence of CHD. Specifically, after statistically controlling for all other known risk factors, the presence of TABP was associated with approximately twice as many incidents of CHD than in those who did not test positive for this set of characteristics (Type Bs). These studies and subsequent research led an expert review panel convened by the National Institutes of Health to conclude that TABP is an independent risk factor for developing CHD, as significant as other risk factors such as elevated blood cholesterol, hypertension, or smoking (National Heart, Lung, and Blood Institute, 1981).

Subsequently, studies began to yield negative results suggesting that the National Heart, Lung, and Blood Institute's conclusion was premature (for reviews see Myrtek, 1995; Siegman, 1994a). Arguably, the largest study yet done to date, the

Multiple Risk Factor Intervention Trial, followed 12,700 men free of CHD at baseline for an average of 7 years (Shekelle et al., 1985). The results of this study revealed that TABP is unrelated to the incidence of CHD. Similarly, in the Aspirin Myocardial Infarction Study, which examined survivors of a first myocardial infarction, men with TABP, it was found, did not have a greater risk of a second myocardial infarction or death related to CHD, compared to those without TABP (Ruberman, Weinblatt, Goldberg, & Chaudhury, 1984). Likewise, a recent review of ten studies by Cohen, Ardjoen, & Sewpersad (1997) failed to find an association between TABP and the risk of death or cardiac morbidity following a myocardial infarction, compared to those without this behavior pattern. The literature regarding TABP led Eysenck (1990) to comment that "Both the positive and negative results are neatly balanced to show that as a predictor Type A behaviour is of doubtful value, and may be quite useless. Weighting the results by numbers of participants, it is doubtful if the total can be regarded as significant in a socially meaningful rather than a statistical sense" (p. 26).

Investigators have more recently proposed that mixed findings regarding TABP result from the fact that only particular components of the TABP are related to CHD. Recently, research focused predominately on the component of hostility after a number of studies suggested that this construct is the primary toxic element related to CHD (Dembroski & Costa, 1988; Dembroski, MacDougall, Costa, & Grandits, 1989; Hecker, Chesney, Black, & Frautschi, 1988). Siegman (1994a) insists that the negative findings (Dembroski, MacDougall, Williams, Haney, & Blumenthal, 1985; Hearn, Murray, & Luepker, 1989; Helmer, Ragland, & Syme, 1991; Leon, Finn, Murray, & Bailey, 1988) for the association between hostility and CHD may result from a failure to appropriately conceptualize hostility as a multidimensional construct. Furthermore, he notes that only some of the dimensions of hostility may be related to CHD. For example, research suggests that it may be the expression of hostility and not simply its experience that may be related to CHD (Siegman, 1994b).

The mechanism by which hostility may influence coronary morbidity has prompted the development of a number of theoretical models. Williams, Barefoot, and Shekelle (1985) proposed a psychophysiological model. This model suggests that individuals high in hostility have greater reac-

tivity in blood pressure, heart rate, and stress hormone release in response to stressors. Over time, this exaggerated reactivity may initiate and speed the development of CHD or other illnesses. Alternatively, Smith and Frohm (1985) proposed the psychosocial vulnerability model. This model argues that hostile individuals simply have a more difficult interpersonal environment, which leads to deleterious effects on their health. A third model, the transactional model, proposes that hostile individuals themselves create more frequent and severe contacts with stressors and maintain a high level of interpersonal conflict in their lives (Smith & Pope, 1990). Thus, negative health impacts are seen as caused by both increased reactivity to everyday stressors and also by additional irritants caused by a hostile style of interaction. A fourth model, proposed by Leiker and Hailey (1988) asserts that hostile people have an increased risk of illness because they have poor health habits. Finally, the constitutional vulnerability model (Krantz & Durel, 1983) suggests a biological diathesis (i.e., a genetic and/or acquired physiological predisposition is combined with exposure to critical environmental factors). Some degree of evidence exists for each of these models, and the mechanisms outlined in each of these models might complement those of the other models; that is, these models may not be mutually exclusive. A thorough review of the literature addressing the mechanisms that links hostility to health is beyond the scope of this chapter. The interested reader is referred to Smith (1992) for a review.

In summary, despite recent evidence of an association between hostility and CHD (Lahad, Heckbert, Koepsell, Psaty, & Patrick, 1997; for a review, see Miller, Smith, Turner, Gujjarro, & Hallet, 1996), the status of the literature is currently equivocal. Future research needs to isolate which components of hostility are related to CHD and how these components can be measured in a standardized manner (Helmers, Posluszny, & Krantz, 1994). In addition, researchers need to continue to delineate the mechanisms by which hostility impacts illness.

Stress and Illness

Interest in the concept of stress can be traced to the early work of Claude Bernard, Walter Cannon, and Hans Selye. Bernard (1865/1961) asserted that the survival of an organism depends on maintain-

ing the internal environment of the organism constant, regardless of changing external environmental conditions. Out of this viewpoint arose the notion that challenges to the integrity of the organism provoke responses designed to counteract those threats. Cannon's (1935) work can be seen as building on that of Bernard and is concerned with the *stimulus* properties of physical or emotional stress in disrupting internal homeostatic mechanisms. Somewhat later, Selye (1956, 1976) became interested in the way that stress produced a *response* in organisms. The confusion inherent in these two seemingly opposing approaches has persisted in the stress literature and influenced study panels both at the Institute of Medicine and the National Academy of Sciences. These panels concluded in 1979 that, "after thirty-five years, no one has formulated a definition of stress that satisfies even a majority of stress researchers" (Elliot & Eisdorfer, 1982, p. 11). This situation remains largely unchanged today, twenty-two years after the initial report by the panel.

Presently there are three primary means of conceptualizing stress. Stress may be viewed (1) as a response, in accordance to Selye's notions; (2) as a stimulus, similar to Cannon's notion; or (3) as an interaction or relationship between environmental events and appraisal by the individual (see Figure 1). Although many researchers retain an allegiance to one of these three viewpoints, some commentators have argued that the concept of stress has become so arbitrary as to be meaningless (see Engel, 1985).

The early work of Selye stands out as principal among the response theorists. Essentially, Selye (1976) thought that it was the body's pattern of physiological responses that defined stress. Additionally, Selye asserted that a variety of stressors (e.g., emotional arousal, pain, injury, positive events) could produce stress. Thus, both cognitive and emotional factors, as well as physical stressors, could evoke stress. Finally, Selye was careful to note that stress is not inherently a negative experience. Rather, he proposed that stressors might also be experienced as positive events and labeled the response associated with positive stressors, *eustress* (Selye, 1974). Alternatively, *distress* resulted from the harmful effects of demands.

Selye (1976) formulated the idea that stress is manifested by a triphasic pattern of adaptive responses. Either a sufficient number or intensity of stressors results in a general response, which Selye

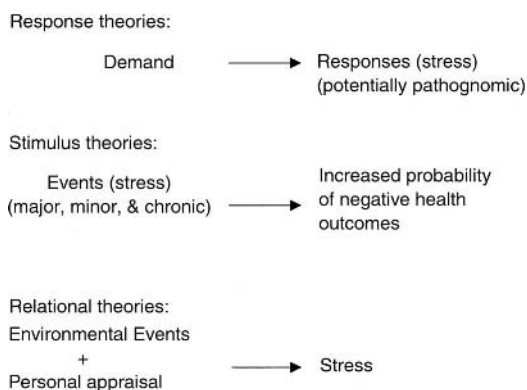

Figure 1. Conceptualization of stress.

labeled the *general adaptation syndrome* (GAS). The first phase, the *alarm reaction*, consists of a relatively short-lived period during which the body's physiological defenses are alerted. Note that the alarm reaction phase is generally considered equivalent to the fight or flight response. The underlying physiological responses of the alarm reaction include arousal of the sympathetic nervous system (SNS), neuroendocrine stimulation of the adrenal medulla, and the release of hormones by the anterior pituitary (Cotton, 1990).

Continued exposure to the stressor leads to the second phase of the GAS, the stage of *resistance*, in which the most appropriate bodily defenses against a given stressor are determined. During this stage, there is an increased secretion of cortisol, which results in heightened metabolism, increased muscle strength, decreases in swelling and inflammation, and decreased immunity (Cotton, 1990). Thus, although the organism is attempting to provide maximum resistance to the identified stressor, it is susceptible to other stressors. Additionally, because Selye's model of stress postulates a closed system, continued activation of this stage depletes the organism's resources, and unless the stress is resolved, the organism's defenses will ultimately weaken.

Once prolonged exposure to the stressor has depleted the organism's adaptation energy, the third and final stage occurs, the stage of *exhaustion*. Once this stage is attained, adaptation no longer prevails, and the effects of high levels of cortisol begin to exert pronounced negative effects (Cotton, 1990). During this stage, shock, de-

Table 1. Physiological Responses in the General Adaptation Syndrome^a

Alarm stage
Adrenal medullary stimulation
ACTH release
Cortisol release
Growth hormone release
Prolactin release
Increased thyroid activity
Gonadotropin activity increased
Resistance stage
Reduction in adrenal cortical activity
Reduction in sympathetic nervous system activity
Homeostatic mechanisms engaged
Exhaustion phase
Enlargement of lymphatic structures
Target organ disease/dysfunction manifest
Increased vulnerability to opportunistic disease
Psychological exhaustion: depression
Physiological exhaustion: disease → death?

creased resistance to infection, tissue damage, and, in the most extreme cases, death results. Table 1 presents a summary of the physiological events associated with the GAS.

Despite the fact that Selye's work was the impetus for much of the later stress research, his theory has not stood without criticism. Researchers have criticized Selye's theory for three major reasons (for a review see Steptoe, 1991). First, research has called into question Selye's emphasis on the non-specificity of the response. Second, the hypothesis that the physiological stress response is adapted to enhance the organism's biological defenses appears in conflict with the anti-inflammatory response and immunosuppression. Third, Selye's view that peripheral physiological changes result from central nervous system activation has been called into question by evidence suggesting bidirectional traffic between the two. Despite the criticisms that have been leveled against it, Selye's model provided the first systematic theoretical notion of potential changes in physiological functioning resulting from psychological stimuli. The proposed physiological changes posited by Selye would later be an important means of investigating the relationship between stress and illness.

Cannon's (1935) early work led to the development of another tradition within the field of stress research, that of conceptualizing stress as a stimulus linked to environmental events (Dohronwend & Dohronwend, 1974). Thus, stress was defined and measured in terms of exposure to stressful life events (Brantley & Jones, 1993). Much of the early research that examined the role of life events as stressors was conducted by Holmes and Rahe (1967) and involved examining the link between major life events and subsequent physical illness. Examples of major life events include stress associated with marriage, the birth of a child, or the death of a loved one and reportedly significantly increase the likelihood of developing a variety of physical disorders (Holmes & Rahe, 1967). The occurrence of life events is currently believed to be a risk factor for a variety of adverse health outcomes.

More recently, investigators interested in the relationship between stress and illness have focused their attention on "daily minor stressors," also referred to as "small life events" or "hassles" (Eckenrode & Bolger, 1995). Examples of minor stressors include having automobile trouble, running out of pocket money, getting stuck in traffic, or performing poorly on a task. Compared to life events, minor stressors occur more frequently, possibly daily, and are perceived as less intense (Brantley & Jones, 1989). Interestingly, a number of studies that assessed both life events and minor stressors have suggested that minor stressors may be better predictors of health outcomes than major stressors (Brantley, Waggoner, Jones, & Rappaport, 1987; DeLongis, Coyne, Dakof, Folkman, & Lazarus, 1982; Garrett, Brantley, Jones, & McKnight, 1991; Holahan & Holahan, 1987; Kanner, Coyne, Schaefer, and Lazarus, 1981; Monroe, 1983; Weinberger, Hiner, & Tierney, 1987). Despite this, most investigations of stress continue to measure both major and minor life events in an attempt to obtain a comprehensive assessment of stress.

Along with life events and daily minor stressors, investigations have examined the impact of chronic stressors on health and disease (Cohen et al., 1998). "Chronic stressors are usually conceived of as discrete events and conditions, or constellations of related events and conditions, that persist over time" (Lepore, 1995, p. 103). Examples of chronic stressors include overcrowding, environmental pollution (e.g., noise pollution, air pollution), un-

employment, or inability to afford the basic necessities of living, such as food or clothing. More recently, measures of minor stress have been used to address the extent to which daily events comprise the elements of the experience of chronic stress (Eckenrode & Bolger, 1995). There is evidence that chronic stressors may be more important in the stress-illness relationship than acute stressors (Cohen et al., 1998).

Lepore has suggested that investigating chronic stressors may be important for a number of reasons. First, he asserts that it is theoretically more plausible to link diseases that have a long-term period of development to persistent stressors, in contrast to those that are acute and time-limited. Second, Lepore notes that emerging evidence has suggested that humans do not always habituate to chronic stressors and that these stressors may enhance the negative impact of acute stressors (see Brown & Harris, 1978; Hebert & Cohen, 1993; McGonagle & Kessler, 1990). Third, attempts to cope with chronic stressors may create psychological or physical fatigue and may lead to decreased mental performance, psychological distress, or dysregulation of neuroendocrine or immunologic functioning. Fourth, Lepore asserts that some chronic stressors may cause individuals to become socially avoidant and decrease their social support resources that might enhance health. Finally, Scarinci, Ames, and Brantley (1999) have found a limited amount of evidence to suggest that individuals may perceive chronic stressors as more intense than minor stressors.

A final approach to conceptualizing stress involves examining the interaction or relationship between potentially stressful stimuli (e.g., environmental events) and personal appraisal (e.g., perceived threat). Lazarus and Folkman (1984) noted that relational theorists argue that an event alone is not sufficient to produce illness and criticize the stimulus and response theories as overly simplistic and at times tautological. Instead, relational theorists assert that a diathesis in the organism is a necessary condition for disease to become manifest. According to this approach, "stress is a particular response between the person and environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being" (Lazarus & Folkman, 1984, p. 21). Thus, relational theorists focus on determining factors that increase vulnerability to environmental events. In sum, these theorists view

both individual (e.g., cognitive appraisal, coping skills) and environmental variables (e.g., predictability or ambiguity of the event) as important influences in susceptibility to stress (for a review see Lazarus & Folkman, 1984).

The Link Between Stress and Illness

Evidence that associates stress with physical and psychological illness has emerged from a variety of research studies (Step toe, 1991). Investigations of the relationship between stress and illness have examined a wide spectrum of factors, ranging from investigations of autonomic, endocrine, and immunologic mechanisms to epidemiological studies that have examined the role of psychosocial factors and health. The relationship between stress and illness is particularly relevant to the 4th ed. of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; APA, 1994) diagnostic category of "psychological factors affecting medical condition." Diagnostic criteria for this disorder require "the presence of one or more specific psychological or behavioral factors that adversely affect a general medical condition" (APA, 1994, p. 675). Further, the DSM-IV notes that physiological reactions to environmental or social stressors may affect a medical condition in a variety of ways, including "development or exacerbation of, or delayed recovery from the medical condition" (APA, 1994, p. 675). As noted before, although evidence is accumulating that stress affects health, not everyone who experiences stress becomes physically ill, nor have scientists identified the precise mechanisms by which stress influences health. Finally, scientists have recognized that different individuals respond to stressors in different ways (Lovallo, 1997). Additionally, it is also recognized that the same stressor, experienced on different occasions or under different circumstances, may also produce very different consequences.

Some stress researchers argue that alterations in physiological functioning that occur secondary to exposure to stressors increase the likelihood of disease or illness. After exposure to prolonged or intense stimuli that elicit a stress response, changes that occur in the functioning of the autonomic nervous system, neuromuscular system, neurotransmitter integrity, endocrine, or immunologic function increase the probability that an illness will develop. In addition to the direct effects on

physiological function that stressors may have, stressors might also have more indirect effects on health. Specifically, an increase in behavioral risk factors for illness (e.g., increased smoking or alcohol consumption, decreased sleep) may accompany increased levels of psychological stress (Cohen, Kessler, & Gordon, 1995).

Another group of investigators argues that stress may trigger a host of psychoneuroimmunologic processes that may reduce the organism's resistance to disease and predispose it to later illness (for a review, see Cohen & Hebert, 1996). Psychoneuroimmunology is the investigation of the interrelationships between the immune system and the central nervous system. Because it is assumed that the relationships between the nervous system and immune system are bidirectional, the term interrelationships is used. Accumulating evidence suggests that both laboratory and naturalistic stressors may compromise the integrity of the immune system and may lead to future susceptibility to a variety of illnesses (Cohen & Hebert, 1996). Specifically, researchers have discovered data suggesting that life events, minor (i.e., daily) stressors, and chronic stressors have immunologic consequences. Further, although it is still in the early stages of development, research also suggests that psychological factors may play a role in autoimmune diseases such as rheumatoid arthritis and cancer.

Although some researchers have found a relationship between stress and immunologic function, a number of important questions remain unanswered. First, as Step toe (1991) indicates, despite evidence that relates stress to illness, the specific mechanisms through which stress responses increase susceptibility to illness continue to remain poorly understood. Second, Step toe asserts that the reasons for individual differences in illness susceptibility are also poorly understood and remain a concern which can only be resolved once the mechanisms by which stress affects illness are better understood. Third, Cohen and Hebert (1996) note that the literature is missing strong evidence that the relationships between psychological factors and illness are attributable to changes in immune function, rather than to changes in health behavior (e.g., adherence to medical regimen, smoking). Even many recent studies fail to adequately measure and control such variables. Fourth, Cohen and Hebert indicate that the question of whether stress reduction interventions can help

alleviate immune deficits, assuming that stress is reliably associated with immune change, has yet to be adequately addressed. In sum, these authors indicate that the few existing studies that have examined this issue fail to provide convincing evidence.

Another hypothesis that has recently received a great deal of attention in the stress–illness relationship is the psychophysiological hyperreactivity hypothesis. “Psychophysiological hyperreactivity is the tendency to respond to behavioural stress with abnormally large autonomic or neuroendocrine reactions, or to display delayed recovery following termination of the stressful encounter” (Steptoe, 1991, pp. 639–640). Psychophysiological hyperreactivity result from physiological diatheses or learned response patterns and may be restricted to particular organ systems. Although, currently, the literature that examines this hypothesis is equivocal, support for the psychophysiological hyperreactivity hypothesis has been found in the hypertension and CHD literature (Carroll, Harris, & Cross, 1991; Everson, Lovallo, Sausen, & Wilson, 1992; Manuck, Kasprowicz, & Muldoon, 1990; for a review, see Blascovich & Katkin, 1993). Related to the psychophysiological hyperactivity hypothesis, some researchers argue that intense physiological reactions to stressors may act through an additional mechanism termed the disease stability process (Steptoe, 1991). Central to this hypothesis is the notion that physiological responses to stressors may affect the progression or stability of an illness.

Still other researchers assert that stress may affect health when an individual’s ability to cope effectively with the stressor is exceeded (Steptoe, 1991). Important variables in this relationship include current psychosocial demands; the intensity, chronicity, and complexity of the stressor, and the stressor’s novelty, predictability, and foreseeable controllability. Additionally, the coping resources that the individual has available are also important. Such factors as prior experience with threatening situations, optimism, hardiness, and the presence of social support may modulate the ability of the individual to cope with the situation. Steptoe adds that, although a number of different coping resources have been identified, currently researchers are trying to better understand which coping responses are most adaptive in different situations. Figure 2 graphically presents the models of stress and illness reviewed before.

Although the theories reviewed help assess hypotheses about the relationship of stress and illness, currently no definitive model exists that shows how stress may cause or increase an individual’s vulnerability to illness. Additionally, none of the hypotheses reviewed earlier are mutually exclusive. Thus, the current status of the literature suggests a need for a comprehensive model of stress. Further, this model needs to incorporate multiple variables to adequately explain the stress–illness relationship.

Illness as Learned Behavior

Individuals display a wide variety of reactions to illness. Although, several patients may have a similar illness in terms of laboratory indexes, they may each present with very different symptom profiles. Likewise, some individuals may present as being fairly indifferent to their symptoms continue to go about their daily routines in the same manner as they did before contracting their illness, and complain only when they are very ill. On the other hand, other individuals may complain at the slightest perception of pain or discomfort. Overall, responses to illness are difficult to explain if solely pathophysiological changes in the body are relied upon (Dworkin & Wilson, 1993). Prior learning experiences can be an important source of variance in accounting for the divergent ways that different individuals experience the same physical illness. Specifically, previous learning may be one factor that might account for the reasons that some individuals readily accept the “sick role” and arrange much of their lives around their illness, whereas others resist changing their daily routine. Prior learning experiences may also help account for the reason that some individuals seek medical attention for minor ailments, whereas others are reluctant to seek medical care for potentially life-threatening problems. According to a number of conceptualizations of illness as a learned behavior, operant and classical conditioning factors may help to explain these differences.

As a concept, *illness behavior* represents an attempt to explain the way individuals monitor their bodies, interpret and define their symptoms, and seek and use medical care in an attempt to relieve their symptoms (Mechanic, 1962, 1966, 1982). Illness behavior can be considered adaptive and appropriate when an individual’s behavior is

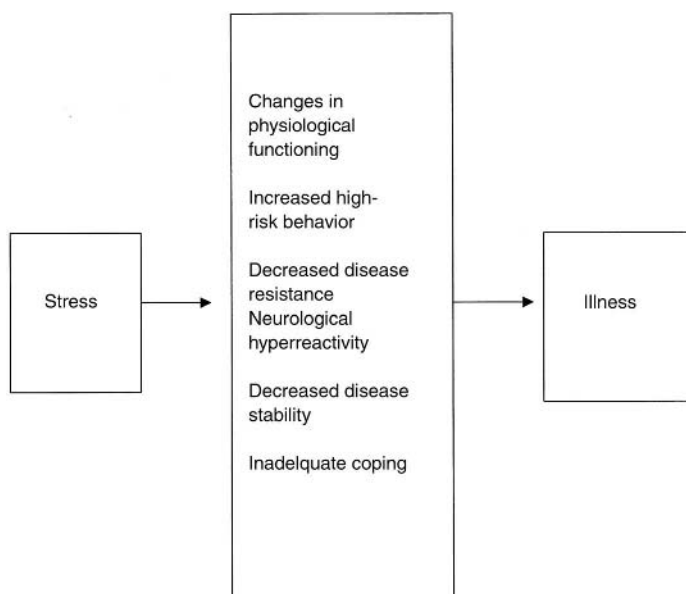

Figure 2. Models of stress and illness.

viewed as acceptable by the social reference group and results in an acceptable method of intervention (Schwartz, Gramling, & Mancini, 1994). However, illness behavior can also be viewed as maladaptive in the case of Somatoform Disorders. Other researchers (e.g., Blackwell, Wooley, & Whitehead, 1974) have referred to a syndrome of behavior, including disability disproportionate to the illness, a life-style centered on illness, and a continual search for medical care, as *chronic illness behavior*. Naturally, when a patient's illness behavior is perceived by a physician as maladaptive or when the patient's symptoms remain continually disproportionate to the illness, mutual frustration and dissatisfaction on the part of the doctor and patient alike often results (Dworkin, 1991). Consequently, patients who exhibit excessive illness or maladaptive behaviors often come to the attention of psychologists who work in medical settings.

Inherent in the concept of illness behavior is the notion that illness results from an interaction of biological, psychological, and sociological influences (Dworkin, 1991). In his review, Dworkin discusses two additional fundamental premises that define the concept of illness behavior: (1) the *disease-illness distinction* and (2) the *sick role*

concept. Dworkin asserts that particular dangers exist when providing treatment as if the dimensions of disease and illness are equivalent. Disease can be defined as a physiological event resulting from a disruption of a body structure or system due to physiological change. In contrast, illness may be defined as the subjective experience of physical discomfort, alterations in emotion, behavioral limitations, and psychosocial disruption. Thus, disease and illness may require different interventions, for though bodily systems may become diseased, individuals manifest illness behavior based on the subjective knowledge that a disease is present.

The second fundamental premise in the concept of illness behavior is the concept of a sick role. The concept of a sick role incorporates the notion that illness experience is shaped by prior learning, cultural definition, social climate, personal needs, and pathophysiological change (Dworkin, 1991; Mechanic, 1992). The sick role is viewed as appropriate only when the individual recognizes that it is a generally undesirable role that consists of an obligation to cooperate with medical professionals to restore health and return to the role of an adequately functioning member of society.

The DSM-IV (APA, 1994) diagnostic category

of Pain Disorder is the disorder where it can be most clearly seen that the concept of illness behavior has a significant role. As indicated in the DSM-IV, an essential feature of Pain Disorder is that, "psychological factors are judged to play a significant role in the onset, severity, exacerbation, or maintenance of the pain" (APA, 1994, p. 458). Similarly, models of chronic pain have relied heavily on environmental influences on overt pain behaviors (e.g., pain complaints, posturing, requests for medication) to account for the maintenance of subjective pain in the absence of medically verifiable pain-producing stimuli (Fordyce, 1976). Additionally, a body of evidence suggests that a number of other environmental and psychological factors may have important roles. Specifically, these factors include social learning, operant learning, respondent conditioning, beliefs about pain, beliefs about controllability of pain, self-efficacy, coping skills, and mood (see Turk, 1996 for a review). Other environmental contingencies may also influence behavior associated with Pain Disorder and more generally Hypochondriasis and Conversion Disorder. Environmental reinforcers such as disability payments, attention from caregivers, and escape from anxiety provoking or unpleasant situations (e.g., work, school) may have a role in maintaining behaviors associated with somatoform disorders (Maldonado, 1989; Turk, 1996).

Acquisition of Illness Behavior

Evidence suggests that prior learning is an important determinant of illness behavior. As noted earlier, different individuals vary widely in their responses to illness. Further, researchers have discovered that individuals vary in their desire to seek medical care when suffering from the same symptoms, and in their response to identical treatments (Turk, 1996). Ethnic group membership also influences the way individuals perceive, label, respond to, and communicate physical symptoms, as well as how and from whom care is sought (Mechanic, 1978; Segall, 1988; Weidman, 1988). Social learning may influence the way different groups interact with those who are ill, and it may also influence the relationship that a patient has with the health care provider (Turk, 1996). Researchers have attempted to account for these individual and cultural differences by examining the ways that social learning, operant conditioning, and classical conditioning impact the acquisition of illness behavior.

Illness behavior may be acquired through social

learning which includes both observational learning and modeling processes. Thus, individuals may acquire new behaviors by observing others who respond in similar ways. According to Bandura's social learning theory, vicarious learning occurs after observing behavior completed by another individual (Bandura, 1969). Behaviors that are reinforced are more likely to be performed again in the future by the observer. A number of studies have demonstrated that adulthood health care utilization and the frequency of somatic symptoms are associated with modeled sick role behavior during childhood (Jamison & Walker, 1992; Whitehead et al., 1994).

Operant approaches to illness behavior focus on the way the consequences of a behavior may lead to future occurrences of that behavior (Fordyce, 1976), that is, the operant conditioning model proposes that reinforced behaviors are more likely to occur than behaviors that have been punished. Thus, direct reinforcement of illness behaviors increase the likelihood that these behaviors will be performed again in the future. In support of this notion, a number of studies have discovered a positive relationship between pain behaviors and positive reinforcement provided by a family member, as would be predicted by the operant conditioning model (Turk & Okifuji, 1997). Additionally, illness behavior may be maintained by negative reinforcement because it increases the likelihood that an individual can escape from noxious stimulation by using drugs or rest or by avoiding undesirable activities such as work (Turk, 1996). Third, normal behavior may not be adequately reinforced, and as a result the more rewarding illness behavior may be maintained. Because the consequences of behavior maintain the occurrence of certain future behaviors, the operant model explains why illness behaviors tend to persist long after the illness is over.

Health care professionals and family members may help maintain these behaviors at a high level of frequency by shaping or reinforcement. For example, an individual who sustained a back injury as a result of an automobile accident may originally have had a recognized pathophysiological mechanism for the experience of pain. The pain initially experienced as a result of the back injury is viewed as respondent pain, that is, pain that results from physiological injury caused by the accident (Fordyce, 1976). As a direct result of the pain the individual is experiencing, he is allowed to avoid an aversive job and household

chores, while receiving a high level of care and attention from his spouse. Over time, behaviors associated with expression of pain are seen as coming under the control of environmental contingencies. Illness behaviors that are now associated with positive consequences or that have been negatively reinforced as a result begin to occur more frequently. These pain behaviors that are now being maintained by their positive consequences are what Fordyce (1976) labeled operant pain. As a result of operant conditioning, operant pain can persist over time without an existing pathophysiological mechanism.

Classical (respondent) conditioning is the third approach that has been used to explain the way illness behaviors are acquired. According to this model, a previously benign stimulus repeatedly paired with an unconditioned stimulus elicits a conditioned response. When this model is applied to illness behaviors, it predicts that a previously neutral experience can elicit discomfort associated with a given disorder. For example, an individual who is suffering from chronic back pain may experience an exacerbation in pain (unconditioned response) as a result of being seated in a chair (unconditioned stimulus) all day at work. Over time, the sight of a chair, preparing for work, or even thinking about going to work (conditioned stimulus) may result in the onset of back pain (conditioned response). Interestingly, classical conditioning has been shown capable of modifying immune responses in animals (Ader & Cohen, 1993).

In sum, learning is viewed as an important determinant of illness behavior. However, the degree to which learning processes influence illness behavior may vary between different individuals and across different disorders. Some behaviors may be influenced more by one type of learning, or multiple types of conditioning may be interacting. Although conditioning influences may vary across different individuals in their impact on symptom acquisition and maintenance, it is important to acknowledge that learning processes may be influencing illness behavior when assessing patients presenting with somatic complaints.

Health Behavior

The ultimate efficacy of any medical intervention is based on the willingness of the individual to perform the necessary behaviors (e.g., taking med-

ication) or abstain from injurious activities (e.g., cigarette smoking) (Becker, 1990). Unfortunately, research reveals that individuals frequently fail to comply with professional advice whenever some form of discretionary action or self-administration is required. Further, the therapeutic benefits of medical treatment are often compromised by chronically ill individuals because they do not consistently adhere to prescribed medical regimens (Dunbar-Jacob, Burke, & Puczynski, 1995; German, 1988). Sackett (1976) estimated that half of medical patients do not take prescription medications as instructed. Other estimates indicate that 20–80% of patients drop out of long-term treatment and that as many as 20–50% of medical appointments are missed (Becker, 1985; Sackett, 1976). Health behavior is an issue that is important to every patient because as many as 80% of patients may be at least partially nonadherent to their medical regimen at some time during treatment (Dunbar-Jacob et al., 1995).

Interest in the study of health behavior is based on two fundamental assumptions. First, it is assumed that in industrialized nations a significant proportion of mortality from the leading causes of death is due to particular patterns of behavior (Stroebe & Stroebe, 1995, cited in Conner & Norman, 1995). Second, the study of health behavior assumes that these behaviors, once identified, are modifiable. As it becomes more widely recognized that health behavior (e.g., diet, exercise, cigarette smoking) is an important and modifiable factor in preventing disease, more research continues to be generated. Recently, research has focused on identifying the processes that underlie health behavior and conversely, on identifying the processes that inhibit choosing healthy ways of behaving. Out of this interest, a number of models of illness behavior and health behavior have been constructed in an attempt to account for these factors.

Obstacles to Healthy Behavior

Numerous factors can inhibit one's ability to discontinue unhealthy behaviors or adopt healthier ways of living. The term *compliance* has been defined in a number of different ways in the literature. Haynes' (1979) classic definition defines compliance as "the extent to which a person's behavior (in terms of taking medications, following diets, or executing lifestyle changes) coincides with medical or health advice" (pp. 2–3). Al-

Table 2. Factors Affecting Adherence

Type of treatment
Curative vs. preventive
Length of treatment
Life-style change required
Complexity of regimen
Illness variables
Symptomatic vs. asymptomatic
Concern about physical condition
Provider-patient relationship
Patient satisfaction with care
Consistency of care
Cognitive variables
Knowledge of treatment regimen
Coping skills
Beliefs
Motivation
Self-concept
Intelligence
Locus of control
Biological variables
Side effects of medication
Side effects of nonmedication treatments
Interference of health behaviors with biological re- inforcers
Physical or cognitive deficits
Absence or misinterpretation of biological cues
Substance abuse
Environmental variables
Social support
Stress
Cultural influences

though Haynes' definition is very general and allows a great deal of variability in assessing compliance, some theorists have objected to it because they feel it implies that the patient assumes full responsibility for complying with a medical regimen. Originating from this position, some believe that the term compliance denotes a passive, subservient state of agreement with an authoritarian health care provider (Turk, Salovey, & Litt, 1986). In contrast, *adherence* implies a collaborative approach, where the patient and the health care provider share joint responsibility for compliance (Gerber, 1986). Finally, Barofsky (1978) suggested using the term *therapeutic alliance* to highlight the fact that an interactive or reciprocal relationship exists. Although it has been shown that the behavior that the health care provider displays

toward the patient influences patient cooperation, as discussed later, for the purposes of this review, the terms *compliance* and *adherence* will be used interchangeably. Potential influences on adherence are listed in Table 2.

A number of techniques have been identified that have been successful in increasing patient adherence (see Becker, 1990, for a review). Additionally, Becker notes that these factors might influence treatment adherence when used by any member of a health care team (e.g., physician, nurse, social worker). In a review of the compliance literature, Leventhal and Cameron (1987) suggest that an integrated, multidimensional approach may be the best model of nonadherence, that is, an integration of models that focuses on health beliefs, learning theory, and self-regulation may help explain how multiple factors (i.e., cognitive, affective, and behavioral variables) interact to influence compliance. However, to date, relatively few investigators have conducted comprehensive studies that examined the interaction of multiple determinants of adherence (Kaplan De-Nour, 1986).

Although differences in adherence rates may be partially attributable to the characteristics of both setting and subject, recent reviews indicate that a number of factors may influence treatment adherence (Becker, 1990; German, 1988; Grunberg & Lord, 1990; Joos & Hickam, 1990). First, higher rates of noncompliance are typically found for prophylactic as opposed to curative treatments. Further, if the individual is asymptomatic or has difficulty identifying signs of improved health, individuals will be less likely to adhere to their medical regimen than if it produced a noticeable improvement in their symptoms (e.g., rid them of an infection). Second, individuals show high nonadherence rates when medical regimens require significant life-style changes (e.g., smoking or dietary changes). Prior estimates have indicated that as many as 80% of individuals discontinue treatments that require significant life-style changes (Dunbar & Stunkard, 1979). Medical regimens that are complicated or have a greater duration also consistently have higher rates of nonadherence (Agras, 1989; Goodall & Halford, 1991). Because longer term treatment regimens are required for those with chronic disorders (e.g., diabetes) and have poor adherence, individuals with chronic medical conditions may have an increased risk of developing side effects from nonadherence.

The relationships that patients have with their

health-care providers may also have an impact on adherence. Investigators have discovered associations between adherence and patient satisfaction with the visit, the therapist, or the clinic. A patient's satisfaction with the clinic typically includes variables such as convenience, waiting times, and consistency of care (Becker, 1990). The literature suggests that, in general, adherence is greater when patients perceive that their expectations have been met, when the health-care provider elicits and respects patients' concerns and provides information about their conditions and progress, and when sincere concern and sympathy are shown.

Knowledge of the treatment regimen, it has been shown, influences the likelihood of patient adherence. Svarstad (1979, cited in Becker, 1990) found that 50% of low-income patients at a neighborhood health center could not correctly report how long they were to take their medications. Seventeen percent could not report how often they were to take their medications, 16% felt that their medications marked "prn" were to be taken regularly, and 23% could not identify the purpose of each medication they were taking. Further, 73% of those who could correctly identify their physician's instructions adhered to their prescribed regimen, and 16% of those who made one or more errors about their physicians' instructions adhered to their regimen. Simple and succinct instructions, repetition of instructions, patient repetition of instructions with correction by the health-care provider, telephone calls or mailed reminders of future appointments, and conveying instructions in both written and oral form have a positive impact on adherence (Becker, 1990; Joos & Hickman, 1990).

A number of other cognitive variables such as coping skills, illness attitudes and beliefs, self-concept, intelligence, and locus of control may also impact patient adherence. However, generally speaking, researchers agree much less on the impact of these variables than those previously discussed.

Biological variables may effect the cognitive abilities of the patient (Grunberg & Lord, 1990). For example, a patient's dementia may interfere with the exchange of information between the health care provider and the patient. Unpleasant medication side effects (e.g., impaired sexual functioning), side effects of nonmedication treatment (e.g., skeletal muscle pain resulting from physical therapy), or interference of health behav-

iors with biological pleasures (e.g., restrictive diets) may also reduce adherence rates. Finally, substances that have reinforcing biological effects (e.g., opioids, nicotine, alcohol) may interfere with adherence as a result of either physiological or psychological dependence, or may reduce competence or motivation to comply with prescribed health behaviors.

Evidence is accumulating that social support, support of one's family, cultural variables, and environmental stressors are also important factors that influence adherence (Becker, 1990; German, 1988). Social support, it has been found, is associated with keeping appointments, taking medication, and making life-style changes (German, 1988). Social support is especially important when treatment plans require the patient to maintain long-term, continuous behavioral changes (Becker, 1990). Other researchers have found that living in a family setting and garnering assistance from one's spouse may impact treatment adherence positively (Hartman & Becker, 1978; O'Brien, 1980).

Environmental stressors may also negatively influence adherence. Daily, minor stressors, it has been found, are related to noncompliant behavior as measured by intersession weight gain in hemodialysis patients (Everett et al., 1993). However, the incidence of daily stress, it was found, is related to measures of depression. These results suggest that stressors may directly or indirectly affect treatment adherence. Further research is required to better examine how environmental stressors may impact treatment adherence.

Models of Health Behavior

A number of models have been proposed to account for the mechanisms that influence health behavior change or account for factors that maintain health behavior, such as abstinence (Schwartz, 1992). However, these two lines of research originate from separate traditions. Some models have been created to explain and predict the intention of behavior change, and other models have originated from a desire to better explain why individuals fail to maintain health behaviors that they have already initiated (i.e., explain why they relapse). Currently, the literature is missing a unifying theory that accounts for all aspects of health behavior. Although a comprehensive review of all existing health behavior models is outside the scope of this chapter, four of the most well-known

models will be highlighted. These include the health belief model, the social cognitive model, the transtheoretical (stages of change) model, and the relapse model. For reviews of other models, the reader is referred to Clark & Becker (1998) and Rogers & Prentice-Dunn, (1997).

Of all the models of health behavior, the *health belief model* has received the most research attention (Becker, 1990). The original version of this model was developed by psychologists who worked at the U.S. Public Health Service (Rosenstock, 1974). The health belief model rests on the notion that individuals base their health behavior on (1) a desire to avoid illness and (2) the belief that a given health behavior will lead to that goal (Becker, 1974; Maiman & Becker, 1974; Rosenstock, 1974). According to this model, an individual's *perceived susceptibility to illness* (i.e., subjective perception of contracting an illness) in addition to their *perceived severity of the illness* results in a *perceived threat of disease* (Becker, 1990). Additionally, this relationship can be modified by individual differences in demographic (e.g., age, gender, race) and sociopsychological variables (e.g., social support, personality). The individual's perceived threat of disease may also be modified by *cues to action*, including mass media campaigns, advice from others, reminders to schedule doctor's appointments, illness of family members or friends, etc. Thus, an individual's *likelihood of action* is determined by the individual's perceived threat of disease, in addition to a subjective rationale analysis that weighs the perceived benefits of preventive action against the perceived barriers to this action.

Investigations have found that this model can account for considerable variance in initiating preventive health behavior, desire to seek diagnoses, and adherence to a medical regimen. However, this model has been criticized on a number of theoretical grounds (see Schwarzer, 1992).

The social cognitive model is based on Bandura's social cognitive theory which in turn relies heavily on the concept of self-efficacy. Self-efficacy (i.e., a perceived sense of personal control), it has been found, is related to better health, higher achievement, and better social integration (see Schwarzer, 1992; Schwarzer & Fuchs, 1995, for reviews). Further, evidence suggests that individuals' ability to change undesirable behavior is related to their perception of the self-efficacy of the behavior in question. According to Bandura's (1977, 1986, 1991, 1992) social cognitive theory,

behavior is governed by incentives and expectancies. Expectancies can be subdivided into three categories: (1) *situation-outcome expectancies*, in which consequences will occur without personal action; (2) *action-outcome expectancies*, in which outcomes occur as result of personal action; and (3) *perceived self-efficacy*, which is one's own perception of one's capability of performing a behavior to attain a desired outcome (Schwarzer, 1992; Schwarzer & Fuchs, 1995). Therefore, the likelihood that an individual will discontinue a harmful habit or adopt a healthy behavior depends on three types of cognitions: (1) the expectancy that one's health is at risk, (2) the expectancy that behavior change will reduce this risk, and (3) the expectancy that one is capable of adopting a healthy behavior or abstaining from an unhealthy one.

Before a new behavior change occurs, individuals first form an intention to change and then attempt to execute the change (i.e., action phase). Although outcome expectancies are important determinants in forming intentions to change behavior, they are generally viewed as less important in the action phase. However, self-efficacy is viewed as having an important impact on both stages because it represents the individuals' view that they serve as active agents of change and possess the skills necessary to initiate and maintain change and to regain control should relapse occur.

The transtheoretical model originated from the work of Prochaska and DiClemente (1982, 1984). This model represents an attempt to integrate several previous models of behavior change. It was developed from a desire to present a comprehensive model of the process of behavior change that would be useful to health professionals in their attempts to motivate their patients. Using this approach, motivation is viewed as an individual's current state of readiness for change. Thus, the transtheoretical model is based on the notion that motivation is an internal state that can be influenced by external factors.

The model proposes that individuals pass through discrete *stages of change* as they alter their behavior. In the *precontemplation* stage, individuals have not yet made a personal commitment to change given behaviors. Rather, they may feel coerced by the legal system or by significant others (e.g., their physician wants them to quit smoking, but they are currently not interested in quitting). In the *contemplation* stage, individuals

are aware that distressing life situations exist and are interested in determining whether their problems are resolvable and whether treatment would benefit them. In the determination or *preparation* stage, individuals attempt to understand the parameters of the problem area and they typically make commitments to change. In the *action stage*, the individual engages in actual behaviors intended to bring about a change. Finally, in the *maintenance* stage, the challenge is to sustain the behavior change accomplished by prior action and to avoid relapse.

The transtheoretical model also outlines specific *processes of change* that may be used to alter behavior. One is of these processes is *consciousness-raising* which may involve educating an individual about the causes, course, and consequences of a behavior. Another process of change is *counterconditioning* that consists of learning new behaviors to substitute for undesirable behaviors (e.g., learning assertiveness to refuse your mom's offer of another serving of dessert). The transtheoretical model proposes that processes of change need to be matched to appropriate stages of change to assure success. For example, an individual in precontemplation to stop smoking is highly unlikely to benefit from efforts to teach them to restrict their smoking to only a few locations or times of day (i.e., process of *stimulus control*). Instead treatment efforts that involve the process of consciousness-raising are likely to be most helpful in moving the individual to the next stage of the change process. Behavioral medicine professionals are often called upon to assess patients' readiness for change and to make treatment recommendations.

Research on the stages of change has established that they provide a reliable method of measuring change in both clinical and nonclinical populations (Prochaska & DiClemente, 1982; McConaughy, DiClemente, Prochaska, & Velicer, 1989; Prochaska, DiClemente, & Norcross, 1992). Research generally supports the notion that when individuals change, they do so predictably from one stage to the next. However, there is some evidence that individuals can be involved in attitudes and behaviors characteristic of more than one stage at the same time (McConaughy et al., 1989).

The first three models focus on attempts to change behavior, but the last model provides a structure for understanding relapse. Based on the

work of Marlatt and his associates (Marlatt, 1978; Marlatt & George, 1998), this model postulates that individuals who have made a desirable health behavior change (e.g., stopped smoking) experience a sense of control that grows stronger the longer they are compliant. This sense of control is threatened, however, when the individual encounters a high-risk situation. In their analysis of potential high-risk situations, Marlatt and colleagues identified three major categories most likely to produce relapse. These include negative emotional states, interpersonal conflict, and social pressure. This model suggests that any behavior change effort that desires long-term change must address attitudes, beliefs, and behaviors associated with potential high-risk situations. This model proposes a wide variety of treatment strategies that can be categorized into three areas: (1) *skills training* in behavioral and cognitive coping strategies, (2) *cognitive reframing* to lessen the impact of high-risk situations and minor relapses, and (3) *life-style rebalancing* strategies such as relaxation training and meditation. Research that examined components of this model and their ability to predict relapse is promising (Marlatt and George, 1998).

Summary

Researchers have proposed a number of models to account for the way psychological factors impact health. Based on Freudian theory, early personality theorists attempted to explain illness in terms of specific traits, attitudes, or conflicts. Although these early specificity theories are no longer considered adequate to account for the development of illness, interest in the role of personality in illness has continued. Modern investigation of the relationship between personality and health has focused on examining factors that are believed to contribute to the incidence of cardiovascular disease. Although this remains a controversial area of interest, research on TABP, and more recently trait hostility, typifies modern research on personality and illness.

A second area in which the impact of psychological factors that affect illness has been examined involves the impact of stress on health. Models that account for a stress-illness relationship have focused primarily on physiological changes that accompany stress, the effects of

stress on immunity and vulnerability to disease, and the role of coping. Although no single model of stress and illness currently predominates, research suggests that the effects of stress on health may be complex and multiply determined. A third approach to explaining the role of psychological factors in health focuses on the role of learning or conditioning variables. Investigators have proposed that social learning, classical conditioning, and operant conditioning models may partially determine health outcome.

Finally, the ultimate efficacy of a given medical intervention rests on the individual participating in recommended health behaviors. A number of biopsychosocial factors have been discovered that impact adherence, or the likelihood that an individual will perform the necessary health behaviors. Additionally, models have been developed to account for factors that lead to initiating positive health behavior changes or that account for factors that influence discontinuation of unhealthy habits.

Each of the psychosocial or psychobiological models of illness reviewed in this chapter makes significant contributions to understanding how psychological factors may influence health or illness. However, no one model is superior or adequate to account for the impact of psychological factors on health. Further, the models presented are not mutually exclusive; numerous factors may interact to increase the likelihood that illness will develop. Evidence that a multitude of variables is at least partially involved in the development of illness suggests that a comprehensive model that incorporates personality influences, biological variables, life-style factors, the effects of stress, and learning influences will be required to adequately explain the effects of biopsychosocial factors on health.

Emotional Disorders and Medical Illness

Richard L. Gibson and Earl A. Burch

Introduction

The emotional reactions to illness may be more troublesome than the illness itself, particularly if the illness is chronic and results in significant lifestyle changes. These emotional reactions are distressing to the person but do not always meet the criteria set out in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV; American Psychiatric Association, 1994) or the *International Classification of Diseases*, 10th ed. (ICD-10; World Health Organization, 1992) for a specific disorder. In this chapter, we are particularly concerned with chronic medical illness, but much of what is reviewed also applies to acute illness.

It is undisputed that medical illness, especially chronic illness, is stressful and may be associated with emotional disorders. However, the nature of the association, particularly with regard to causal relationships and proper classification, remains unclear. Both the DSM-IV and the ICD-10 classify reactions to stress into three principle groups: (1) acute reactions, in DSM-IV called acute stress disorder; (2) adjustment disorder, classified in

both the ICD-10 and the DSM-IV according to predominant symptoms, such as with depression, with mixed anxiety and depression, with disturbance of conduct, and with disturbance of emotions and conduct; (3) posttraumatic stress disorder (PTSD), an abnormal response to a severe stressor with symptoms that involve intrusive recollection, emotional numbing or avoidance, and arousal. Although PTSD and Acute Stress reactions are seldom diagnosed in connection with medical illness, adjustment disorders certainly are, and in patients with cancer, the prevalence may be nearly 50% (Spiegel, 1996).

Coexisting symptoms of anxiety and depression are prominent among the emotional responses in ill patients that are difficult to classify. It has been known for years that these symptoms are commonly present in medically ill patients and are difficult to separate (Lewis, 1956). The ICD-10 has a category called "mixed anxiety and depressive disorder" which is used when symptoms are not severe enough to meet criteria for a specific disorder and where the association with a stressor is not close enough to warrant a diagnosis of adjustment disorder. The DSM-IV has no such diagnosis, but the appendix includes both "mixed anxiety and depressive disorder" and "minor depressive disorder," either of which could be applicable. The DSM-IV suggests that at present there is insufficient empirical evidence to support including these conditions in the classification. In the *Oxford Textbook of Psychiatry*, 3rd ed. (Gelder, Guth, Mayon, & Cowen, 1996) these symptoms are

Richard L. Gibson • Mississippi State Hospital, Whitfield, Mississippi 39193. **Earl A. Burch** • William Jennings Bryan Dorn Veterans Hospital, Columbia, South Carolina 29201.

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

called "minor affective disorders," and the clinical picture includes anxiety, depression, insomnia, fatigue, irritability, and poor concentration. Such somatic symptoms due, it is thought, to psychological factors, were present in 52% of patients presenting to a primary care practice. However, in such a group of patients, one should not assume that the symptoms are due to psychological factors, and the etiology must be investigated.

Classification is not simple; neither is cause and effect. Notions of cause and effect abound, but they are seldom evidence-based. In the case of psychiatric disorders, three major theoretical constructs relate stress and illness, (although there are many variations) all described by Dohrenwend and Dohrenwend (1981). The first is the *innocent victim* model, in which there is exposure to some stressful circumstance. If the stressor is severe enough or if there is special susceptibility, illness occurs. This model accounts well for PTSD and adjustment disorders, but is otherwise lacking. Building on the first model, the *vulnerability hypothesis* says that stress triggers illness in those already predisposed to develop psychiatric illnesses; and the source of the vulnerability can include genetics, social relationships, or early childhood experiences. This model is popular and invoked often for many illnesses, including depression. The third model builds on the first two and is called the *interactive model*, which postulates that deficient coping skills result in the inability to prevent undesirable events and perhaps even cause undesirable events, which then result in illness.

Having introduced the notion of coping, we will now examine it in some detail, because at least a basic understanding of coping is necessary to work effectively with people who are ill. Traditional psychiatric views of coping and especially defense mechanisms stem from the theoretical work of Sigmund Freud and his followers, and a hierarchical developmental system is usually employed to classify defensive strategies as either mature/healthy (usually called coping strategies and including such things as humor and suppression) or immature/not so healthy (such as projective identification, psychotic denial, and splitting). George Vaillant has described this system very well (Vaillant, 1977, 1992).

Coping can also be viewed as a process, rather than a hierarchy based at least in part on preconceived notions of health and illness. This approach

has been reviewed by Lazarus (1993) who divides coping strategies into adaptive and maladaptive. Adaptive strategies may be further divided into problem solving strategies, which modify some adverse circumstance so as to reduce stress, and emotion-reducing strategies, which enhance one's ability to deal with stress.

Examples of problem solving include obtaining advice or help, making a plan to deal with the problem, or confronting someone about behavior.

Examples of emotion-reducing strategies include ventilation (expressing emotion), avoidance (not thinking about or dealing with a problem right away), accepting or rejecting responsibility for a problem, and reframing the experience so that it is viewed in a positive light.

In our culture, problem solving strategies are often valued more highly than emotion-reducing strategies, but both may be equally effective.

Horowitz (1997) combined elements of process and hierarchy into a unique scheme for looking at response to stress on an individual in terms of *controls* that are used to regulate emotional reaction to a stressful life event. Controls maintain an emotional state or mind-set and may also be responsible for the transition from one state to another. The scheme includes controls of mental set, concepts of self and others, and information flow. Table 1, dealing with control of self-concept is reproduced here to illustrate the method.

As an illustration of the advantage of using a process approach to evaluate coping, consider denial, which is a relatively primitive or immature way of coping in a hierarchical defensive system; yet, research clearly shows that denial can be adaptive in some circumstances, and use of denial may actually improve prognosis (Levenson et al., 1994; Ness & Ende, 1994). Note that Vaillant continues to generate data supporting the use of a hierarchical system (Soldz & Vaillant, 1998). The terminology used to describe hierarchical defenses is widely known and will be briefly reviewed.

In Freudian theory, defense mechanisms are considered unconscious processes, that is, they are not employed deliberately, and the person who uses them is unaware of doing so. Common defense mechanisms include

- Regression, or a return to behavior appropriate to an earlier stage of development.
- Reaction formation, or behaving in a way that reflects the opposite of one's true feelings.

Table 1. Controls of Self-Concept^a

Processes	Sample outcomes		
	Coping	Defense	Succumbing to stress
Altering self-schema that are activated self-concepts	Heightened sense of identity by using the most competent self-concept in the subject's repertoire of self-views	Omnipotent denial of personal vulnerability, "as-if" concepts, regressions to earlier self-concepts	Depersonalization, chaotic lapse of identity, annihilation anxiety
Altering dominance hierarchy of available role relationship models and scripts	Seeking help, sublimation	Dissociations and splitting passive-dependent expectations	Sensation of helplessness, separation anxiety
Altering dominance hierarchy of available world views	Increased sense of unity or ideological commitment, altruism, increased sense of reality, sublimation	Altruistic surrender, increased self-centeredness	Sense of meaninglessness or derealization

^a*Stress responses syndrome: PTSD, grief, and adjustment disorders*, (p. 106), by M. J. Horowitz, 1997, Northvale, NJ: Jason Aronson Inc. Modified with permission.

- Repression, probably the only defense mechanism described by Sigmund Freud, is the exclusion from consciousness of memories or emotions that would be distressing.
- Denial, mentioned before, is inferred when a person behaves as though unaware of something that should be known. For example, a person told of having a terminal illness may act as if unaware of the diagnosis and may continue normal activities; and as mentioned previously, sometimes this may be adaptive. Denial is frequently inferred in evaluating patients with suspected substance use disorder, and at least in some cases the observed behavior may be due to neurological deficits, not a psychodynamic process (Duffy, 1995).
- Rationalization, unconsciously providing an acceptable explanation for behavior that actually has some other cause.
- Displacement, the transfer of emotion from one person, object, or situation to another (presumably less threatening) person, object, or situation.
- Projection, the attribution to someone else of thoughts or feelings similar to one's own thoughts or feelings.
- Identification, unconsciously adopting the characteristics or activities of another.
- Sublimation, the unconscious diversion of unacceptable impulses into acceptable outlets. For example, turning a need to dominate into organizing a drive for charity.
- Suppression, a *conscious* decision to remove something troubling from immediate awareness until a later date. Because this is a *conscious* decision, some would argue that it is not a defense mechanism but rather a coping skill. The result is the same. Table 2 shows some defense mechanisms arranged hierarchically.

There is no doubt that such mental phenomena occur and can be identified in clinical practice. However, interrater reliability in identifying defense mechanisms is quite poor even when precise definitions are provided (Perry & Cooper, 1989).

How often do emotional disorders occur in patients with medical illness? Superficially, this may seem a simple question but it is fraught with problems of definition. How does one define "emotional disorder?" Rates may differ among acute medical illness, chronic medical illness, *terminal* medical illness, painful illness, disfiguring illness, or combinations. Are we to exclude emotional disorders caused by treating the medical illness or include them? Rate, or the occurrence of cases in a

Table 2. Hierarchical Classification of Defense Mechanisms (Level)

Adaptive level	
Humor	Anticipation
Suppression	Self-assertion
Sublimation	Denial ^a
Compromise (neurotic) level	
Repression	Undoing
Intellectualization	Reaction formation
Displacement	Denial ^a
Primitive level	
Acting out	Projection
Passive aggression	Dissociation
Hypochondriasis	Denial ^a
Very primitive level	
Splitting	Projective identification
Omnipotence	Denial ^a
Distortion	

^aDenial is placed at all levels to indicate (1) denial can be understood in different ways; (2) the basic problem of a hierarchical system—preconceived notions of whether or not a mental operation is healthy.

population, is the basis of epidemiology. In the case of emotional disorders and medical illness, it has been impossible to define “case” or “population” rigorously, so we are left with estimates. It has been said that “the most conspicuous feature of the emotional response of most people to serious physical illness is their resilience” (Gelder et al., 1996, p. 358), that is, psychiatric disorder does not occur in most people with serious medical illness, but it may occur in 30% or more of those who have serious illness, especially progressive illness that results in a changed life-style.

In addition to psychological reactions to illness and hospitalization, emotional symptoms can represent the direct effects of the physical illness or the treatment process (e.g., drug-induced confusion). In fact, the first step in evaluating a medically ill patient is to consider organic etiologies first and purely psychological reactions second. This is supported by data from large series of consecutive consultations in general hospitals. Knights and Folstein (1977) reported that 37% of general medical ward patients with cognitive impairment went undiagnosed by ward physicians. Additionally, nurses failed to identify 55%, and

medical students overlooked 46%. DePaulo and Folstein (1978) examined thirty-three patients with cognitive impairment on a neurological inpatient ward and found that 30% were not diagnosed by the attending neurologists. Folks and Ford (1985) evaluated 195 patients (60-years old or older) at the request of their primary care physicians. An organic mental disorder was diagnosed in 42%, but in 62% of these cases, the physicians who requested the consultations had not recognized the presence of cognitive dysfunction.

A survey of 118 male veteran patients examined by a psychiatric consultation team diagnosed cognitive dysfunction at a significantly higher rate in older than in younger male patients. Using the Mini-Mental State Exam (MMSE; Folstein, Folstein, & McHugh, 1975), 49.3% of seventy-five male patients 55-years old or older scored abnormally low as compared to 11.6% of forty-three men younger than age 55 (MMSE mean score = 21.4 vs. 27.4; normal: 24–30; paired t-test: $p < .0001$; Chiarello & Burch, 1989).

As a general guideline, sudden changes in “personality” in an adult with no previous psychiatric history should alert the clinician to the possibility of a nonpsychiatric illness. Some case examples will be used to illustrate this point.

Case 1. Mr. A was a 57-year-old white man who was brought to the emergency room (ER) because of increased agitation, anorexia, tearfulness, and suicidal ideation. The patient stated that his change in mood occurred 2 weeks before admission when he tried to get into his car to drive. He had difficulty remembering how to use his keys to unlock the car door and once in the car, could not remember how to drive. His family had interpreted this as a driving phobia. On examination, Mr. A was anxious and tearful, with decreased concentration, short-term memory problems, suicidal ideation, and paranoia. He demonstrated components of expressive and receptive aphasia, with limb and ideational apraxias. His MMSE score was 15 out of 30. Because he had undergone a radical neck dissection for squamous cell cancer 1 year previously, a CT scan of the brain was ordered to rule out metastasis. The CT revealed multiple cystic metastatic lesions in the frontal lobes, with widespread edema. Treatment with radiation and steroids improved his mood, and his MMSE score increased to 24.

Case 2. Mr. B was a 49-year-old white man with no previous medical or psychiatric treatment who

came to the ER complaining of the acute onset of slurred speech and lethargy during the previous 24 hours. He was overweight and hypertensive (blood pressure = 168/110 mmHg). He had mild ankle edema and an irregular pulse. A neurological exam was normal except for the slurred speech (drug or alcohol intoxication was suspected); a CT of the brain was read as normal. He was admitted to the medical service for treatment of his hypertension and heart failure. Psychiatry was consulted to evaluate Mr. B's depression. It was noted that he had decreased verbal output and was lethargic and disheveled (he was not shaving, combing his hair, or brushing his teeth). Although he did look and sound depressed, his MMSE score was 22, with deficits in calculating ability, short-term recall, spontaneous writing, and design copying. More detailed testing yielded the diagnostic impression of aphasic syndrome with buccofacial and limb apraxias. A repeat CT scan of the brain revealed a small hypodense area in the region of the caudate nucleus (subcortical stroke).

This patient's depressive symptoms improved spontaneously as his aphasia and apraxias resolved. However, it has been reported that 30–60% of acutely and chronically ill poststroke patients have significant levels of depression (Lipsey, Spencer, Rabins, & Robinson, 1986). Because about half of the depressions fulfill the criteria for major depression and last more than 6 months (Lipsey et al., 1986), treatment is important in reducing chronic disability. This is especially true given that poststroke depression is responsive to antidepressant intervention (Lipsey, Robinson, Pearlson, Rao, & Price, 1984).

Case 3. Mr. C was a 27-year-old Black female who became anxious when she discovered that her husband was seeing another woman. When her husband asked for a legal separation, the patient went to live with her parents in another state. But Ms. C became increasingly anxious, prompting her family to take her to their medical doctor. The physician referred her to a mental health center, where she was diagnosed with paranoid schizophrenia and treated with 400 mg per day of chlorpromazine. She continued to worsen, with increased agitation and paranoia. The family took her again to the family physician who performed a physical exam and noted an enlarged and palpable thyroid. Thyroxine (T4) level was “too high to measure,” and Ms. C was treated with a thyroid-blocking medication and chlorpromazine. Once

the thyroid function normalized, her mental status returned to normal, and she underwent a subtotal thyroidectomy. She was able to become employed, live in the community, and did not require psychiatric drugs.

Case 4. Mr. D was a 64-year-old Black man who was brought to the ER by his wife because of a 3-week personality change. Just before Mr. D's personality began changing, he had an argument with his daughter over finances, and she stated that she never wanted to see him again. Mr. D became withdrawn and depressed, had crying spells, and would sit motionless in his chair each day. One week before the hospital visit, it was noted that he was more talkative, animated, and hyperreligious, believing that he was “the Messiah.” On examination, he was pacing, hyperactive, and talkative. His speech was pressured, and he demanded that everyone bow down because he was the Messiah. His affect was labile, and he would intermittently become agitated and aggressive. Because he had an history of chronic obstructive pulmonary disease, mitral valve disease, cardiac arrhythmias, and congestive heart failure, he was admitted to the medicine service. The psychiatry consultant medicated him with intramuscular haloperidol so that he could be given a physical exam. Once it was determined that his medical status was stable, he was transferred to the inpatient psychiatry service and placed on oral haloperidol. A CT scan of the brain revealed multiple infarcts, including an apparently recent right occipital infarct. Interestingly, the neurological exam was “nonfocal”; the diagnostic impression was organic mood disorder secondary to cerebral embolization. During the next year, Mr. D developed signs of multi-infarct dementia.

Case 5. Mr. E was a 58-year-old man with a long history of hypertension who had been recently discharged from the hospital with congestive heart failure. His blood pressure regimen was changed to methyl dopa, and his wife reported that he had developed a personality change since his discharge. He was lethargic, exhibited little interest, and suffered crying spells. He had begun to consider that life was not worth living but was too religious to commit suicide. On examination, Mr. E was tearful and depressed, and he showed psychomotor retardation. His MMSE score was 20. He had no previous psychiatric history. A tentative diagnosis of drug-induced depression was proposed, and it was recommended that his antihyper-

tensive drug be changed to atenolol (he had tolerated this in the past, and it may cause less depression than methyl dopa) (Henningsen & Mattiasson, 1979). Two weeks after the medicine change, Mr. E was no longer depressed. Thus, his hypertension could be controlled with atenolol while avoiding the drug-induced depression associated with methyl dopa. Likewise, by correctly diagnosing a drug-induced depression (organic mood disorder), Mr. E was spared treatment with an antidepressant medication that would have exposed him to additional side effects.

Case 6. Mr. G was a 30-year-old Black male who was HIV positive and was admitted to the coronary care unit for monitoring because of an arrhythmia. Psychiatry was consulted because the patient was highly anxious and agitated over being diagnosed HIV positive. He stated that when he told his girlfriend, she started screaming and told him that she never wanted to see him again. Likewise, his male friends called him a homosexual, which he fervently denied. He also denied drug use and could not understand how this could have happened. He said that he knew it was a "death sentence" because every time he read the newspapers the headlines would say, "No Cure for AIDS." Because of the diagnosis, he felt that his sex life was over, he felt overwhelmed and could not sleep. He was glad to have someone to talk with after so many rejections. Treated with lorazepam, his anxiety symptoms and insomnia improved.

In view of the current AIDS pandemic, it is particularly important to consider the multitude of emotional reactions associated with the diagnosis of HIV infection. The mental health consultant should keep in mind that HIV infection has a predilection for the brain (Gabuzda & Hirsch, 1987) and that invasion of the brain by this virus can cause a variety of changes in personality and mental status, including cognitive and psychotic alterations (Femandez & Ruiz, 1989).

Psychodiagnosis and Psychological Testing

Psychodiagnosis improved dramatically in reliability with the introduction of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 3rd ed. (DSM-III; 1980). The manual is periodically revised and

the current edition is the DSM-IV. To achieve interrater reliability, specific and explicit criteria are set forth for each disorder using a polythetic scheme (criteria for different disorders overlap). The *kappa statistic*, proposed in 1960 (Cohen, 1960) as a way of measuring agreement among clinicians, was used in the DSM-III and subsequent DSM editions to assess reliability. Reliability is considered poor if kappa is less than .40, fair if between .40 and .59, good if between .60 and .74, and excellent at or above .75 (Fieiss, 1981; Perry, 1992).

It is generally agreed that acceptable reliability in diagnosing Axis I disorders was achieved by publication of the DSM-III (Grove, 1981, 1987). However, a few disagree (Kutchins & Kirk, 1986).

Unweighted kappa coefficients in phase one and two of the DSM-III field trials were 0.68 and 0.72, respectively, for Axis I disorders in adults, and 0.56 and 0.64, respectively, for Axis II disorders in adults (American Psychiatric Association, 1980, pp. 470–471). Considerably lower kappa coefficients have been reported when diagnosing personality disorder. For instance in one study, clinicians first determined if a personality disorder was present or not; kappa for that was 0.41. For diagnosis of specific personality disorders, kappa was still lower; for example, for borderline personality disorder, it was only 0.29 (Mellsoop, Varghese, Joshua, & Hicks, 1982).

Achieving reliability in diagnosis depends largely on adherence to diagnostic criteria. However, there is abundant evidence that clinicians frequently do not apply criteria strictly when making diagnoses, and therefore reliability suffers (Davis, Blashfield, & McEllroy, 1993; Morey & Ochon, 1989). Although it may sound simple, the most important element of making a reliable diagnosis is strict adherence to the diagnostic criteria. Does psychological testing add something if diagnostic criteria are strictly applied? For projective tests, probably not (Garb, 1998). For objective tests such as the MMPI-II, perhaps; in the authors' opinion, the best use of psychological testing is to improve the database used in determining whether criteria are met. For example, neuropsychological testing will determine whether memory loss or visuospatial defects are present in a person suspected of having early dementia, and intelligence testing assists in diagnosing mental retardation.

Garb (1998) suggests several other factors that will improve diagnostic accuracy, such as atten-

tion to research; awareness of cultural bias; description of patients' strengths as well as weaknesses; a systematic, comprehensive approach; use of specific strategies to reduce bias; and being very cautious when attempting difficult diagnostic tasks such as predicting violence or making judgments about personality in a depressed patient.

Evaluating Depression

In a general hospital, "evaluate for depression" is a frequent request to mental health specialists who consult on the medically ill. Of 118 consultations to the New Orleans VA psychiatric consultation service, more than one-third (36%) were for suspected depression (Chiarello & Burch, 1989). The Beck Depression Inventory (BDI); (Beck, 1967) continues to be used to screen for depression among the medically ill; using a BDI cutoff score of 14, Moffic and Paykel (1975) reported that 28.7% of the medically ill they surveyed met the criteria for depression. But would all these patients be classified depressed by the DSM-IV criteria? Probably not, because the BDI is weighted with somatic items and the underlying physical illness must be considered when interpreting the score. Between 50 and 80% of medically ill patients report psychomotor retardation, work inhibition, fatigue, appetite disturbance, weight loss, sleep disturbances, and somatic distress (Cavanaugh, 1984). Complicating further the picture of depression in the medically ill, Cavanaugh, Clark, and Gibbons (1983) reported the presence of a common emotional response in about one-third of medical inpatients that consisted of irritability, sadness, crying, mild dissatisfaction, mild discouragement with the future, and mild indecisiveness. No somatic symptoms were found that were valid, consistent discriminators of medically ill depressed from nonmedically ill depressed patients. These authors, however, concluded that the presence of four affective/cognitive symptoms were important in identifying depression in the medically ill: sense of failure, loss of social interest, sense of punishment, and suicidal ideation.

Craven, Rodin, Johnson, and Kennedy (1987) studied a group of renal dialysis patients using the Diagnostic Interview Schedule (Robins, Helzer, Croughan, Williams, & Spitzer, 1981) and applying the DSM-III criteria. Eight percent of the sample met criteria for major depression, and half of

these had histories of major depressive episodes. Compared to patients without current major depression, patients with major depression were distinguished by the following criteria: depressed mood or loss of interest, feelings of worthlessness or excessive guilt, anorexia or weight loss, and slowed or mixed up thought. Somatic symptoms did not differ in depressed and nondepressed patients. Rapp and Vrana (1989) also used nonsomatic symptoms to diagnose depression in a group of 150 elderly male medical inpatients. The four symptoms they used, tearfulness/depressed appearance, social withdrawal/decreased talkativeness, brooding/self-pity/pessimism, and lack of reactivity to environmental events, were significantly more accurate in diagnosing depression than somatic symptoms.

Evaluating Substance Use Disorders

Currently, research into the biology of addictions is proceeding at an explosive rate; but for decades, observers have studied the psychology of addictions, and there are important insights from those studies that should not be neglected. For example, Kohut proposed that drugs act as a replacement for some defect in the psychic structure, thereby enabling addicts to cope with rage, shame, hurt, and loneliness (Kohut, 1971). Cognitive behaviorists take the view that alcoholism and drug dependence are maladaptive coping mechanisms that can be changed by learning new ways of coping and new problem solving skills (Beck, 1993). Although such insights are valuable in understanding and treating addicted persons, it is clear that there indeed is a biological foundation of addiction. The psychodynamic theorist George Vaillant studied alcoholism prospectively for 30 years and refuted the idea of an addictive personality (Vaillant, 1983); and catecholamine depletion in the central nervous system, it has been shown, is associated with the desire to reuse drugs, making ego-deficits and unhappy childhoods irrelevant in many cases (Koob & Bloom, 1980).

Diagnosis of substance use disorders requires familiarity with the DSM-IV, which divides substance-related disorders into use disorders (further divided into dependence and abuse syndromes) and induced disorders, which include intoxication,

withdrawal, mood disorder, anxiety disorder, delirium, dementia, and others.

Therefore, the differential diagnosis is broad, and diagnosis is often confounded by the fact that patients and families may distort, deny, minimize, or lie about substance use and related problems. A high degree of suspicion about drug use is required, and permission should be sought to obtain collateral data from family members and other sources. Common presentations include insomnia, chronic pain, mood disorder, and anxiety. Psychotic symptoms also occur, as do many others.

The term dual diagnosis generally is applied to persons with comorbid psychiatric and addictive disorders and is clearly one of the major problems within the mental health field currently (Committee on Training & Education in Addiction Psychiatry, 1994). Rates of comorbid disorders range from 15–40% (Regier, 1990; Kessler et al., 1994). At least one reason for the high rate of comorbid disorders is that those who have comorbid psychological and drug problems (alcohol in this study) are more likely to seek help (Helzer & Pryzbeck, 1988). Helzer and Pryzbeck also emphasized that prematurely labeling a psychiatric syndrome of depression, anxiety, or psychosis as major depressive disorder, panic disorder, or schizophrenia can delay treating the actual problem. It is amply demonstrated that the course of a substance-induced psychiatric syndrome is different from the course of a psychiatric disorder not induced by a substance; symptoms are not disorders (Weingold et al., 1968; Brown & Schuckit, 1988; Shuckit et al., 1990; Anthenelli, 1993).

Correct diagnosis is made more difficult because individuals who have primary psychiatric disorders such as schizophrenia or bipolar disorder are at much higher risk of a substance use disorder than nonmentally ill persons. For instance, more than 50% of bipolar patients have substance use disorders at some time in their lives (Regier, 1990; Anthenelli, 1994).

Important aids to accurate diagnosis include

1. Maintain a high index of suspicion for drug use.
2. Use collateral data.
3. Distinguish psychiatric symptoms from psychiatric disorders.
4. Follow the patient and remain flexible.
5. Consider drug screens.

Treatment of addicted patients, especially patients with comorbid psychiatric addictive disorders, is not easy. The authors believe that there is a biological basis underlying the addictive use of substances and that patients are more likely to accept treatment when the diagnosis is couched in terms of illness rather than moral failure (Clark, 1981).

However, broad knowledge of psychology is essential preparation for treating addicted patients who almost universally manifest various defense mechanisms such as denial, rationalization, minimalization, and projection. These psychological mechanisms must be recognized and strategies developed for undermining or supporting the defense, whichever is more appropriate.

Outcome studies do not allow making definitive statements about treatment programs, but in general a multidisciplinary approach seems important (Fox, 1968), as does regular and prolonged outpatient care (Pittman & Tate, 1969; Vannicelli, 1978).

The role, length, and need for inpatient hospitalization versus outpatient treatment remains controversial (Adelman & Weiss, 1989; Cole et al., 1981; Stein et al., 1975). The cost-effectiveness of treating alcoholism is not a settled question either, although the authors believe that the weight of the evidence is solidly on the side that treatment is cost-effective (Rundell & Pardees, 1979; Holder & Hallan, 1986; National Association of Addiction Treatment Providers, 1991).

Psychopharmacology

The following section is a brief review of psychopharmacology that emphasizes the patient who has both medical and psychiatric illness. It is not intended to be comprehensive or exhaustive, and the reader is referred to other sources for more information, including material on psychotropic drug use in pregnancy, which is not covered here.

Antipsychotics

Antipsychotic drugs are also called neuroleptics and major tranquilizers. Neuroleptic refers to side effects, and the term major tranquilizer can mislead as to the principal use of the drug; so antipsychotic is used here. A large number of antipsychotic drugs are available, and many are listed in

Table 3. Generic and Trade Names of Psychotropic Medications Discussed

Generic name	Trade name	Generic name	Trade name
Antipsychotics		Benzodiazepines	
Chlorpromazine	Thorazine	Alprazolam	Xanax
Droperidol	Inapsine	Chlordiazepoxide	Librium
Haloperidol	Haldol	Clonazepam	Klonopin
Loxapine	Loxitane	Diazepam	Valium
Mesoridazine	Serentil	Flurazepam	Dalmane
Molindone	Moban	Lorazepam	Ativan
Pimozide	Orap	Oxazepam	Serax
Thioridazine	Mellaril	Triazolam	Halcion
Thiothixine	Navane		
Antidepressants			
Atypical agents		Amitriptyline	Elavil
Clozapine	Clozaril	Bupropion	Wellbutrin
Olanzapin	Zyprexa	Desipramine	Norpramine
Quetiapine	Seroquel	Doxepin	Sinequan
Risperidone	Risperdal	Fluoxetine	Prozac
Mood stabilizers		Fluvoxamine	Luvox
Carbamazepine	Tegretol	Imipramine	Tofranil
Lithium carbonate	Eskalith	Mirtazapine	Remaron
	Lithobid	Nefazodone	Serzone
	Lithane	Nortriptyline	Pamelor
Sodium valproate	Depakote	Trazodone	Desyrel
	Depakene	Venlafaxine	Effexor
Miscellaneous			
Zolpidem	Ambien		

Table 3. The table distinguishes newer, so called "atypical" antipsychotic drugs; the reason for this is that these newer agents have assumed great importance in treating psychotic illness because they are effective in improving the negative symptoms of schizophrenia (anhedonia, alogia, apathy, blunt affect), whereas the older drugs are not. The newer agents are also less likely to cause extrapyramidal (neuroleptic) side effects. The first of the newer agents to become available, clozapine, it was shown in controlled studies, results in improvement in up to 50% of patients who were not helped by other drugs (Kane et al., 1988). Unfortunately, there is a significant risk of agranulocytosis (1–2%), which can be fatal and which requires

regular hematologic monitoring. The newer atypical antipsychotics, risperidone, olanzapine, and quetiapine, have some of the benefits of clozapine without the risk of agranulocytosis. They are all too new to make specific recommendations about their use, but certainly they should be tried if older antipsychotics have failed and should be considered drugs of choice for a patients with significant negative symptoms.

All antipsychotics have in common an ability to block dopamine receptors, which may account for the therapeutic effect, although this is still being investigated. Most antipsychotic drugs, especially the older ones, bind strongly to the dopamine D2 receptor, and this appears to account for both anti-

psychotic action and the development of movement disorders. Clozapine, one of the newer agents, has a relatively weak affinity for D2 receptors, and the antipsychotic effect may be due to blockade of multiple receptors, including dopamine D4 and serotonin 5-HT receptors (Coward, 1992). Movement disorders are unlikely to occur with clozapine.

Side Effects. Detailed side effects of individual drugs can be found in any standard clinical pharmacology reference, which should be consulted before prescribing any agent. Here we review only a few major areas. *Extrapyramidal effects:* The effects result from dopamine blockade and can be divided into four major categories: *Acute dystonia* occurs soon after treatment begins, especially in young men. It is prevented by using low doses of antipsychotics and can be treated by anticholinergic agents (benztropine mesylate) or antihistaminic drugs (diphenhydramine). Acute dystonia involves spasm of large muscle groups, particularly in the upper body and neck and may need to be treated with IM or IV drug if severe, and especially if there is respiratory distress because of laryngeal spasm. *Akathisia* is a very unpleasant sensation of restlessness, resulting in an inability to stay still. It is treated with dose reduction, anticholinergic drugs, or beta-blockers. *Parkinsonism* is characterized by akinesia, rigidity, tremor, expressionless face, stooped posture, and occasionally festinating gait. It is treated with anti-Parkinson drugs, but usually not L-dopa for fear the psychosis will worsen. *Tardive dyskinesia* is characterized by involuntary movements of the mouth and tongue which may resemble chewing, grimacing, or sucking, by choreoathetoid movements of the upper extremities, and by truncal ataxia in severe cases. It may not reverse when the drugs are stopped, and there is no effective treatment, so this is a particularly serious problem. The older antipsychotics are more likely to cause these problems than the newer ones, hence the increasing popularity of the newer agents.

Which Drug to Choose?

It is a general rule of psychotropic drug use that if a patient is doing well on a particular drug or has done well on it in the past, use that drug. If negative symptoms are present, use a newer "atypical" drug. The authors now start most new patients on

olanzapine or risperidone. Risperidone is quite useful in low doses in elderly patients who may be prone to extrapyramidal effects and who may be oversedated with olanzapine or quetiapine.

Chlorpromazine, droperidol, and haloperidol may all be given IM to produce rapid calming (IM chlorpromazine is quite painful). It is also common practice to combine haloperidol with lorazepam (a benzodiazepine) as an IM mixture to produce rapid calming. At this time, the newer atypical agents are not available for IM or IV use. Haloperidol can be given IV, and there is considerable experience with it, but it is an "off label use," one that is not approved by the FDA; the prescriber should be aware that, although such use is perfectly legal, there is added responsibility to inform the patient or the patient's surrogate.

Antidepressants

Depressive disorders are common in the medically ill, although not so common as popularly believed. For instance, Silverstone found that only 27% in a group of 313 medically ill patients met criteria for any DSM-IV disorder and about 5% had major depressive disorder (Silverstone, 1996). The rate of any depressive disorder may be higher in patients with chronic medical illness such as cancer (Spiegel, 1996). Studies have consistently shown that in a primary care setting, depression is both underrecognized and undertreated. Depression does have substantial morbidity and even mortality, and therefore recognition and adequate treatment are important. Serotonin specific reuptake inhibitors (SSRIs) have become the most popular first-line treatment for depression because they are easy to use (not much dose adjustment is necessary) and they have few side effects. Practitioners develop preferences for one SSRI over another based (probably) on episodic successful use (a form of intermittent reinforcement). There actually is little data to suggest that one is better than another. There are questions about the efficacy of SSRIs in treating severe depression (Rudorfer & Potter, 1989). For severe depression not responsive to an SSRI, the addition of a tricyclic (TCA) or another agent may enhance the antidepressant response. Some newer agents that deserve mention are venlafaxine, nefazodone, bupropion, and mirtazapine. Venlafaxine (Effexor) blocks serotonin and norepinephrine re-uptake and has little in the way of sedative or anticholinergic side ef-

fects (Feighner, 1994). Nefazodone (Serzone), is related to trazodone but is not as sedating. Bupropion (Wellbutrin) was introduced in the United States in the mid-1980s, withdrawn because of an association with seizures, and then reintroduced in 1989. It is effective, seizure incidence is not alarming if the dose is not too high, and it has no sexual side effects. Mirtazapine (Remeron) is the newest antidepressant drug available at this time. It is structurally different from any other antidepressant available in the United States and enhances both noradrenergic and serotonergic transmission, probably its mechanism of action.

In the decade from 1988 (Prozac introduced) to 1998, there has been a paradigm shift in antidepressant prescribing patterns. The drugs mentioned earlier are used almost exclusively to treat depression and various other disorders for which antidepressants may be indicated; drugs in use before 1988, the TCAs and the monoamine oxidase inhibitors (MAOIs), are infrequently used now. As mentioned, the reasons for this shift are that the newer agents have few side effects, dose-response relationships are simple, and they are generally effective. TCAs and MAOIs have multiple side effects, and dosing is difficult, but they are very effective if adequate doses are given.

Which Drug to Use?

The authors recommend an SSRI as the first-line treatment for depression; venlafaxine or mirtazapine can be used for patients with a history of SSRI nonresponsiveness, and bupropion may be helpful if sexual side effects are a problem. TCAs and MAOIs still have a place but probably should be used only by experts. The combination of a TCA plus an SSRI is effective, but care must be taken to ensure that the TCA blood level does not reach the toxic range (Bell & Cole, 1988; Kahn, 1990; Vaughn, 1988). In particular patients, antidepressant choice may be influenced by potential drug interactions related to the cytochrome P450 system, especially among the medically ill (Nemeroff et al., 1996).

Anxiolytics

Antidepressants, especially SSRIs and TCAs, may be useful in treating anxiety. Both SSRIs and TCAs are effective in blocking panic attacks;

TCAs are effective in generalized anxiety disorder, and MAOIs may be effective in both but are difficult to use.

Antihistamines are sometimes used to treat anxiety when prescribers are concerned about benzodiazepine (BZ) abuse. Although clearly less effective than BZs, they may be indicated for some patients. Hydroxyzine is most commonly used but is anticholinergic and should be used with caution, especially for the elderly.

Barbiturates are less effective than BZs, less safe, and more likely to be abused. They should no longer be used to treat anxiety.

Buspirone (Buspar) is chemically different from the BZs. It does not impair arousal or reaction time and has no abuse potential. It is effective for generalized anxiety disorder, although less effective for individuals previously treated with BZs. It has many characteristics of an ideal antianxiety drug but has been somewhat disappointing in clinical practice for reasons not entirely clear. It is not effective at all in treating panic disorder. Buspar does have mild antidepressant actions at doses higher than its anxiolytic dosage (Fabre, 1990).

Mood Stabilizers

Lithium carbonate has been used for decades to treat acute mania, but valproate is becoming a favored alternative. Lithium is inexpensive, and most clinicians are familiar with it, but it can be toxic to the kidneys, and renal function must be monitored during its use. A further limitation in medically ill patients is that diuretics, nonsteroidal anti-inflammatory agents, and several other drugs, can raise lithium levels. Levels should be monitored to prevent toxicity. Lithium may have neurotoxic effects, even at therapeutic levels, and patients with preexisting brain disease (e.g., stroke or dementia) are more sensitive to these effects, which include headache, decreased memory, poor concentration, muscle weakness, and tremor.

Valproic acid has been used to treat seizures since the 1960s. In 1995, divalproex sodium, an enteric-coated equimolar combination of valproic acid and sodium valproate, was approved for treating acute mania (Bowden, Brugger, & Swan, 1994). It may be started in fairly small divided doses (250 mg, two to three times a day), and the doses are gradually increased, or a loading dose of 20 mg/kg may be started and continued until levels are between 50 and 125 mg/mL. The response may

be very rapid if loading doses are used (McElroy et al., 1996).

Carbamazepine (CBZ), structurally related to the TCAs, is generally considered effective in treating acute mania and may prevent recurrence of bipolar illness, but firm proof is lacking. CBZ may be used with lithium, valproate, a neuroleptic, or as mono therapy. If used with another agent, especially valproate, levels of each agent should be monitored. CBZ induces its own metabolism, making it necessary to adjust dosage to maintain an effective level. It may also cause cardiac conduction abnormalities, thus limiting its usefulness in patients with heart disease.

Lamotrigine (Lamictal), another anticonvulsant drug, may have antidepressant and mood stabilizing effects, but it has not been well studied.

Particular Stresses on Health Care Providers

Burnout

Burnout has been much talked about and has been actually studied fairly well. There are several definitions of the term and the authors prefer the one derived by Pines and Aronson (1988) which is that burnout is "a state of physical, emotional, and mental exhaustion caused by long term involvement in emotionally demanding situations." It has been studied specifically in mental health workers where high levels of burnout were found that resulted in low morale, high absenteeism, and high job turnover (Pines & Maslach, 1978).

Burnout occurs when people who are highly invested in their work, usually demanding work, do not achieve what they expect. People want their work to be significant, to mean something, and if they think they have failed, burnout occurs.

Case Example. A psychiatrist was consulted by the head nurse of a medical unit to assist in resolving a crisis among the nursing staff who worked on the unit. A meeting was scheduled for the nurses, and they described the following scenario. A nursing colleague they all knew and loved had been hospitalized on their unit (at their request). This nurse was dying of chronic hepatitis that she contracted while working in the hospital. She was being treated by the most respected liver specialist in the community (this was in the days before liver transplantation). But the nurses were angry and

frustrated about the care this physician was providing: "He's not doing enough for her. She's deteriorating every day. There's got to be more that can be done!" At this point, all the nurses were crying. They understood that their friend was dying, but emotionally, they identified with her: "It could be any of us lying there suffering." In this tragic situation, they felt they had failed and also displaced part of the blame for this failure onto the physician. When confronted, they admitted they could not think of anything else that could be done. They acknowledged that their attempts to provide physical and psychological support to their friend were helping her be more comfortable but that the emotional energies devoted to their friend were not leaving time or energy to care for the other patients.

Several things were accomplished with this consultation. First, the nurses were able to admit that everything was being done that was medically available and that their interventions were appreciated by the patient. Furthermore, their interventions had led to a greater level of comfort for the patient. Acknowledging that having their friend on the unit was overwhelming, they agreed to transfer her to another ward. Because this was the consultant's decision, the nurses did not feel guilty for abandoning their friend, which they might otherwise have done. There was a sense of relief after the transfer occurred.

Dealing with burnout requires understanding *coping*, introduced earlier in this chapter. Coping can also be understood as an effort to overcome challenges or threats of harm when an automatic response is not available (Monat & Lazarus, 1985). Coping does not imply success in dealing with a stressful situation, only that an effort is made. It is the link between stress and adaptation; four categories of coping have been identified in studies of burnout:

1. active, direct (e.g., confront and alter the stress)
2. inactive, direct (e.g., ignore or leave the stressful situation)
3. active, indirect (e.g., talk about the stress with a supportive person)
4. inactive, indirect (e.g., use alcohol or drugs).

The active strategies tend to work best and successful coping requires four things:

1. awareness of the problem

2. taking responsibilities for dealing with the problem
3. clarifying what can possibly be changed and what probably cannot
4. improving existing coping skills & developing new ones (Pines & Kafry, 1981; Pines & Aronson, 1988; Pines, 1993).

Malpractice

A claim of malpractice is particularly stressful for health care workers because it calls their professional competency into question. The process is unfamiliar to most health care workers and is controlled by lawyers and judges, so that the accused health care worker feels powerless, and "failure" is certainly implied. This is true whether or not a malpractice claim has merit. If indeed there has been some degree of negligence, an element of guilt is added which contributes to the feelings of failure and may accelerate burnout (Ely et al., 1995). Malpractice suits commonly involve physicians, but all other health care workers are subject to suit as well, and this sometimes leads to conflicts among health care workers as one worker tries to place blame for an incident on another. Although not well studied, in the authors' experience, it is not uncommon for physicians being sued to present for treatment with significant symptoms, including depression, sleeplessness, anxiety, and substance use problems.

HIV Infection

The AIDS epidemic has taken a staggering toll. In 1998, the World Health Organization reported there had been 130,000 adult deaths in the United States and 2.3 million worldwide; 2.5 million people in the United States are HIV positive and more than 30 million are positive worldwide (WHO, 1998). The disease is transmittable, not curable, and working with infected patients has added tremendous stress on the health care profession. Wallack (1989) conducted a survey of house staff (resident physicians) and nurses at a New York City hospital in 1985 regarding attitudes and beliefs about AIDS. Sixty-five percent of the house staff and 63% of the nursing staff felt that they were at risk of contracting HIV infection, even if they followed the hospital's infection control policies. Eighty-seven percent of those surveyed admitted to experiencing greater anxiety when car-

ing for AIDS patients, compared to other patients. These attitudes can affect the kind of care that is delivered. Avoidance of entering an AIDS patient's room can lead to isolation when the patient needs psychological support. On the other hand, transmission of the incurable viral infection through needle sticks or via blood splashing in the eye or into a cut is a daily reality for health care providers.

AIDS is an incurable disease that affects mainly young patients, and overidentification can add to the emotional responses among health care providers.

Dying Patients

There is an extensive and rapidly growing literature on the way to deal with patients who are dying, including advice on responding to requests for assistance in dying, how to manage pain, and what to do about other physical or emotional problems. There is little data, however, about the effects on caregivers of dealing with dying patients. Block and Andrews have written about many aspects of working with dying patients, and they believe (as do the authors) that "for many physicians a dying patient represents a personal failure" and that the responses of caregivers to working with dying patients may include depression, avoidance, anger, denial, and guilt (Block & Billings, 1998). The mental health consultant may be asked to deal with these problems in caregivers and may have to suggest tactfully that the caregiver's response is the problem that needs to be addressed because the problem may not be recognized by those dealing with the patient, as illustrated by the case example in this section.

Behavioral Disorders Associated with Central Nervous System Dysfunction

Steven A. Castellon, Charles H. Hinkin,
and Paul Satz

Introduction

In this chapter, we introduce some of the behavioral disturbances that are associated with acquired insult or injury to the central nervous system (CNS). Because the CNS ultimately mediates all aspects of human behavior, neurological disorder, regardless of etiology, can produce changes in cognition, perception, emotion, affect, and/or personality. In this chapter, we have chosen to focus our attention on the changes in emotion, affect, and personality that accompany neurological disease/disorder.

Study of the behavioral expression of neurological disorder has been a contribution of the fields of neuropsychology, neuropsychiatry, and behavioral neurology. The cognitive/intellectual deficits associated with specific neurological conditions have been well characterized elsewhere (e.g. Kolb & Wishaw, 1995; Lezak, 1995) and in this chapter, we only briefly address these changes.

Instead we devote most of our attention to the less thoroughly studied realm of *psychiatric* morbidity in neurological conditions. This chapter, after providing some basic background information, provides an overview of the main classes of psychiatric symptoms and signs that may occur in diseases and disorders of the CNS. Then, we examine several specific neurological conditions with particular regard to the types of psychopathology seen in each.

Background Considerations

Much of what we know about the functioning of the brain has been learned by studying individuals who have suffered some form of brain pathology. The behavioral consequences of brain insult or injury vary extraordinarily depending on multiple factors, including age, gender, and the affected individual's previous level of intellectual function. Perhaps more important is the type of injury or insult incurred. Lesion size and location often have reliable and predictable effects on the behavioral disturbances noticed. It is well beyond the scope of this chapter to detail the neuroanatomy and behavioral geography of the human brain, but we will briefly introduce a few key concepts.

Organization of the Human Brain. Providing any but the most basic neuroanatomy of the

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

brain is well beyond the scope of this chapter. Where possible and practical, we will attempt to provide basic background information necessary to understand the more relevant concepts. The human brain can be very roughly divided along three organizational planes: lateral, longitudinal, and vertical. *Lateralization* refers to differences between the right and left hemispheres of the brain, which for the most part are mirror images of one another. The primary sensory and motor areas of the brain are positioned in both hemispheres, and with few exceptions, these centers in each cerebral hemisphere predominate in mediating the activities of the contralateral half of the body. In general, in the vast majority of individuals, the left hemisphere plays a dominant role in verbal, symbolic, and analytic function, whereas the right hemisphere is crucial in nonverbal and spatial processing. As we will detail later, there are some important differences in the types of emotional and personality disturbances seen following left-versus right-sided lesions. Longitudinally, the brain can be roughly divided into *anterior* and *posterior* regions. Although a vast oversimplification, the anterior portion of the brain mediates motor response and executive function (the initiation, coordination, execution, and oversight of purposeful behavior), and the posterior portion of the brain is related to sensory and perceptual function. Vertical organization refers to differences between cortical and subcortical areas, which we describe in greater detail later.

Finally, two prominent fissures on the surface of the brain, as well as visually prominent sulci, divide the brain into four lobes—frontal, parietal, temporal, and occipital. Note that these lobes are defined solely on the basis of surface markings, rather than more functional characteristics. In terms of the way these different brain regions relate to behavior, there is a rich and extensive history of theory about brain–behavior relations. Theories of localization implied that specific mental operations/functions resided in specific areas in the brain, and lateralization theories suggested that some functions were predominately mediated by one hemisphere or the other. A more integrative and widely accepted theory is that of parallel distributed processing (PDP). PDP implies the existence of integrated neuronal circuits that are widely distributed in the brain and can be modified (within limits) by learning. Any point in the circuit may interconnect with other circuits; hence, there

can be multiple potential effects from a single lesion. It follows then that similar effects could emerge from lesions at different points within the same circuit. Note that a PDP model of brain behavior relationships is not inconsistent with the assertion that certain brain structures or regions are intimately tied to certain types of behavioral outputs.

History and Terminology: Functional versus Organic. A long history of classifying behavioral disorders as “functional” or “organic” is giving way to a conceptualization of behavior that sees both psychiatric and cognitive behaviors as dual-pronged manifestations of CNS activity. The term “idiopathic” to describe those symptoms or syndromes that have no known or likely neurological precipitant and “neuropsychiatric” to describe those that do is a more useful way of viewing psychiatric symptoms/signs. Another useful classification scheme is *primary* versus *secondary* disorders. Primary disorders are those that are idiopathic, whereas secondary disorders are those that are known, or at least it is thought, have a neurological, systemic, or pharmacological cause. Many of the disorders described in earlier chapters (e.g., schizophrenia, unipolar and bipolar depression), which have traditionally been labeled as “functional” disorders, involve dramatically altered neurochemistry and response to “organic” interventions (e.g., pharmacological manipulation of brain neurotransmitter levels).

In general, any type of behavior observed in idiopathic (i.e., primary) psychiatric syndromes can occur in association with a neurological disorder. For this reason, it is often hard to differentiate primary psychiatric disorders from secondary neuropsychiatric disorders. Late-onset disorders are likely to be related to brain disease, but neuropsychiatric disorders are not limited to the elderly. Patients with neuropsychiatric illnesses often lack the premorbid psychiatric or personality alterations that occur in many idiopathic psychiatric disorders. Also, they often lack the family history of psychiatric disability common in those with idiopathic psychiatric disorders (an exception is hereditary neurological illnesses such as Huntington’s disease).

While changes in mood, affect, personality, and cognition may be direct effects of CNS insult, many individuals will suffer indirect or reactive changes in these domains. Often, CNS injury leads to losses of important capacities or functions such

as physical mobility or intellectual acuity. Clearly, the often chronic frustration and life-style changes that accompany such losses can trigger profound mood and personality changes that are not primary consequences of the CNS injury. In reality, it is difficult to state conclusively whether a mood or personality alteration is the direct effect of CNS injury or a secondary reaction to the injury. Most likely, a complex and dynamic interaction of primary and secondary factors is at work when psychopathological conditions are noted following CNS disturbance.

Prevalence of CNS Disorders in the United States.

Behavioral disorders, ranging from subtle personality change to full blown dementia, are common following insult or injury to the CNS. Estimates of the prevalence of CNS disorders vary dramatically, depending on the criteria used to define "disorder." It is challenging to accurately estimate the number of individuals in the United States who have some degree of acquired CNS dysfunction because not all affected individuals will present to health care professionals. For example, many of the elderly who might meet criteria for a CNS degenerative disorder such as Alzheimer's disease may function with the help of family members and do not seek treatment. Many CNS diseases, such as neurodegenerative conditions like Alzheimer's and Parkinson's disease, also have long latency periods that precede symptom onset. As will be discussed in more detail later, CNS disease/disorder can affect individuals of any age, although increasing age is a primary risk factor for many CNS diseases, such as stroke, Alzheimer's disease, and Parkinson's disease (Aronson et al., 1991; Cummings, 1992; Jorm & Jolley, 1998). On the other hand, brain tumors, HIV/AIDS-associated dementia, and head injury are CNS disorders that are at least as likely to affect individuals in younger age groups (i.e., <50) as they are to affect the elderly. Estimates of the number of individuals suffering from CNS disorders in the United States are shown in Table 1.

Neuropsychiatric Symptoms Following CNS Injury

Introduction

It has long been noted that insult or injury to certain brain regions can produce relatively selec-

Table 1. Estimated Prevalence of Persons in the United States with Diseases and/or Disorders of the CNS

Disease or disorder	Estimated number of cases
Alzheimer's disease	2,500,000–4,000,000
Frontotemporal degeneration	750,000–1,000,000
Parkinson's disease	500,000–600,000
Huntington's disease	20,000–50,000
Cerebrovascular event (stroke)	3,000,000 ^a
Head injury	1,000,000–2,500,000

^aThis number represents an estimate of the number of individuals living in the United States who have suffered and/or still suffer disability (physical, cognitive, and/or emotional) due to stroke. Approximately 500,000 persons are disabled to some extent due to stroke each year.

tive deficits in behavior. More than 100 years ago, surgeon Paul Broca observed that damage to the anterior part of the left side of the brain led to an inability to produce speech but spared the ability to comprehend speech. Considerable brain-behavior specificity exists with regard to the genesis of sensorimotor deficits and, to a lesser degree, cognitive deficits. For example, ablation of the left precentral gyrus will inevitably give rise to a right-sided hemiparesis. No such anatomic specificity is present for the neuroanatomic underpinnings of emotion. Nonetheless, damage to certain brain structures, most notably prefrontal cortex and/or temporal-limbic region structures such as the amygdala, are far more likely to result in neuropsychiatric disturbance.

The Frontal Lobes and Frontal-Subcortical Circuits.

The frontal lobes comprise approximately one-third of the total cortical surface area of the brain and are by far the largest of the four lobes. In terms of our phylogenetic history, they represent the latest evolutionary addition. The frontal lobes play an important role in mediating complex human behavior. Frontal cortical areas subserve *executive functions*, those behaviors that allow us to organize, coordinate, initiate, and execute purposeful behavior. Social and goal-directed cognition, behavior, and emotion are intimately associated with and depend on the frontal lobes (Damasio & Anderson, 1993).

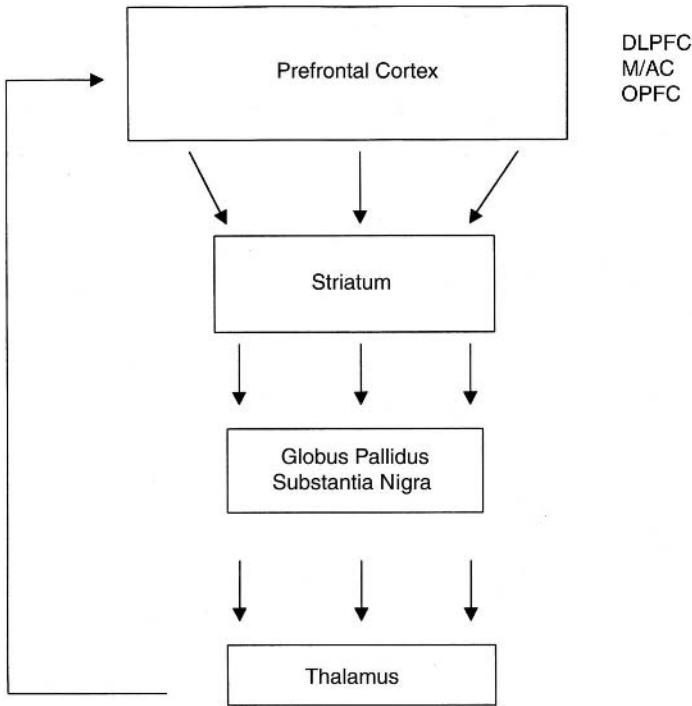

Figure 1. General organization of the frontal-subcortical-thalamic circuits. Three circuits are most closely associated with behavioral disturbance in CNS disease/disorder. Note: DLPFC, dorsolateral prefrontal cortex; M/AC, mesial frontal–anterior cingulate; OPFC, orbitofrontal prefrontal cortex. Adapted from Cummings (1993).

Alexander and colleagues (1986) introduced the concept of parallel but segregated frontal-subcortical circuits that have important behavioral functions. Cummings (1993) identified three major behavioral syndromes associated with the pathology of different prefrontal regions or the circuit connecting those regions with subcortical and thalamic structures. It is important to note that disruption anywhere along the circuit can lead to similar behavioral deficits, which mean that subcortical pathology can produce the same constellation of symptoms as prefrontal lesions. The three prefrontal regions are the dorsolateral area (i.e., the outer convexity of the frontal lobe), the orbitofrontal area (the parts of the frontal lobe resting above the orbital bone), and the mesial-frontal/cingulate area (middle, deeper portions) of the frontal lobes. Figure 1 shows a schematic representation of the frontal-subcortical circuits. As diagramed in Figure 1, three specific circuits, each with prefrontal, subcortical, and thalamic connections, have been

identified. In general, lesions to the prefrontal cortex produce more distinct behavioral syndromes than similarly-sized lesions to the smaller subcortical-thalamic structures. In other words, when the site of pathology is subcortical, there is a greater chance of disrupting more than one circuit and thereby, seeing neuropsychiatric phenomena from more than one frontal-subcortical syndrome.

The dorsolateral prefrontal cortex (DLPFC) is that area of the frontal lobe on the outer convexity of the frontal lobe. Patients with damage to the DLPFC or connected subcortical structures often show deficits in planning and organizing behavior. These individuals may be unusually dependent on environmental cues and less able than neurologically normal persons to adapt to an ever changing, novel environment. Many times these patients will seem unable to use environmental cues effectively or to profit maximally from experience. It is not uncommon for patients with damage anywhere along the DLPFC circuit to show

perseverative behavior, in which they repeat an act unwittingly and often involuntarily. Mood changes are common with dorsolateral prefrontal lesions. A large number of individuals with DLPFC lesions have depressive symptoms, and approximately half of these meet criteria for Major Depression.

The orbitofrontal syndrome leads to the most dramatic behavioral disturbances of the frontal lobe syndromes. This area of the prefrontal cortex is especially vulnerable to injury during motor vehicle accidents or other causes of head injuries because it rests above the bony orbital roof. Frequently, individuals with previously normal behavior, who have suffered injury to orbitofrontal structures or circuits, are entirely transformed (as illustrated later in the Personality Alterations section where we discuss the case of Phineas Gage). Typically these individuals show deficits in empathic, civil, and socially appropriate behavior and display prominent *disinhibition* and an obvious lack of behavioral restraint (Duffy & Campbell, 1994). Individuals with this syndrome ignore social conventions and exhibit undue familiarity by talking to strangers and touching or fondling others without permission. They are often tactless in conversation and may make uncivil or lewd remarks. Many times, these individuals are extremely impulsive and respond immediately (and unpredictably) to changing environmental circumstances. They lack conscientiousness and fail to complete assigned tasks. A salient characteristic of their behavior is that they seem unconcerned about the consequences of their behavior and may in fact engage in activities that endanger themselves or others. Risk assessment is typically impaired in these individuals (Cummings, 1993). Mood alterations often accompany the orbitofrontal syndrome. Lability and irritability, both of which are discussed in detail later, are the most common changes. Patients with orbitofrontal damage may rapidly shift from happiness or an empty euphoria to anger and/or sadness. Mood changes are only rarely sustained, and anger often dissipates as the individual's attention is drawn to some new activity or stimulus. Hypomania and mania may accompany orbitofrontal dysfunction (Duffy & Campbell, 1994).

Apathy, anergia, indifference, and emotional withdrawal characterize the mesial prefrontal/cingulate syndrome. Many patients with disturbance of this circuit appear depressed, but they often lack

the dysphoria seen in depression (Cummings, 1993). Both motor and information-processing slowing is often evident among individuals with cingulate pathology or disruption somewhere along this circuit. Decreased creativity and spontaneity are common (Chow & Cummings, 1999). At times, the apathy and indifference is so profound as to leave patients unresponsive to their environments. Interestingly, many of these profoundly apathetic patients deny distress, although they are aware that they have undergone personality change.

Mood and Affective Disorders

Disturbances of mood and affect are among the most common behavioral concomitants of CNS disturbance. *Mood* can be defined as a pervasive and sustained (even if only briefly) emotion that is subjectively experienced and reported by the individual. *Affect* is the observed outward behavioral expression of emotion. Typically, mood and affect are consistent with one another (i.e., someone who says that they are sad typically looks sad), but this is not always the case. For example, we will briefly discuss later a syndrome known as pseudobulbar affect in which patients often show a dramatic disconnection between mood and affect. Patients with this disorder often have episodes of laughing or crying without being aware of feeling either happy or sad. This condition is typically thought of as involving a disturbance in affect (i.e., it is disconnected from mood), but diseases or disorders that lead to disturbance of both mood and affect are much more common. Several types of mood disorder may occur following damage to the CNS. We will focus on three of the most common varieties of mood disturbance: depression, mania, and increased anxiety.

Depression. Depression is an alteration of mood that involves either prominent sadness and/or *anhedonia*, a term used to describe the experience of diminished interest in or pleasure from daily activities. A constellation of cognitive symptoms (e.g., pessimism regarding the future, guilty feelings, self-reproach) often accompanies sad mood and/or anhedonia. Additionally, somatic symptoms and signs, such as sleep and appetite disturbance, fatigue, and diminished libido, are often part of a depressive syndrome. As detailed in Chapter 11, according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition

(DSM-IV; American Psychiatric Association [APA], 1994), the clinical syndrome of Major Depression exists when a constellation of at least five of these symptoms (one of which must be either depressed mood or anhedonia) is present and prominent for at least 2 weeks. For a diagnosis of Major Depression according to the DSM-IV, an important criterion is that the depressive symptoms and signs are not better accounted for by a systemic/medical illness, that is, they have an idiopathic etiology. When depressive symptomatology appears to be secondary to a CNS disturbance (e.g., stroke) and/or medical condition (e.g., hypothyroidism), the DSM labels this diagnostic category "Mood Disorder Due to a General Medical Condition." Finally, specifiers such as "with depressive features" or "with major depressive-like episode" qualify the intensity of the observed depressive syndrome.

Idiopathic (i.e., primary) and secondary depression share certain characteristics. Both have been shown to be consistently associated with decreased serotonin levels (McAllister-Williams, Ferrier, & Young, 1998), and both respond well to antidepressant medications. Functional neuroimaging such as positron emission tomography (PET) or single photon emission computerized tomography (SPECT) consistently demonstrate the involvement of both frontal and subcortical structures (especially caudate) and circuits in both primary and secondary depression (Mayberg, Mahurin, & Brannan, 1998). Information-processing slowing, retrieval deficits, attentional disruption, and difficulty with executive functioning characterize the pattern of cognitive deficits seen among a subset of individuals with depression, whether of idiopathic or neurological etiology. That this pattern emerges in both primary and secondary depression implies that each may be a consequence of disturbance of frontal-subcortical regions that subserve both affect and cognition.

As suggested earlier, there is no obligatory relationship between the site of CNS pathology and mood disorder. However, insult or injury to certain regions/structures/circuits increases the likelihood that significant depressive features will emerge. For example, depression is a fairly common consequence of neurological disorders that affect the left prefrontal cortex (Cummings, 1994; Royall, 1999). Functional neuroimaging studies have shown greater involvement of left frontal than of

right frontal regions in depressed neurological patients and some have suggested that the intensity/severity of depression seen in neurological disease is associated with the distance of the lesion from the left frontal pole (Buchsbbaum et al., 1984; Robinson & Starkstein, 1990). Among patients who have suffered a stroke, depression is far more common when the site of the infarct is anterior rather than posterior and is on the left rather than the right; left prefrontal infarcts then are the most likely to lead to a major depressive episode (Cummings, 1994; Robinson & Price, 1982).

Depression is an extremely common consequence of cerebrovascular disease (Robinson & Starkstein, 1997). Estimates of the prevalence of depression vary (largely based on sampling techniques and/or the definition of depression that is used), but anywhere from 30–50% of patients experience prominent depression following a stroke. Astrom and colleagues (1993) conducted a 3-year longitudinal study of stroke patients and reported that approximately 40% had some sort of clinical depression (either major depression or minor depression/dysthymia). Additionally, the phenomenology of depression associated with cerebrovascular disease is quite similar to that seen in patients with primary (idiopathic) depressive disorders (Robinson & Starkstein, 1997).

Another secondary cause of depression is disorders that involve the endocrine system. Both hyper- and hypothyroidism involve endocrine system dysfunction and have depression prevalence rates exceeding those found in the general population. Hypothyroidism often leads to a constellation of symptoms, including depression, lethargy, and concentration difficulty (Lezak, 1995) that can often be effectively treated with thyroid replacement therapy. Table 2 lists some of the CNS diseases and disorders in which depression often occurs.

Depression is a common consequence of CNS disturbance, but measuring it is not always straightforward. Often, individuals with neurological (or other medical) disorders, which may give rise to mood disturbance, also have somatic complaints (e.g., insomnia, appetite loss, preoccupation with physical status) that are diagnostically ambiguous. Clearly, such complaints among physically healthy individuals with evidence of depression are best conceptualized as part of a depressive syndrome. However, such complaints among those with medical illness usually do not indicate mood disorder

	Chronic fatigue syndrome

^aDiscussed in detail in the current chapter.

in the absence of prominent cognitive/affective mood disturbance. Instead, complaints of weight loss, diminished appetite, and insomnia are not unexpected correlates of being physically ill.

Mania. Mania refers to an affective syndrome that features an elevated, expansive, and/or irritable mood. In addition, other symptoms and signs are often present, including a sense of grandiosity, decreased need for sleep, increased talkativeness or pressured speech, flight of ideas, psychomotor agitation, heightened distractibility, and excessive involvement in pleasurable and/or high-risk behavior. When these symptoms or signs arise secondary to a neurological disorder or a toxic/

metabolic process, they are commonly termed secondary mania (Krauthammer & Klerman, 1978). As noted in Chapter 11, according to the DSM-IV (APA, 1994), a primary manic episode is diagnosed only when a constellation of these symptoms is present for at least 1 week and *is not* due to the effects of a substance (street drug or prescribed medication) or a medical (i.e., neurological) condition. Secondary manic episodes are referred to in the DSM-IV as "Mood Disorder Due to a General Medical Condition." Then, they are labeled "with manic features" if primarily euphoric, elated, or irritable symptoms predominate, or "with mixed features" if both manic and depressed symptoms are present.

There is compelling evidence that at least some individuals with primary (i.e., idiopathic) mania have brain irregularities. For example, Dupont and colleagues (1995) found that patients with bipolar disorder but no evidence of current or past neurologic illness had subcortical brain abnormalities, as measured by MRI. A study using functional neuroimaging techniques found that some, but not all, of the primary manic individuals had blood flow irregularities, especially in the right hemisphere (El-Hilu et al., 1998). More specifically, among five patients with primary mania, SPECT scanning revealed significantly lower blood flow in the basal portion of the right temporal lobe, compared to matched non-manic controls (Migliorelli, Starkstein, Teson, & de Quiros, 1993). Individuals with a history of primary mania may have subtle neuroanatomical and/or neurochemical irregularities, but it has been suggested that they are generally less likely to be cognitively impaired than patients with secondary mania (Hoff, Shukla, Cook, & Aronson, 1988).

Secondary mania has been observed in a wide variety of neurologic conditions. Nearly all lesions and/or neurologic conditions that produce mania involve the right hemisphere and/or the frontal lobes. As noted before, pathology in the orbitofrontal cortex, caudate nuclei, and/or temporal limbic structures often produces mania. In Huntington's disease (discussed in detail later), a disorder that involves pathology of the caudate nuclei, mania is commonly observed in a subset of affected patients. In fact, manic symptomatology may antedate the appearance of either movement disorder or cognitive deterioration in this disease (Folstein, Brandt, & Folstein, 1990). Additionally,

heightened rates of aggressive outbursts and sexual promiscuity, both characteristic manic phenomena, are not uncommon in this disease (Maricle, 1989). Mania is much more common among head-injured patients with prominent orbitofrontal and/or temporal limbic damage than in the general population (Shukla et al., 1987). Starkstein and colleagues (1990) used positron emission tomography to explore cerebral metabolism in eight brain-injured patients who had developed a secondary manic syndrome and found that right-sided metabolic abnormalities were evident in all eight patients. Euphoria and prolonged manic periods have been observed in a subset of individuals with multiple sclerosis who also show prominent involvement of prefrontal white matter (Fillee, 1994; Pine, Douglas, Charles, & Davies, 1995). Finally, in conditions where full-blown manic episodes are rare but prominent euphoria is not, there is again evidence of frontal dysfunction. Alzheimer's disease patients with pronounced euphoria were more likely to show metabolic abnormalities in prefrontal regions and neuropsychological impairment suggestive of frontal dysfunction than Alzheimer's patients without prominent euphoria (Lebert, Pasquier, Danel, & Steinling, 1994).

In addition to neurological conditions, secondary mania may also arise from substance-induced and systemic disorders. Prominent manic symptoms, including full-blown manic episodes are not uncommon effects of intoxication by stimulants including cocaine and methamphetamine (Miller, Mena, Giombetti, & Villanueva-Meyer, 1992; Waters & Lapierre, 1981). Mania may occur as a side effect of prescription drugs, including those used to treat neurological conditions such as Parkinson's disease. Systemic disorders such as uremia, hyperthyroidism, or vitamin B₁₂ deficiency (Gogans, 1983; Jack et al., 1983), and post-partum states also lead to mania in a subset of individuals affected by these conditions

Alterations in Personality

"Gage was no longer Gage." This quote, well known to students of neuropsychiatry, captures the aftermath of a head injury suffered by a Mr. Phineas Gage in 1848. A hard working, temperate, conscientious gentleman, Gage was a worker on a railroad crew charged with dynamiting rock before laying track. While tamping down a load of

dynamite, a spark accidentally flew, igniting a charge which propelled Gage's tamping rod (which weighed 13 pounds and was more than 3½ feet long and 1½ inches in diameter at its widest) into his cheekbone, up through his frontal lobes, and out the top of his head, ultimately landing over 100 feet away. Surprisingly, chroniclers of this event report that he barely lost consciousness, if at all. However, he did lose his old personality. He became disinhibited, vulgar, puerile, childish, and impulsive, a drinker, and a fighter. In short, the complete opposite of his former self.

This tragic tale is repeated daily among many patients who suffer damage to the frontal lobes. In addition to stroke, tumor, and frontal lobe dementia, the most common cause of frontal personality disorder is closed head injury such as that sometimes sustained in an automobile accident. The orbitofrontal region of the brain lies directly behind the bony protuberances where the eyes rest in the skull. Damage to this area of the brain frequently gives rise to disinhibited, inappropriate behavior. This is particularly true when the damage is to the right orbitofrontal lobe. Damage to the left orbitofrontal cortex has been associated with a radically different constellation of behavioral changes, including withdrawal, apathy, inertia, and depression.

It has long been recognized that disturbance in brain structure, physiology, or chemistry can lead to prominent changes in personality, but it has not always been easy to codify these changes. The three most recent editions of the DSM give increasingly more attention to the concept of personality alteration as an important sequelae of brain insult or injury. The DSM-III (APA, 1980) describes an "Organic Personality Syndrome" that is characterized by emotional lability and pronounced impulsivity. As we will make evident later, this characterization does not do justice to the wide variety of personality alterations that may accompany CNS disease/disorder. The revision of the 3rd edition of the DSM (APA, 1987) left the term "Organic Personality Syndrome" in place but added several additional behavioral descriptors as potential symptoms and signs. These additions included suspiciousness or paranoid ideation, marked apathy and indifference, affective instability (e.g., marked shifts from normal mood to depression, irritability, or anxiety) and recurrent aggressive outbursts. The DSM-IV (APA, 1994) uses the term "Personality Change Due to A Gen-

eral Medical Condition” and has added five specific subtypes of personality change. These subtypes are as follows: Labile (e.g., affective lability), Disinhibited (e.g., poor impulse control), Aggressive, Apathetic (e.g., marked apathy or indifference), and Paranoid. Mixed types are probably more common than not. We describe here two of the more common personality alterations that occur secondary to CNS disturbance.

Apathy/Indifference. Apathy is a reduction in goal-related thoughts, emotions, and behavioral responses and occurs secondary to reduced or absent motivation (Marin, 1991). Apathy is a behavioral domain that significantly overlaps with, but can be reliably discriminated from, depression, as it has been in several CNS diseases/disorders (Castellon, Hinkin, Wood, Yarema, 1998; Levy et al., 1998; Marin, Firinciogullari, & Biedrzycki, 1994). As noted earlier, apathy is a common neuropsychiatric consequence of disruption to the mesial-cingulate prefrontal circuit. In subcortical conditions such as Parkinson’s disease and HIV-1 infection, apathy has been associated with other indicators of CNS disturbance such as cognitive impairment, especially executive dysfunction (Castellon et al., 1998; Castellon, Hinkin, & Myers, 2000; Starkstein et al., 1992). In several of the CNS disorders discussed here, including stroke and Alzheimer’s disease, the presence of apathy was associated with prefrontal and temporal reduced blood flow and hypometabolism (Craig et al., 1996; Duffy & Kant, 1997; Okada et al., 1997; Ott, Noto, & Fogel, 1996).

Aggressive/Irritable/Agitated. There is significant evidence for the role of serotonergic dysregulation in impulsive aggression. A decrease in serotonin is found in the brain stems of aggressive rats that spontaneously kill mice introduced into their cages, and the introduction of tryptophan (the precursor of serotonin) reduces or abolishes this violence (Sabrie, 1986). Prefrontal and temporal limbic structures have been implicated in the neuroanatomy of agitation/irritability. Two recent studies of patients with temporal lobe epilepsy (TLE) have implicated both prefrontal cortex and the amygdala as crucial regions associated with violent and/or aggressive outbursts (Woermann et al., 2000; van Elst et al., 2000). Limbic system tumors, infections, and blood vessel abnormalities have been associated with violence (Cherkasky and Hollander, 1997). The prefrontal cortex modulates limbic and hypothalamic activity and, it is

thought, is associated with the social and judgmental aspects of aggression. The coordination of timing social cues, often before the expression of associated emotions, is among the myriad responsibilities of the prefrontal cortex (Cherkasky & Hollander, 1997). Patients with violent behavior have a high frequency of frontal lobe lesions (Kandel & Freed, 1989). Some have proposed that prefrontal damage may cause aggression by a secondary process that involves lack of inhibition of the limbic area.

Finally, it should be noted that Axis II diagnostic categories such as Antisocial and Borderline Personality Disorder clearly have biological underpinnings (also see Chapters 15 and 16 of this volume) for at least a subset of individuals so diagnosed. A recent study by De la Fuente and colleagues (1997) of patients diagnosed with Borderline Personality Disorder found cerebral metabolic abnormalities in the cingulate cortex and in parts of the caudate and thalamus by using positron emission tomography. EEG and other brain abnormalities have also been observed in patients diagnosed with antisocial personality disorder (Deckel, Hesselbrock, & Bauer, 1996; Finn, Ramsey, & Earlywine, 2000).

Psychotic-Spectrum Disorders

Neurological disease can give rise to a wide array of psychotic symptomatology, including hallucinations and delusions. A *hallucination* is a false sensory perception not associated with real external stimuli. Hallucinations may occur in any sensory modality and may or may not be associated with a delusional interpretation of the false perceptual experience. A *delusion* is a firmly held false belief based on an incorrect inference about external reality that is not consistent with the individual’s level of intelligence and cultural background. As mentioned in Chapters 13 and 14 of this volume, these symptoms are key elements of psychotic-spectrum disorders such as schizophrenia or schizoaffective disorder. As with the mood disorders, when these symptoms are a prominent and enduring part of the symptom picture and arise secondarily to a neurological condition, DSM-IV states that they are *not* considered schizophrenia. Rather, when delusions or hallucinations follow CNS insult, they should be labeled “Psychotic Disorder Due to General Medical Condition.” An exception to this coding would be if the psychotic

Table 3. Different Types of Delusions

Persecution	False belief that one is being harassed, cheated, or persecuted
Grandeur	Exaggerated conception of one's own importance, power, or identity
Reference	False belief that the behavior of others refers to oneself; that events, objects or others have a particular and unusual significance
Control	One's will, thoughts, or feelings are being controlled by external forces
Thought withdrawal	One's thoughts are being removed from individual's mind by another person or force
Thought insertion	Thoughts are being implanted in one's mind by another person or force
Thought broadcasting	False belief that one's thoughts can be heard by others as though they were being broadcast into the air
Thought control	Delusional belief that one's thoughts are being controlled by other persons or forces
Erotomaniac	Delusional belief that someone is deeply in love with the individual
Othello	Delusional belief that the individual's spouse is unfaithful
Parasitosis	False belief that the individual is infested with insects, worms, lice, or other vermin

phenomenology is observed secondarily to a disease process such as Alzheimer's disease, in which case the proper diagnostic label would be "Dementia of the Alzheimer's Type, With Delusions." In any event, all cases of delusions or hallucinations secondary to CNS disturbance are typically called secondary psychosis.

Although secondary psychoses triggered by central nervous system disease/insult share considerable phenomenological overlap with primary or idiopathic psychosis, there are several ways in which the two classes of psychosis can be distinguished. First, secondary psychoses tend to have a later age of onset. For example, schizophrenia typically has an onset in the late teens and twenties, whereas secondary psychoses are more common in older individuals. Second, patients with a primary psychosis are more likely to have a family history of psychosis. Third, there tends to be a correlation among patients with secondary psychoses between degree of intellectual impairment and how well elaborated their delusions and hallucinations are. Finally, secondary psychoses tend to be more ego-dystonic.

Delusions. Delusions can be seen in a wide variety of neurological diseases, including Alzheimer's disease, vascular dementia, closed head injury, cerebral neoplasm, multiple sclerosis, and Huntington's disease (Table 3). They are more common in diseases that affect subcortical rather than cortical brain structures, particularly diseases that affect the limbic system and medial temporal lobes or their projections to basal ganglia, thalamus, and rostral brain stem structures. It has been

estimated that up to one-half of all patients with Alzheimer's disease will manifest delusional thinking at some point in their disease. Members of our group (Sultzer et al., 1995) have found that frontal hypometabolism among patients with Alzheimer's disease, as indexed by positron emission tomography, is linked to delusions as well as hallucinations. This finding converges with evidence using structural imaging that has reported heightened rates of frontal white matter lesions in Alzheimer's and vascular dementia patients with prominent delusions (Binetti, Padovani, Magni, & Bianchetti, 1995). Excessive dopamine is also known to play an important role in psychotic phenomenology. Two prominent dopamine systems in which disruption is known to lead to psychotic symptomatology are the mesocortico-limbic and nigrostriatal dopamine systems.

Clarke and colleagues (1998) relate a case study of a patient with multiple sclerosis (MS), a disease that affects subcortical structures and white matter, who repeatedly stabbed himself in the stomach due to self-loathing and persecutory delusions. Although delusions are not a typical presentation of this disease, they are seen more commonly among MS patients, who may suffer from psychotic depression, than in the general population (Clarke et al., 1998).

Although virtually every type of delusion can be seen among patients with CNS disease, Schneiderian first-rank delusions such as thought insertion, withdrawal, and broadcasting tend to be uncommon. Demented patients, instead, commonly present with persecutory delusions or delusions of

jealousy. One can speculate that such delusions may at least in part reflect a rational response to their cognitive decline. The individual with severe short-term memory impairment who cannot remember that his wife has only momentarily run out to the store may instead believe she has run off with another. The patient who cannot recall where she has left her keys may conclude that somebody has stolen them.

Several types of delusions tend to be overrepresented in patients with dementing disorders. One such delusion is the *phantom boarder delusion*, in which patients will contend that a stranger is living in their homes against their wishes. *Capgras syndrome* is the delusional belief that members of one's own family or friends have been replaced with identically-appearing impostors. Capgras syndrome is more common among patients who have suffered damage to the right as opposed to the left hemisphere (Singer, 1992). A related delusion is the *Fregoli syndrome* in which patients believe that their persecutor can mimic the appearance of others.

Delusional jealousy, also known as the "*Othello syndrome*," is the delusional belief that one's spouse or partner has been unfaithful. The delusional belief that a famous individual is actually secretly in love with you is termed erotomania, or more colorfully, *De Clarambault syndrome*. Somatic delusions are also common in CNS dysfunction. Among the more florid delusions are *lycanthropy*—the belief that you are a werewolf, and delusions of infestation or *parasitophobia*—the delusional belief that one's body has been invaded by insects, parasites, worms, etc. Delusions of infestation are particularly common in metabolic/toxic psychoses and deficiency syndromes (e.g., B₁₂ deficiency). Heutoscopy, or the *Doppelganger syndrome*, is the delusional belief in the existence of an exact duplicate of oneself. This needs to be distinguished from *autoscopy*—a visual hallucination of oneself which the individual realizes is illusory.

Among the most fascinating delusional syndromes is *anosognosia* which is the unawareness of a deficit. Most commonly seen in patients who have suffered right parietal stroke, anosognosia has also been seen in patients with left parietal lesions, frontal lobe damage, especially secondary to closed head injury and anterior subcortical structures, as well as in progressive dementias such as Alzheimer's disease and frontotemporal

dementia. The anosognosic patient may deny even the most dramatic impairment. For example, a patient who is hemiplegic following a right middle cerebral artery stroke may claim that there is nothing wrong with the paralyzed arm. Another example is the patient with *Anton's syndrome* who is cortically blind after suffering bilateral occipital lobe damage but nonetheless claims to be able to see. For a thorough review of anosognosia, the interested reader is directed to the work of McGlynn & Schacter (1997).

Hallucinations. Hallucinations are not uncommon among patients with CNS disease. Patients with secondary hallucinations tend to recognize that their hallucinations are not real, a degree of insight not always shared by psychiatric patients. Such patients may react to their hallucinations with a range of emotions ranging from bemused fascination to terror. Unlike the functional psychoses like schizophrenia in which the frequency of auditory hallucinations far outweighs visual hallucinations, visual hallucinations tend to be the most common among patients with secondary hallucinations. Visual hallucinations can range from the most mundane, such as unformed flashes of light, to the bizarre and outlandish. Patients may hallucinate copies of themselves (*autoscopy*). Objects in their visual field may appear very small (*Lilliputian hallucinations*) or very large (*Brobdingnagian hallucinations*). This alteration in the size of objects needs to be distinguished from *micropsia* and *macropsia* in which the entire visual field is altered in size. *Psychedelic hallucinations* such as repetitive geometric shapes, lattice work, etc., may occur as can *palinopsia*—the persistence of a visual image after its removal, a benign form of which can be triggered in normals by a camera flashbulb. Visual hallucinations also need to be distinguished from *illusions* in which patients misinterpret actual visual stimuli.

Visual hallucinations of animals (*zoopsia*) are also common among patients with secondary psychosis. Among patients with structural lesions who hallucinate, right hemisphere lesions are more likely than left to give rise to visual hallucinations. The more posterior the lesion (i.e., occipital lobes), the more poorly formed the hallucination.

Patients with seizure disorders frequently report hallucinatory experiences as part of the peri-ictal experiences. Such "auras" can be auditory, visual, tactile, olfactory, and even gustatory. Sub-

stance intoxication and withdrawal stages also give rise to hallucinations. The “pink elephants” seen in alcohol hallucinosis and delirium tremens are well chronicled. Stimulant intoxication has been linked to delusions (particularly paranoid), as well as to hallucinations. One specific type of stimulant-induced hallucination is tactile hallucinations in which patients feel that insects are crawling on or under their skin. This condition is known as formication or “the cocaine bugs.” Patients in the midst of deliriums, or acute confusional state, are at high risk for delusions and hallucinations, as well as agitation. Sensory deprivation, common in older patients with visual impairments such as cataracts or hearing loss, can also give rise to hallucinations and delusions.

Specific Neurological Conditions and Their Behavioral Sequelae

Degenerative Disorders of the CNS

Several disease processes involve progressive deterioration of brain tissue and behavior. Some of these conditions are relatively commonplace, whereas others are quite rare. The prevalence of dementia in individuals over the age of 65 in North America is approximately 6–10% (Hendrie, 1998), although this is a dramatic underestimate if milder cases of dementia are included. As our population continues to age and medical technology enables us to live longer, the number of patients with degenerative diseases will grow dramatically. Of these diseases, Alzheimer’s disease is by far the most prevalent and accounts for nearly two-thirds of all cases of dementia. Following, we discuss several degenerative diseases of the CNS in some detail. We start with the most common and some would say, the prototypical degenerative disorder, Alzheimer’s disease, before turning to frontotemporal degeneration and two of the more common subcortical degenerative disorders, Parkinson’s and Huntington’s diseases.

Alzheimer’s Disease

Introduction. Alzheimer’s disease (AD) is a progressive neurological disorder that primarily affects cortical neurons. Most typically, AD is a disorder of later life and onset rarely occurs before

age 45. There is currently no diagnostic test for AD, and a definite diagnosis can be made only by autopsy or biopsy of the brain. As mentioned before, it is far and away the most common form of degenerative dementia (Cummings and Benson, 1992; Hendrie, 1998; LaRue, 1992) and currently afflicts roughly 4 million U.S. citizens. It is estimated that approximately 10% of all individuals over the age of 65 are affected by AD (LaRue, 1992).

The cardinal neuropathological sign of AD is the presence of senile *plaques*, *neurofibrillary tangles*, and amyloid angiopathy. Plaques are caused by neuronal degeneration and can be found in all areas of the cerebral cortex but are often most common in the parietal lobe and hippocampal and amygdaloid regions. Neurofibrillary tangles are tangled bundles of fine fibers within the cell bodies of neurons that occur throughout the brain but particularly around the hippocampus. Autopsies indicate that 50–60% of clinically demented individuals have brain changes that are consistent with diagnoses of Alzheimer’s disease and another 10–20% show AD-consistent changes in combination with other neuropathology (Katzman, 1986). The most common neuroanatomical changes seen in the brains of individuals with AD include prominent atrophy in the gyri of the associative areas of the cerebral cortex, with the primary motor and sensory areas of the cortex relatively unaffected (Katzman, 1986). In Alzheimer’s, multiple neurotransmitter abnormalities have been documented, but the most reliable and striking changes occur in the cholinergic system (La Rue, 1992).

There are several risk factors for developing AD; advancing age is the most robust. A Finnish study found that approximately 2% of their sample between the ages of 65 and 74 had AD, whereas 6% of those between 75 and 84 and 15% of those over 85 had the disease (Sulkava et al., 1985). Other studies that examined more restricted populations reported somewhat higher rates, especially for the older age categories (Evans et al., 1989; Pfeffer, Afifi, & Chance, 1987). Women may be at slightly greater risk for developing AD than men (Amaducci, Rocca, & Schoenberg, 1986; Sulkava et al., 1985), and there is some evidence that individuals with prior histories of head injury have a greater risk of developing AD (Mortimer, French, Hutton, & Schuman, 1985). A family history of AD also confers higher risk (Cummings & Ben-

son, 1992; Kay, 1989), although the magnitude of the risk is unclear. This strongly implicates a genetic component of the disease. Another relatively recently discovered risk factor for AD is the presence of a particular form of the ApoE gene, the $\epsilon 4$ allele ApoE (apolipoprotein E) is a cholesterol-transporting protein that is produced mainly in the liver and the CNS. Individuals who inherit two copies of the ApoE 4 allele have a risk of developing AD that is eight times higher, where those with one $\epsilon 4$ allele have approximately three times the risk (Lopez et al., 1997). The exact role of ApoE in the pathogenesis of AD is currently unclear.

Cognitive Changes Associated with Alzheimer's Disease. AD is known primarily for the profound cognitive and intellectual impairments that follow diagnosis. Consistent with the known sites of neuropathology (parietal and temporal association cortex, limbic structures), the earliest signs of the disease are typically memory and visuospatial impairment. The pattern of memory disturbance seen in AD involves short-term memory deficits characterized by both impaired encoding and retrieval; patients with AD are unable to recall or learn new material effectively. Verbal spontaneity in the AD patient is often deficient because word-finding compromise may impact the flow of speech. The cognitive/intellectual deficits seen in AD and the steadily progressive course of deterioration have been well described elsewhere (see Zec, 1993). For the purposes of this chapter, we wish to point out that the profound cognitive changes that accompany AD, in particular the devastation of short-term memory, often contribute to the psychiatric picture of an affected individual.

Psychiatric Changes Associated with Alzheimer's Disease. The psychiatric changes that accompany AD vary widely from one patient to another. Prominent mood disturbance, including increased rates of depression, irritability, and anxiety, and personality alterations such as apathy, heightened agitation and hostility are common in patients with AD. Inappropriate behavior (e.g., sexual, aggressive), sleep and appetite disturbance, and psychotic symptoms are also commonly observed in the patient with AD.

Estimates of the rate of depression among patients with AD vary considerably, in part due to the dramatically different depression criteria used across studies. Clearly, however, AD patients

have higher rates of depression than seen among individuals of similar age without neurological compromise. Major Depression is less common than more minor variants of depressive syndromes (e.g., dysthymia, minor depression). A prospective longitudinal study by Starkstein and colleagues (1997) showed that 19% of sixty-two patients with probable AD diagnoses suffered a Major Depression, whereas 34% had evidence of a milder mood syndrome. Of note, a majority of those patients with Major Depression at study entry still met criteria for this syndrome at follow-up (1 to 2 years later), whereas only 28% of those with a minor mood syndrome at study entry showed any evidence of mood disturbance at follow-up. Another recent study of 109 patients with probable AD found roughly similar rates of Major Depression (22%) and Minor Depression (27%) in a cross-sectional investigation (Lyketsos et al., 1997). A potential problem with compiling prevalence figures of mood disturbance from direct interviews of AD patients is that they tend to underreport mood disturbance, compared to clinicians or caregivers (Weiner, Svetlik, & Risser, 1997).

Though some suggest that prominent changes in mood and personality are not typical of the earliest stages of AD (Cummings and Benson, 1992), these changes do occur fairly early for some affected individuals. A retrospective study of the course of psychiatric symptoms among 100 individuals with autopsy-confirmed diagnoses of AD reported that psychiatric symptoms often occurred in the year before the patients were diagnosed with AD (Jost and Grossberg, 1996). Clearly, as the disease progresses, pronounced changes in personality become evident. For example, it is not at all uncommon for AD patients to display little interest in self-care, work or household tasks, social or family activities, and/or the emotional needs of other individuals. This apathy often occurs without evidence of prominent depression (Reichman, Coyne, Amirneni, Molino, & Egan, 1996) and often precedes the development of disinhibited, agitated, and aggressive behaviors (Cummings & Benson, 1992). Negative symptoms such as apathy, anhedonia, and avolition are correlated with dementia severity in AD and show an inverse relationship to functional capacity (Reichman et al., 1996).

Delusions and hallucinations occur with regu-

larity in AD. Cummings and Benson (1992) estimate that approximately 50% of patients with AD exhibit delusional beliefs at some point following diagnosis. For some individuals, psychotic symptoms/signs may be the presenting manifestation of the disease. As mentioned earlier, the delusions typically seen in schizophrenia (e.g., thought broadcasting, thought withdrawal) are not common in AD. Instead, delusions are often persecutory and involve theft of property or infidelity of the spouse. A fascinating delusional belief that is not uncommon in AD is Capgras syndrome, the belief that a familiar person, often the spouse, has been replaced by an impostor (Rubin, Drevets, & Burke, 1988). Two recent studies have shown that psychotic symptoms are fairly common and that delusions are more prevalent than hallucinations. One study of fifty-eight patients diagnosed with probable AD reported that 53% had prominent delusions and 35% had experienced hallucinations (Klatka, Louis, & Schiffer, 1996). Another recent study reported that 34% of the 70 subjects examined had delusions in the previous month and 11% had suffered hallucinations (Gormley & Rizwan, 1998). The latter study found that men experienced more psychotic symptoms than women and that these symptoms were not associated with age at illness onset, dementia severity, or scores on a depression rating scale. A recent interesting study using SPECT found that AD patients with delusions had decreased cerebral blood flow in the left prefrontal region, whereas patients with hallucinations had right parietal hypoperfusion (Kotrla, Chacko, Harper, Jhingran, & Doody, 1995).

Ramachandran and colleagues (1996) reported that both depression and psychosis were three times as prevalent in AD patients who had at least one copy of the ApoE 4 allele, compared to AD patients without this allele. They concluded that the phenotype of AD associated with the $\epsilon 4$ allele is more likely to include psychiatric manifestations. However, a recent study by Lopez and colleagues (1997) failed to find such a connection. They examined psychiatric symptomatology in 194 patients with AD (115 of whom had at least one copy of the $\epsilon 4$ allele) and found that the allele was associated with earlier onset of AD but appeared unrelated to the expression of psychiatric disturbance. Finally, our group (Sultzer et al., 1995) has shown that psychiatric symptomatology is a fundamental expression of the cortical dysfunction seen in AD. Using functional neuroimaging

(PET), significant associations between agitation/disinhibition and cerebral metabolism in the frontal and temporal regions and psychosis and frontal metabolism were observed among twenty-one patients with probable AD.

Frontotemporal Dementia

Introduction. Frontotemporal dementias (FTD) are neurodegenerative diseases that produce disproportionate atrophy and/or neuropathology of the frontal and/or temporal lobes (unlike AD, where the medial temporal lobes and the associative cortex of the parietal and temporal lobes are initially affected). Often there is asymmetric degeneration of these regions, and many cases of FTD show either predominantly right- or predominantly left-sided involvement of the frontal and/or temporal lobes (Miller et al., 1991). However, in most FTD patients, both hemispheres are somewhat involved (Lezak, 1995). There are multiple types of FTD distinguished by subtle neurohistological differences (see Neary & Snowden, 1996), but these different subtypes share enough similarities to permit generalizations about FTD.

As mentioned before, the frontal lobes are the primary sites of the earliest degenerative changes in FTD, and the anterior portions of the temporal lobes are also affected early. The parietal and occipital lobes and the posterior portions of the superior temporal gyrus remain relatively unaffected (Neary & Snowden, 1996). The age of onset for FTD is typically between 50 and 70 years of age, and it may be inherited as an autosomal-dominant disorder in a minority of individuals (Cummings & Benson, 1992). The mean duration of illness for FTD is about 8 years, although there is considerable variability in survival time; many FTD patients survive for 12–15 years after diagnosis (Neary & Snowden, 1996).

Behavioral Characteristics of FTD. Relative to other degenerative disorders, FTD is much more likely to have prominent psychiatric symptoms that predate obvious cognitive or intellectual impairment (Cummings & Benson, 1992; Miller et al., 1991). The most salient and pervasive feature throughout the course of FTD disease is profound alteration in social conduct and personality (Neary & Snowden, 1996). Cognitive/intellectual deterioration inevitably occurs with FTD, but it is overshadowed initially by the often dramatic changes in mood, affect, personality, and behavior. Table 4

Table 4. Behavioral and Affective Symptoms of Frontotemporal Dementia as Outlined by the Research Groups in Lund, Sweden, and Manchester, England

Insidious onset and slow progression
Early loss of personal and social awareness
Early loss of insight
Early signs of disinhibition (e.g., unrestrained sexuality, violent behavior, inappropriate jocularity, restless pacing)
Mental rigidity and inflexibility
Stereotyped and perseverative behavior (e.g., wandering, clapping, singing, hoarding of objects, rituals involving dressing or hygiene)
Hyperorality (e.g., dietary changes, overeating, food fads, excessive smoking and/or alcohol consumption, oral exploration of objects)
Distractibility, impulsivity, and impersistence
Utilization behavior (e.g., unrestrained exploration/use of objects in the environment)
Depression, anxiety, excessive sentimentality
Bizarre somatic preoccupation
Emotional unconcern and remoteness; lack of empathy
Inertia, apathy, lack of spontaneity

lists the most typical behavioral and affective symptoms/signs of FTD, as outlined by the research groups from Lund, Sweden, and Manchester, England (Brun et al., 1994).

Typically, signs of disinhibition appear early in the course of the disease and include physical restlessness, impulsivity, irritability, aggressiveness, and excessive sentimentality (Brun & Gustafson, 1999). Some patients with FTD will crave affection and sexual contact and may become easily and frequently provoked when these needs are not met. A lack of empathy for the feelings and concerns of others, including family members and significant others, often makes FTD patients difficult to manage. The presence of stereotyped behavior often develops early in the course of FTD and occasionally manifests in hoarding behavior or habitual shopping. Self-care is almost inevitably affected in FTD; patients become less concerned with their personal appearance (Brun & Gustafson, 1999).

The personality disruption observed in FTD is not uniform; some individuals become restless, agitated, disinhibited, and overly jocular, and

others become apathetic and inert and lack drive, motivation, and initiative. Most patients diagnosed with FTD have relatively normal premorbid personality and the neuropsychiatric features of FTD are typically much more strongly associated with the distribution of cerebral dysfunction than with premorbid personality characteristics (Lebert, Pasquier, & Petit, 1995; Miller et al., 1993). One of the most striking behavioral syndromes associated with FTD is the Kluver–Bucy syndrome. In this syndrome, which was originally seen in monkeys with ablated amygdalae, emotional blunting with loss of fear and affective response, altered dietary preferences, mandatory oral exploration of novel environmental stimuli, and hypersexuality are observed. FTD does not inevitably lead to Kluver–Bucy, but many of these behavioral manifestations will be present in a subset of affected individuals.

Typically, FTD is easily distinguished from the early stages of AD. A study that compared the neuropsychiatric symptom profile of FTD with that of patients with AD found that, as a group, patients with FTD had significantly higher levels of disinhibition, apathy, euphoria, and aberrant motor behavior (stereotyped movements, motor tics), and lower levels of depression and anxiety than early stage AD patients (Levy, Miller, Cummings, Fairbanks, & Craig, 1996). However, as AD progresses and begins to involve more anterior cortical regions (i.e., the prefrontal cortex) the two disorders may look more similar from a neuropsychiatric perspective; at this point, the AD patient will often show much more profound cognitive/intellectual deficits than the FTD individual.

Subcortical Disorders/Diseases

Subcortical Versus Cortical Dementia. Whereas syndromes such as AD and FTD involve pathology that, at least initially, affects cortical regions of the brain, other syndromes cause prominent behavioral disturbances that first affect subcortical structures and circuits. Two of the most common of the subcortical disorders, Parkinson's disease (PD) and Huntington's disease (HD), can first appear without prominent cognitive disruption. When intellectual deterioration (i.e., dementia) is present in individuals with PD and HD, one of the most prominent neurocognitive deficits is pronounced slowing of information-processing speed. Additionally, disturbances of attention and

concentration, memory problems characterized by retrieval deficits, and executive dysfunction are typical sequelae of these subcortical syndromes (Lezak, 1995). Below we examine two of the most common forms of subcortical degenerative disorders here.

Parkinson's Disease

Introduction. Parkinson's disease (PD) is a movement disorder that can, and often does, lead to prominent changes in cognitive function and psychological status. It has been estimated that from 20–40% of all patients with PD eventually develop a dementia syndrome (Brown & Mardesen, 1984; Lerner et al., 1997; Mayeux et al., 1988; Rajput, 1992). The rate of progression of PD symptoms varies, but it is generally accepted that most individuals with PD will show significant physical disability within 10–15 years of diagnosis (Freedman, 1990). The likelihood of intellectual and psychological deterioration increases as the illness progresses (Lerner et al., 1997).

It is important to clarify the difference between *Parkinsonism* and Parkinson's disease. Parkinsonism is a generic term used to describe a cluster of motor symptoms that includes difficulty in initiating movement and bradykinesia (slowness of movement), in addition to tremor, rigidity, gait disturbance (e.g., shuffling gait with many rapid, small steps), and postural changes (i.e., stooped posture). These symptoms and signs can result from a variety of specific illnesses (e.g., viral encephalitis) and/or toxin exposure (e.g., manganese poisoning) and are often seen as side effects of long-term use of antipsychotic medications (La Rue, 1992). Parkinson's Disease (PD) is the occurrence of this constellation of symptoms with a gradual onset and progressive course without a specific cause or etiology. Lezak (1995) has suggested that approximately 80% of all cases that involve prominent Parkinsonism are idiopathic.

The most common neuropathological features of PD are neuron loss in the substantia nigra and other pigmented brain-stem nuclei (Gibb, 1989). The substantia nigra is a principal site of dopaminergic neurons, and cell death in this region produces a deficiency in dopamine in associated brain regions, including the striatum and prefrontal regions. This dopaminergic disruption, it is thought, is responsible for the motor disturbances seen in PD.

PD is primarily a disease of late middle age and beyond. According to La Rue (1992), the average age at onset of PD ranges from 59–62 years. PD is quite uncommon before age 40, after which incidence rates increase sharply to the ages of 70–79 years (Marttila, 1987). PD affects approximately 1 million individuals in North America (Lerner et al., 1997). It has been suggested that PD is more common in men than in women (Diamond et al., 1990); this is not consistently borne out by epidemiological studies, some of which have found similar prevalence rates for both sexes (Marttila, 1987). There are few clear risk factors for developing PD other than advancing age and a family history of dementia. Note that although nearly one-third of all cases of idiopathic PD are familial, relative to other diseases (e.g., AD, Huntington's disease), genetics are not strongly implicated in this disorder (Payami & Zarepari, 1998; Viegge, Schiffke, Friedrich, & Muller, 1992).

Cognitive and Motor Changes Associated with Parkinson's Disease. As noted earlier, many patients with PD show cognitive impairment, although often not severe enough to warrant a label of dementia. Only a small minority of patients present with dementia as the first sign of PD (Hedera et al., 1994). Slowed cognition (bradyphrenia) is the most common cognitive change. Forgetfulness and executive dysfunction, such as difficulty in planning, sequencing, and problem solving are also relatively common in PD. For excellent reviews of the cognitive deficits associated with PD, see Lezak (1995) and La Rue (1992). The motor signs of PD are typically easily identified and include the posture and gait abnormalities mentioned before, resting tremor, and speech irregularities such as hypophonia (reduced voice volume) and dysarthria (difficulty producing speech).

Psychiatric Characteristics of Parkinson's Disease. Tremor and other motor disturbances are typically the most common presenting signs of PD, but depression or other psychiatric problems may predate obvious motor abnormalities in a small minority of cases (Mayeux, 1987). As mentioned before, depression is a very common feature of PD. Cummings (1992) suggested that it is the most common neuropsychiatric feature of this disease, and approximately 40–50% of all PD patients experience prominent depression at some time during their illness. Based on two longitudinal studies of depression in PD, Cummings noted

that there is some degree of mood stability over the course of PD; those who are depressed at study entry tended to be depressed at follow-up, and those who were not depressed at study entry tended to remain unaffected. Though mood disturbance may occur in reaction to the losses and stressors that accompany PD, evidence suggests that the majority of depression in PD results directly from CNS disturbance. Depression, for example, is not associated with the degree of disability in PD, a finding that runs counter to a reactive depression hypothesis (Troster et al., 1995). In contrast, depression is associated with other markers of frontal-subcortical pathology in PD (Kostic et al., 1994; Mayberg et al., 1990; Wertmann et al., 1993).

Some have suggested that depression is more common among patients with early-onset PD and is especially likely to be associated with neurocognitive impairment in this group (Kostic et al., 1994; Starkstein et al., 1989). However, others have found no differences in age of onset in depression (Dubois et al., 1990; Ludin & Ludin, 1989). Brain imaging of depressed PD patients suggests that metabolic activity in the caudate and orbital regions of the frontal lobes is reduced relative to age and disability-matched nondepressed PD patients (Mayberg et al., 1990). The literature on gender differences in rates of depression in PD is mixed. Some investigators have found higher rates of depression among women with PD than among men (Brown and MacCarthy, 1990; Gotham, Brown, & Mardsen, 1986), but this finding has not always been confirmed (Mayeux et al., 1984).

PD patients with depression often show a profile of depressive symptoms that differs in important ways from patients with idiopathic depressive disorders. Depressed PD patients were less likely to complain of feelings of guilt, failure, or self-reproach but are instead more likely to manifest irritability, anxiety, sad mood, and pessimism regarding their future (Cummings, 1992). A recent study has also suggested that a subset of PD patients show deficits in processing and interpreting materials with emotional content (Benke, Boesch, & Andree, 1998). Mixed results have emerged from studies that examined whether depression is associated with cognitive deficits in PD; clearly, however, such an association does exist among the more severely depressed PD patients (Boller, Marcie, Starkstein, & Traykov, 1998).

Psychotic-spectrum symptoms occur in PD but

are less prevalent than in AD. However, hallucinations are not uncommon consequences of long term *treatment* of PD (Factor, Molho, Podskalny, & Brown, 1995). These hallucinations are typically vivid, visual hallucinations that occur with well-preserved orientation and awareness. A recent study found that approximately 15% of a sample of twenty-six autopsy-confirmed PD patients showed evidence of delusions, compared to 53% of all AD patients (Klatka et al., 1996).

Huntington's Disease

Introduction. Huntington's disease (HD) is a genetically transmitted, progressive, degenerative disorder whose clinical manifestations typically first become obvious between the ages of 30 and 50. Three features characterize this degenerative disorder: movement disorder, dementia, and familial transmission. The earliest manifestations of the movement disorder in HD involve brief, irregular, jerking movements (choreaform), along with slower, snake-like, writhing motions that tend to occur when action is initiated. Early in the course of HD, these movement irregularities can occasionally be suppressed or minimized to a certain extent. In the later stages of the illness, movements become far less controllable, and almost constant grimacing, nodding, head bobbing, and a "dancing" gait are seen (Lerner, Strauss, & Whitehouse, 1997). It is not uncommon for psychiatric disturbance to precede the onset of movement disorder in HD. We do not spend much time discussing the typical neurocognitive profile of HD (see Lezak, 1995 for more thorough coverage), other than to mention that executive functions, psychomotor speed, short-term episodic memory retrieval (not encoding), visuospatial skills, and procedural memory are often affected to varying degrees.

The average age of onset is between 35 and 40 years of age, but a juvenile onset variant of the disease occurs in 3–10% of all diagnosed cases of HD (Lerner et al., 1997). HD gradually progresses over many years and ends in death an average of 12–17 years after onset, although a high number of completed suicides obviously shorten group life expectancy post-diagnosis (Mendez, 1994). The main types of neuropathology in HD are atrophy and neuronal loss in the striatum, which begins in the medial caudate nucleus and progresses laterally to involve other areas of the caudate and putamen (Folstein, Brandt, & Folstein, 1990). HD

is transmitted as an autosomal dominant trait with complete lifetime penetrance, which means that children of an individual with HD have a 50% probability of developing the disease. Men and women are equally likely to be affected by HD, and, though estimates of the prevalence of HD vary considerably by population, it is believed that somewhere between forty to seventy persons per million population are affected (Cummings & Benson, 1992). CT and MRI scans often reveal enlarged ventricles in structural brain images in HD ("box-car ventricles") as a result of the degeneration of the caudate nucleus and prominent atrophy in the frontal lobes. Functional imaging such as positron emission or single photon computerized tomography typically reveals decreased glucose metabolism in caudate and other basal ganglia structures, whereas cortical metabolism remains roughly normal (Bamford et al., 1989; Nagel et al., 1988).

Psychiatric Characteristics of Huntington's Disease. Individuals with HD often undergo significant personality changes that can precede the appearance of movement disorder and/or cognitive deficits (Folstein et al., 1990). As noted by Lerner and colleagues (1997), George Huntington, from whom HD takes its name, described one of three cardinal features as "insanity with a tendency to suicide" and, indeed, studies have documented increased rates of completed suicide in HD (Folstein et al., 1990). Several studies have suggested that as many as half of all patients ultimately diagnosed with HD first present with psychiatric symptoms and anywhere from 35–50% of HD patients have psychiatric disorders (Cummings, 1995).

Depression, the most common psychiatric disorder, affects an estimated 38–60% of all HD patients at some time, and 20% suffer chronic depression (Cummings, 1995). The depression seen in HD can be conceptualized as an understandable reaction to a terrible disease, but several lines of evidence suggest that depressive disorders are not solely reactive to diagnosis. Mood disturbances tend to be episodic and not closely associated with the degree of physical or cognitive deterioration (Zappacosta et al., 1996). A significant minority of HD patients also show evidence of a bipolar mood disorder with prominent and frequent manic episodes (Folstein et al., 1990). Perhaps the most convincing line of evidence can be

found in studies of HD patients who were adopted and thus are unaware that they were at risk of developing the disease. These individuals have a significantly higher rate of psychiatric disorder, including suicide, *before* the onset of the motor symptoms of HD, and thus before they knew they were at risk of the disease, indicating that a reactive-depression hypothesis can be discarded.

There is an elevated incidence of pronounced irritability and "intermittent explosive disorder" among patients with HD. Studies summarized by S. E. Folstein (1989) suggested that 31% of 186 patients surveyed met criteria for the DSM-III diagnostic category of Intermittent Explosive Disorder. Shiwach (1994) reported that significant personality alterations were noted in 72% of a sample of 110 HD patients, and irritability and hostility were quite common. A recent study of neuropsychiatric symptomatology among patients with HD found that in twenty-nine patients with agitation, irritability and anxiety were among the most common and salient symptoms (Litvan, Paulsen, Mega, & Cummings, 1998). These personality changes, which often include increased hostility, aggression, and/or irritability, may be harbingers of the onset of HD in individuals known to be at risk for the disease. Baxter and colleagues (1992) reported that among fifty-two at-risk subjects, those determined most likely to develop HD (based on genetic marker studies and functional neuroimaging) had higher anger/hostility ratings on a semistructured mood inventory than at-risk subjects determined less likely to develop HD. Clinical lore and retrospective review of the history of those with HD suggest that increased irritability or hostility is often triggered by events that previously never provoked such a reaction. Increased rates of sexual aggression, promiscuity, exhibitionism, and pedophilia have been noted among individuals with HD (Cummings, 1995). As noted by Lerner et al. (1997), these types of personality changes often go unreported by the HD patient, making it of utmost importance that other informants (e.g., caregiver, spouse) be queried regarding the patient's psychiatric status. A recent literature review by DeMarchi and Mennela (2000) concluded that the precise characterization of both the psychiatric status of the HD patients showing psychopathological changes and of their families might help to identify or delineate different subtypes of HD.

In addition to prominent mood disturbance, HD patients may present with psychotic symptoms such as delusions and/or hallucinations (Folstein et al., 1990; Brooks, Murphy, Janota, & Lishman, 1987). Maricle (1989) points out that the bizarre kinds of hallucinations and delusions that are first-rank symptoms of schizophrenia are rare. Instead, HD patients are more likely to be jealous, suspicious, or obsessional. Prominent psychotic-spectrum symptoms are typically first noted after motor and cognitive irregularities are obvious, but this is not always the case (e.g., Lovestone, Hodgson, Sham, Differ, & Levy, 1996).

Because HD is a familial disease and offspring of affected individuals are at heightened risk of developing the disease themselves, there is considerable interest in the psychiatric status of "at-risk" individuals. Some studies have found that psychiatric symptoms/disorders are more common among these individuals (Baxter et al., 1992), and others have found no differences between their psychiatric functioning and that of controls (Jensen et al., 1993; Shiwach & Norbury, 1994).

Stroke

Introduction. Although the incidence of stroke is declining, most likely due to advances in the treatment of hypertension among elderly adults, nonetheless, it is one of the leading causes of mortality and morbidity in the United States. It is the third leading cause of death in the United States (Robinson & Starkstein, 1997). Stroke has been defined as a "focal neurological disorder of abrupt development due to a pathological process in blood vessels" (Walton, 1994); the mechanism of pathology is disruption of the supply of oxygen (and nutrients such as glucose) to the brain as a result of disrupted blood flow. Without oxygen and glucose, brain tissue dies or is damaged. These areas of tissue damage are termed *infarcts*. The two main classes of strokes are the obstructive and hemorrhagic types; each has slightly different behavioral sequelae, as discussed later. Obstructive strokes represent roughly 75–85% of all strokes (see Powers, 1990; Robinson & Starkstein, 1997) and occur when the buildup of materials in the arterial walls prevents blood from traveling freely and bringing oxygen and nutrients to brain tissue. Hemorrhagic strokes often result from hypertension that causes weakening and eventual rupturing

of brain blood vessels but may also occur secondarily to aneurysms. Hypertensive hemorrhagic strokes are considerably more common among elderly individuals, whereas younger persons are more likely to suffer ruptured aneurysms (Lezak, 1995).

Psychiatric Changes Associated with Stroke. Stroke can lead to a wide range of cognitive, emotional, and personality changes that at least partially depend on the location and nature of the pathology. Depressive symptomatology is the most common neuropsychiatric disturbance associated with stroke. Estimates of the prevalence of depression following stroke vary, but an estimate of 40–50% is reasonable. One reason for the tremendous variability in estimates of depression prevalence among studies is that very different criteria for defining depression are used (e.g., structured diagnostic criteria versus self-report rating scales). The 4th edition of the DSM (APA, 1994) labels a pronounced mood syndrome following a stroke, "Mood disorder due to stroke with major depressive-like episode," and less severe symptoms, "Mood disorder due to stroke with depressive features" (p. 370). Often, however, studies of poststroke depression use rating scales, rather than structured diagnostic interviews, to assess depressive symptomatology. As we discuss later, high scores on these scales do not necessarily indicate the presence of a clinical syndrome.

Depression is a far more likely occurrence following left-hemisphere strokes, especially when the site of pathology is anterior (i.e., frontal). Several studies have suggested that the distance of the lesion (or infarction) from the left frontal pole is inversely correlated with the severity of depression (Morris, Robinson, & Raphael, 1992; Robinson & Szetela, 1981). Members of our group conducted a longitudinal study to investigate emotional change following stroke at acute, 2-month, and 6-month intervals (Nelson, Cicchetti, Satz, & Stern, 1993). Indifference and depression were both significantly more common among patients who had suffered a left-hemisphere infarction, and these symptoms often persisted throughout the follow-up period. Clearly then, depression is often not merely an acute reaction to stroke but rather a lasting problem. Robinson and Starkstein (1997) reported that nearly one-third of a sample of patients who were not depressed immediately fol-

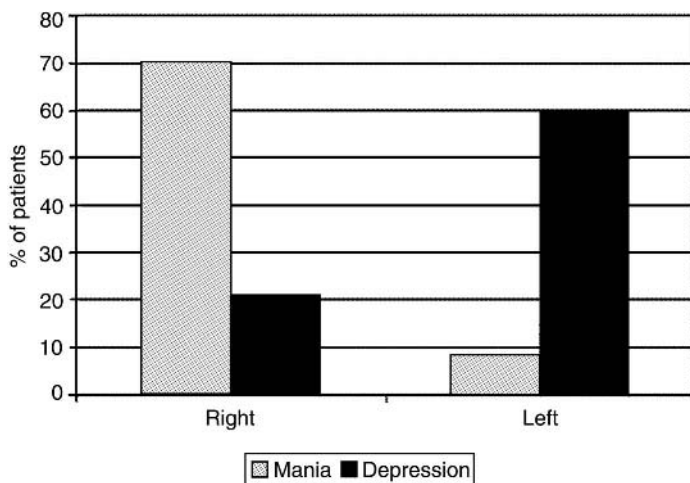

Figure 2. Percentages of individuals with mania or major depression following stroke, divided by lesion location as visualized with computerized tomography scan. Adapted from Robinson *et al.* (1988).

lowing their stroke became depressed sometime following discharge from the hospital. Similarly, Astrom and colleagues (1993) found that twenty-seven of their 80 patients had developed major depressive syndromes either in the hospital or by 3-months after hospital discharge and that twelve of these patients (15% of the original sample) continued to show prominent depression 3 years following the stroke. Note that depression is not limited to left-hemisphere stroke as studies have shown that right posterior strokes (especially in the parietal white matter) can lead to elevated rates of depression (e.g., Finset, 1988).

The caregivers of patients who suffered a left-hemisphere stroke reported high rates of blunted emotional expression among their affected relatives and highlighted the need to consider apathy as well as depression when evaluating the psychiatric sequelae of stroke (Nelson, Cicchetti, Satz, & Stern, 1993). As mentioned before, apathy is not uncommon following a stroke and may exist independently of depression in a subset of stroke patients (Starkstein *et al.*, 1993). Patients who had suffered lesions that involved the posterior limb of the internal capsule were most likely to be apathetic but not depressed.

Manic syndromes may occur poststroke, but they are much less common than depression (Cummings & Mendez, 1984). When secondary mania does occur, it is often phenomenologically

indistinguishable from primary mania (Starkstein, Boston, & Robinson, 1988). Poststroke mania is most commonly seen when right-sided lesions, especially in limbic-related areas, are present. Although lesions to the right limbic areas are more likely to produce secondary mania, they clearly do not in the majority of patients with such lesions. Figure 2 adapted from Robinson and colleagues (1988), captures the right/left differences seen in depression versus mania. Robinson and Starkstein (1997) suggested that a risk factor for secondary mania may be a family history of mood disorder, implicating a genetic predisposition.

Secondary psychotic symptoms are relatively rare following stroke, but they can occur. When present, they are most often associated with right-sided lesions that involve frontal and parietal areas. There is some preliminary evidence to suggest that subcortical pathology in the context of right frontal-parietal or temporal-parietal lesions may be most likely to produce poststroke psychosis (Robinson & Starkstein, 1997). An interesting behavioral disturbance that may emerge following stroke is pronounced emotional lability characterized by rapid alternation of the patient between laughter and crying. In most emotionally labile patients, the affective outburst is mood-congruent (that is, crying will accompany a sad mood) and inappropriate only in its intensity and seemingly uncontrollable nature. However, affect

and mood in some individuals are disconnected, and these patients inappropriately burst into episodes of laughing or crying that seemingly have no context. The term emotional incontinence has been used to describe this inability to modulate emotional expression.

Traumatic Brain Injury

Introduction. Traumatic brain injury (TBI) is among the most common precipitants of brain damage. In fact, disorders arising from TBI are more common than any other neurological disease, except headaches (Kurtzke, 1984). Each year several million persons in the United States sustain some degree of head trauma; many of these are from motor vehicle accidents or falls (Satz et al., 1997). The range of severity among individuals who do not die from TBI is dramatic; some show no discernible adverse cognitive or psychiatric effects, whereas others are left profoundly and permanently disabled, both cognitively and psychologically.

There are several mechanisms by which brain damage can occur following TBI; contusions and diffuse axonal injury are the most common primary mechanisms of neuronal damage. *Contusions* affect specific areas of the brain and usually occur as a result of low-velocity injury such as falls or blunt blows to the head. *Diffuse axonal injury* refers to the mechanical or chemical damage to the axons in cerebral white matter that commonly occurs during acceleration or deceleration injuries. Due to the way the brain sits in the skull, shearing or laceration often take place on the bony prominences that surround the orbital, frontal, and temporal areas along the base of the skull. In addition to these primary mechanisms of neuroanatomical and/or neurochemical alterations, secondary effects such as hematomas (subdural, epidural), cerebral edema (i.e., swelling), and increased intracranial pressure may lead to behavioral changes by altering brain function. In addition to the type of head injury incurred, several factors influence the degree to which an individual will show cognitive and/or psychiatric sequelae secondary to TBI.

Mediating Factors. Several studies have shown the people most likely to suffer from brain injury due to head trauma are those in the 15- to 24-year-old age group (Frankowski, Annegers, & Whitman, 1985; Goldstein & Levin, 1990), although

head injury is also more common in the first 5 years of life and in the elderly. One of the best predictors of the likelihood of showing changes in cognition and psychiatric functioning is the severity of the injury, which is often qualified by factors such as the length of loss of consciousness, post-traumatic amnesia, and the need for hospitalization. Obviously, those with more severe head trauma are more likely to show changes in cognitive and psychiatric function.

Psychiatric Disturbance Following TBI. Emotional and personality changes are among the most problematic sequelae of TBI. The case of Mr. Phineas Gage, which we described earlier, is a classic example of TBI that produces profound and socially incapacitating changes in the absence of obvious cognitive deterioration. The family members and caregivers of patients who have suffered significant head injury often report that changes in this domain are more problematic than either the physical or the cognitive/intellectual changes that accompany the injury. Unlike in primary psychiatric disorders, where symptom onset is often gradual, the mood, emotional, and personality changes that follow TBI frequently begin suddenly and are pronounced. Many times, changes in mood and personality secondary to TBI remit with time (e.g., with the reduction of cerebral edema), but in some patients, persistent or even permanent deficits in these domains are observed (Silver, Hales, & Yudofsky, 1997). Among the neuropsychiatric disorders, depression is perhaps the most common following TBI. Prevalence rates of depression are clearly elevated following TBI, although estimates vary dramatically depending on the way depression is defined and on the severity of the head injury surveyed (Bornstein, Miller, & van Schoor, 1989; Satz et al., 1998).

The neuropsychiatric consequences of TBI are not dissimilar to those from stroke in terms of the effects of the lesion site. For example, depression is much more common following left frontal injury, whereas mania is more commonly seen when right frontal or right temporal injury is incurred. Historically, the term pseudopsychopathic has been used to describe the patient who shows extreme irritability, facetiousness, impulsivity, sexual disinhibition, inappropriate social and personal behavior, and lack of concern for others. As mentioned earlier, this behavioral profile often occurs following damage to the orbitofrontal cortex and may be especially likely following right-

sided orbitofrontal pathology (Cummings, 1993). Manic episodes and bipolar disorders have been reported following TBI, but they are much less common than depression (Bamrah & Johnson, 1991; Burstein, 1993). Right-sided damage, particularly to the basal region of the temporal lobe and the orbitofrontal cortex, was most common among secondary manic patients with TBI (Starkstein et al., 1990). Psychosis is relatively rare as an acute reaction following TBI, but previously head-injured patients are typically vastly overrepresented among those with psychotic-spectrum disorders such as schizophrenia (Buckley et al., 1993).

Recent Developments in the Clinical Assessment of Neurobehavioral Disorders

This chapter has provided a brief review of some of the major neurobehavioral disorders and their putative neural substrates. We have attempted to highlight some of the key symptoms and signs that are often associated with these disorders, which, in turn, may aid in the differential diagnosis of an underlying CNS versus psychiatric disorder. As noted in this review, a number of neurological disorders can present with psychiatric/psychological symptoms. Frontal lobe lesions, temporal lobe epilepsy, limbic system damage, Alzheimer's disease, Parkinson's disease, Huntington's disease, stroke, and traumatic brain injury are some of the many neurological conditions that can give rise to neuropsychiatric phenomena. Because of the apparent similarity in clinical presentation among many neurobehavioral and psychiatric disorders, the risk of misdiagnosis and mistreatment is high. This state of affairs has been fostered in part by over reliance on assessment instruments that have been standardized and validated on patients with primary (i.e. idiopathic) psychiatric disorders (although, as we have attempted to point out, mounting evidence shows that these disorders have a neuroanatomic and/or neurochemical substrate). As noted by Nelson et al. (1989), these methods have included personality questionnaires (e.g., MMPI-2, MCMI-III), symptom checklists (SCL-90), and clinician-administered rating scales (e.g., Hamilton Depression Rating Scale). Unfortunately, such assessment instruments were not designed with specific knowledge of brain-behavior relationships in

mind and thus have had little direct applicability to neurological disorders. Although recent efforts have been made to modify existing measures such as the MMPI-2 to improve their ability to detect subtle emotional changes associated with brain injury (Gass, 1991; Satz et al., in press), the risk of misdiagnosis is still high, given their historical psychometric roots in personality theory. An additional concern with some of the personality instruments is their reliance on self-report, which restricts their application to patients whose brain insult may compromise awareness of deficits (anosognosia), energy level, and cognitive capacity. A final concern with traditional psychological instruments has been their failure to account for change, pre- to post-injury. Comparing premorbid with present levels of functioning is crucial to understanding the impact of acquired brain insult.

Following, we describe some recent assessment approaches that have addressed these issues so as to familiarize the reader with the tests and their potential application in clinical and research activity.

1. *Neurobehavioral Rating Scale (NRS: Levin et al., 1987)*. This scale was developed from the Brief Psychiatric Rating Scale (Overall & Gorham, 1962) to focus on neurobehavioral sequelae of traumatic brain injury, rather than on general psychiatric disorders (see Spreen & Strauss, 1998, for a review). A clinician or other informant familiar with the patient completes seven-point ratings on twenty-seven items that represent four factors: cognition/energy (e.g., disorientation, emotional withdrawal, conceptual disorganization, fatigability, blunted affect), metacognition (e.g., inaccurate insight and self-appraisal), somatic/anxiety (e.g., somatic concerns, anxiety), and language function (e.g., comprehension deficits, expressive language deficits). It has been shown that the NRS has adequate psychometric properties (i.e., reliability and validity). Despite the appear of this instrument for use with brain-injured patients, the NRS does require substantial examiner administration and observation time to ensure appropriate reliability and validity. The NRS also provides no preinjury/postinjury comparison of items to control for potential preinjury risk factors. According to Spreen and Strauss (1998), there are no normative data available because "normal healthy subjects" are not expected to show elevations on any of these scales except for "minor elevations in the somatic-anxiety factor area." The scale authors

also note that women who have sustained TBI score slightly higher on depression items, but otherwise sex differences are negligible on the NRS. Presently, no commercial source exists for this instrument.

2. *Neuropsychology Behavior and Affect Profile (NBAP: Nelson et al., 1989)*. This instrument was developed and standardized in the late 1980s by a group of neuropsychologists at UCLA to measure perceived changes in affect and behavior following trauma or suspected brain injury. The instrument consists of 106 items on which explicit behaviors and emotions are rated dichotomously (present or absent) at each of two times (preinjury and postinjury). Both observer and self-rated versions are available, though initial research has focused on using the observer-rated form. Typically, the "observer" is a family member, significant other long-time friend, or caregiver who has known the brain-injured patient well. Five clinical scales were developed on the basis of previous research on patients with neurobehavioral disorders. The items purport to measure the following five constructs, which were constructed on an a priori basis and were subjected to content validation by expert sortings: (1) *indifference* (anosognosia or a tendency to minimize disability, apathy), (2) *inappropriateness* (unusual or bizarre behavior), (3) *pragnosia* (defect in pragmatics of communication), (4) *depression* (sadness, anhedonia), and (5) *mania* (elevated, expansive mood, euphoria, heightened activity level). Several validation studies have been published by the test authors on populations with closed head injury and Alzheimer's and Downs syndrome (see Spreen & Strauss, 1998, for a review).

Despite the reasonable support found for the NBAP's discriminant validity, there are potential problems with any observer-rated instrument, and the NBAP is no exception. Such potential confounds as halo effects, leniency or severity bias, and central tendency or restriction effects should always be considered when an observer rates another individual with an instrument. For this reason, several steps were taken to reduce potential rater inaccuracies and biases. Items were written at a reading level appropriate for the general population; all item wording was specific, concrete, and descriptive. Neutral items (i.e., written without a negative emotional valence) were also added to assess overendorsing tendencies. Some items were also developed to serve as internal consis-

tency checks, and item wording was either almost identical or opposite in meaning to other items. Because of the potential observer bias in cases of litigation, four validity scales were developed for the NBAP that have shown promising discriminant validity (Satz et al., 1996). Finally, to control for undersampling (i.e., insufficient rater knowledge of the subject's behaviors), the NBAP used only informants with sufficient knowledge of the patient's behaviors both pre- and postinjury.

The NBAP, including norms, manual, and scoring instructions, is available for review from the test's publisher, Mind Garden, located in Palo Alto, California.

3. *Neuropsychiatric Inventory (NPI: Cummings et al., 1994)*. The NPI is a tool designed for assessing psychopathology among patients with dementia and other neurological disorders. It is a brief, clinician-administered interview that obtains information about the patient's behavior across twelve neuropsychiatric symptom domains (e.g., delusions, agitation, depression, anxiety, apathy, etc.). NPI items are typically administered to a person intimately familiar with the patient's behavior, such as a family member, significant other, or paid caregiver. The format of NPI dictates that a screening question is asked first (in each of the twelve domains) and is followed up with more specific queries if the response to the screening question suggests disturbance in that particular domain. After administering the specific queries in any domain, informant is asked to rate the frequency and severity of disturbance as well as the degree of distress caused them by the patient's behavior in this domain. A key feature of the NPI is that it is interested in *behavioral change* since the onset of the neurological disease/disorder. For example, patients who were mildly depressed before they received a diagnosis of Alzheimer's disease and remain depressed would be coded only if their depression had changed (i.e., intensified). The behavioral domains sampled by the NPI include depression, anxiety, delusions, hallucinations, agitation, disinhibition, euphoria/elation, apathy/indifference, irritability, aberrant motor behavior, sleep functioning, and appetite/eating change.

It has been shown that scores on the NPI are only minimally influenced by the normal aging process; the vast majority of healthy, normal elderly controls obtains scores of zero on the majority of symptom domains; when symptom domains

are positively endorsed among the normal elderly, they tend to be depression, irritability, and disinhibition (Cummings et al., 1994). The validity and reliability of the NPI symptom scales, as well as the caregiver distress scale, have been demonstrated (Cummings, 1997; Kaufer et al., 1998).

The NPI is similar to both the NBAP and the NRS and recognizes the importance of obtaining information regarding behavioral changes from sources other than the affected patient who may be a less than reliable informant due to cognitive limitations. However, our group has used a modification of the apathy and irritability subscales from the NPI for *direct* administration to relatively high-functioning individuals with CNS diseases such as HIV/AIDS who maintain the ability to accurately report on these symptoms. Using direct administration, we have found interesting relationships between neurocognitive, neurophysiological, and neuropsychiatric variables (Castellon et al., 1998).

These three measurement instruments have in common that they attempt to integrate theory and clinical practice in assessing psychopathology among individuals with CNS disorders. Although they represent significant advances over instruments constructed (and validated) for use with primary psychiatric populations, additional research will be required to continue to integrate neuropsychological empiricism with psychometrically sound measurement theory. This stated, however, it should be noted that many psychopathology instruments initially constructed for use in primary psychiatric/psychological populations, nonetheless, can provide useful information about the symptom profile of brain-injured individuals. When using such instruments, we caution the user to realize that many of the sequelae of CNS insult or injury can be confused with symptoms of psychiatric disorder (e.g., sleep disturbance, fatigue, somatic concerns). To the extent that this occurs, the symptoms of neurological or physical illness might be mistakenly attributed to psychiatric disorder.

Conclusion

We hope that this chapter has conveyed the fact that many of the psychiatric symptoms, signs, and syndromes described in earlier chapters of this text commonly appear following CNS disturbance. Likewise, many of the most prevalent neurological disorders have important psychiatric se-

quelae. Freud, in his *Project for a scientific psychology*, speculated that in the future we would find that "behind every crooked thought lies a crooked neuron," recognizing the intimate relationship between psychological phenomenon and neurophysiology. Fortunately, the Cartesian dualism, which has artificially dichotomized disorders of the mind and disorders of the brain, has faded considerably during the last decade. With the continued advances in neuropsychology and kindred disciplines, especially neuroimaging, Freud's prediction again appears prescient.

Cognitive Approaches to the Memory Disorders of Demented Patients

William C. Heindel and David P. Salmon

Introduction

Dementia is primarily (but not solely) an affliction of the elderly, and the prevalence increases dramatically with age to include almost a third of the population over 85 (Mahandra, 1984). Because of the change in population demographics that has been brought about by increases in life expectancy, in recent years dementia has been elevated from an issue of relative obscurity and neglect to one of the utmost interest and importance. Although this increased attention may create the impression that the study of dementia is of relatively recent origin, interest in this topic in fact dates back to antiquity. The term “dementia” was probably coined in the first century A.D., but for the next millennium or so was generally quite ill-defined and often used (along with delirium) to refer to insanity in general (Lipowski, 1981; Mahandra, 1984). It is also likely that no real distinction was made between dementia and the changes in cognitive function associated with normal aging (Mahandra, 1984).

Early in this century, the term “organic psychosyndrome” was used by Bleuler to refer to a set of behavioral manifestations of chronic diffuse cortical damage. The behavioral manifestations involved decrements in memory, judgment, perceptual discrimination and attention, emotional lability, and defective impulse control (Lipowski, 1981). This was essentially the classification adopted by the American Psychiatric Association (APA) in the early editions of its *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I and DSM-II; APA, 1952, 1968). Specifically, the DSM-II defined “organic brain syndrome” as a “basic mental condition characteristically resulting from diffuse impairment of brain tissue function from whatever cause,” and manifested behaviorally as an impairment in orientation, memory, intellectual functions, judgment, and affect (Lipowski, 1981). In this classification, brain dysfunction resulted in a single behavioral syndrome, regardless of the etiology and site of neuropathology (Lipowski, 1981).

Partly in response to the inadequacy of the simple “organic brain syndrome” classification, the more recent versions of the *Diagnostic Manual* (DSM-III-R and DSM-IV; APA, 1987, 1994) recognize many separate categories of psychopathological syndromes; two of them (Delirium and Dementia) are characterized by relatively global cognitive impairment. Delirium is distinguished from dementia primarily by the clouding of con-

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

sciousness in delirium, but not in dementia, and by the fluctuating nature of the symptoms in delirium versus the relatively stable symptoms in dementia. According to the DSM-IV,

The essential feature of Dementia is the development of multiple cognitive deficits that include memory impairment and at least one of the following cognitive disturbances: aphasia, apraxia, agnosia, or a disturbance of executive functioning. The cognitive deficits must be sufficiently severe to cause impairment in occupational or social functioning and must represent a decline from a previously higher level of functioning. The diagnosis of dementia should not be made if the cognitive deficits occur exclusively during the course of a delirium. However, a dementia and a delirium may both be diagnosed if the dementia is present at times when the delirium is not present. (APA, 1994, pp. 134)

The diagnostic criteria for dementia also require that a specific organic factor (or factors) can be either demonstrated or presumed (through the exclusion of all "functional" mental disorders) to be etiologically related to the disturbance. Dementing disorders that share a common symptom presentation but differ in etiology are distinguished in the DSM-IV. For example, the DSM-IV includes, among others, disorders such as Dementia of the Alzheimer Type, Vascular Dementia, Dementia Due to HIV Disease, Dementia Due to Head Trauma, Dementia Due to Parkinson's Disease, and Dementia Due to Huntington's Disease.

Although it has long been acknowledged that dementia can be associated with a wide range of neuropathology, it has only been relatively recently that clinicians have recognized that dementias can manifest themselves *behaviorally* in different ways as well (Bayles & Kaszniak, 1987). Now, there is increasing awareness that (1) Demented patients do *not* possess a global disorder of intellectual impairment, but instead show areas of relatively *preserved* intellectual ability and (2) The *pattern* of preserved and impaired abilities can *vary* depending on the etiology and neuropathology of the dementia.

One of the major catalysts for this change in awareness has been the proposed distinction between "cortical" and "subcortical" dementias. Albert and his colleagues (Albert, Feldman, & Willis, 1974) referred to the pattern of cognitive dysfunction observed in patients with progressive supranuclear palsy as a subcortical dementia characterized by (1) forgetfulness, (2) slowness of thought processes, (3) altered personality with apathy or depression, and (4) impaired ability to manipulate acquired knowledge. At about the same time, McHugh and Folstein (1975) described

similar cognitive changes in patients with Huntington's disease and contrasted this pattern of impairment with the aphasic, apraxic, and agnostic disturbances observed in demented patients with primary cortical dysfunction (e.g., Alzheimer's disease). Subsequent studies further delineated the qualitative differences in the cognitive deficits associated with so-called "cortical" and "subcortical" dementing disorders (Brandt, Folstein, & Folstein, 1988; Huber, Shuttleworth, Paulson, Bellchambers, & Clapp, 1986; Salmon, Kwo-on-Yuen, Heindel, Butters, & Thal, 1989), which led a number of researchers to suggest that cortical and subcortical dementias should be recognized as distinct clinical syndromes (for reviews, see Cummings, 1990; Cummings & Benson, 1984). Although criticized on a number of grounds (Brown & Marsden, 1988; Whitehouse, 1986), the cortical-subcortical distinction has descriptive and heuristic value and has proven useful for guiding research that compares the cognitive deficits of different dementing disorders. The distinction, however, is somewhat simplistic and artificial, and a more preferable investigative strategy may be to try to relate specific cognitive impairments with specific dementing disorders.

Descriptions of Different Dementing Illnesses

Dementia of the Alzheimer Type

Dementia of the Alzheimer type is the most common form of dementia in the elderly and accounts for roughly 50% of all reported cases (Cummings & Benson, 1992; Katzman, 1986). A large-scale study that sampled elderly individuals who lived in the geographically defined community of East Boston, Massachusetts (Evans et al., 1989) found an overall Alzheimer's disease prevalence estimate of 10.3% among those over age 65 and almost a 50% prevalence rate among those 85 years and over.

Although the cause of Alzheimer's disease (AD) remains unknown, a number of risk factors have been identified. Age is considered the single most important risk factor, given that the prevalence and incidence of AD double approximately every 5 years between the ages of 65 and 85. It is estimated that new cases of AD will be diagnosed each year in approximately 0.5% of individuals between the ages of 65 and 69, 0.75% of those

between the ages of 70 and 74, 1.5% of those between the ages of 75 and 79, 2.5% of those between the ages of 80 and 84, and 4.5% of those age 85 and over (Katzman & Kawas, 1994).

The risk of developing AD is increased approximately fourfold by a family history of the disease in a first-degree relative, and there is little question that this familial association is genetically based. Mutations on three genes have been identified in large families that display an autosomal dominant inheritance pattern of an early-onset form of the disease (i.e., onset generally before the age of 60): the amyloid precursor protein gene on chromosome 21, the presenilin 1 gene on chromosome 14, and the presenilin 2 gene on chromosome 1 (for a review, see Bird, 1999). These forms of familial Alzheimer's disease are rare and account for only about 1–2% of all cases of the disease. A far more common genetic risk factor for sporadic, late-onset Alzheimer's disease is the type $\epsilon 4$ allele of the gene for apolipoprotein E (APOE), a low-density lipoprotein cholesterol carrier. Located on chromosome 19, the APOE $\epsilon 4$ allele has been found in 50–60% of patients with AD (compared to 20–25% of healthy older adults), regardless of whether or not they have a family history of dementia (Strittmatter et al., 1993). Unlike the genes associated with early-onset familial AD, the APOE $\epsilon 4$ allele is not deterministic, but it confers an approximately threefold risk of developing AD if one copy of the $\epsilon 4$ allele is present and an eightfold risk if two copies are present (Katzman & Kawas, 1994).

A number of other risk factors for AD have been identified (Katzman & Kawas, 1994), but they have only a weak association with the disease (generally a twofold risk or less). Women have a slightly greater risk of AD than men; however, this may be attributable, in part, to differential survival after the onset of dementia due to their longer life expectancy. A previous head injury that led to loss of consciousness or hospitalization has been identified as a risk factor for AD, particularly (and perhaps exclusively) in conjunction with the presence of the $\epsilon 4$ allele of the gene for APOE. Several epidemiological studies have shown that lack of education and/or low occupational attainment may be an important risk factor for AD, perhaps because these variables are a surrogate for a brain or cognitive reserve that helps to delay the onset of the usual clinical manifestations of the disorder.

Although a distinction has traditionally been made between AD in the presenium (i.e., before

age 65) and senile dementia of the Alzheimer type, the general lack of any observed bimodality in the distribution of age-specific incidence rates argues against this distinction (Rocca, Amaducci, & Schoenberg, 1986). A study by Huff, Growdon, Corkin, and Rosen (1987), however, did obtain a bimodal distribution of age at onset with a division at about age 65 and also found that the rate of progression of dementia was more rapid in the senile than in the presenile cases. There have also been reports of greater left-hemisphere (i.e., language) vulnerability in early-onset cases and greater right-hemisphere (i.e., visuospatial) vulnerability in late-onset cases (Filley, Kelly, & Heaton, 1986; Seltzer & Sherwin, 1983). Becker, Huff, Nebes, Holland, & Boller (1986) further suggested that, within the language domain, severity of syntactic but not lexical/semantic impairments are related to age at onset.

The primary clinical manifestation of AD is a profound global dementia characterized by severe amnesia with additional deficits in language, "executive" functions, attention, and visuospatial and constructional abilities (Bayler & Kaszniak, 1987; Cummings & Benson, 1992). Alzheimer's disease is characterized neuropathologically by neocortical atrophy and neuronal loss (Terry, Peck, DeTeresa, Schechter, & Horoupian, 1981) and by the presence of neurofibrillary tangles and neuritic plaques (Tomlinson, 1977; Terry & Katzman, 1983a). Plaques and tangles are most extensive in the associative cortices, particularly in the parietal and temporal regions, and primary sensory cortical areas are relatively spared (Brun, 1983). The presence of both plaques and tangles correlates significantly with the presence of dementia (Blessed, Tomlinson, & Roth, 1968; Tomlinson, Blessed, & Roth, 1970; Wilcock & Esiri, 1982). Studies using the synaptic vesicle-associated protein synaptophysin have also found that patients with AD demonstrate an extensive loss of synaptic density (Masliah, Terry, DeTeresa, & Hansen, 1989) and that severity of dementia correlates better with synaptic density than with plaques and tangles (Terry et al., 1991). These results have led Terry et al. (1991) to speculate that synaptic loss may be the primary determinant of the dementia of AD. In terms of subcortical neuropathology, patients with AD reportedly have neuronal loss in the nucleus basalis of Meynert and the nucleus locus coeruleus, along with a corresponding decrement in neocortical levels of cholinergic and noradrenergic markers, respectively (Bondareff, Moutjoy,

& Roth, 1982; Mann, Yates, & Marcyniuk, 1984; Whitehouse, Price, Struble, Clark, Coyle, & DeLong, 1982).

Because there are no known peripheral biological markers for AD, the disease can be definitively diagnosed only by histopathological verification of the presence of the characteristic neurodegenerative abnormalities (i.e., neuritic plaques and neurofibrillary tangles) in the brain. However, documentation of the presence of dementia and the exclusion of all other known potential causes allows clinical diagnosis of dementia of the Alzheimer type during life with some certainty. To aid in this process and to standardize the diagnosis to some degree, criteria for the clinical diagnosis of probable and possible AD were developed by the Work Group on the Diagnosis of Alzheimer's Disease established by the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA; McKhann et al., 1984). Probable AD is indicated when dementia is documented, other causes are excluded, and the disorder aligns with the typical presentation and course. Possible AD refers to those cases of documented dementia in which AD is suspected but the disorder has an atypical onset, presentation, or clinical course, or a second disorder capable of producing dementia (e.g., alcohol abuse) is present, although it is not considered the primary source of cognitive dysfunction. When tested against autopsy verification of AD or one of its variants (i.e., the Lewy body variant of AD, mixed AD, and vascular disease), the accuracy of clinical diagnoses made using the NINCDS-ADRDA criteria ranges from 85–100%, even with the clinical diagnosis is made in the early stages of the disorder.

Vascular Dementia

Vascular dementia is a cumulative decline in cognitive function secondary to multiple or strategically placed infarctions, ischemic injury, or hemorrhagic lesions. Criteria for vascular dementia outlined in the DSM-IV require the presence of multiple cognitive deficits, significant impairment and decline in either social or occupational functioning, and that the deficits not occur exclusively during the course of a delirium. Furthermore, there must be focal neurological signs and symptoms or laboratory (e.g., CT or MRI scan)

evidence indicative of cerebrovascular disease, that are considered etiologically related to the cognitive impairment.

A relationship between dementia and cerebrovascular disease is often indicated if the onset of dementia occurs within several months of a recognized stroke, if there is an abrupt deterioration in cognitive functioning, or if the course of cognitive deterioration is fluctuating or stepwise. Vascular dementia will also sometimes be accompanied by gait disturbances and a history of unsteadiness and frequent falls, urinary disturbances not related to urologic disease, pseudobulbar palsy, and mood and personality changes (e.g., depression, emotional incontinence) (Cummings & Benson, 1992).

The most widely studied form of vascular dementia, Multi-Infarct Dementia (MID), arises primarily from multiple medium or large vessel cortical infarcts. Although epidemiological data on MID is scarce, it is estimated that roughly 18% of the elderly dementia cases are attributable to MID, and another 10% are due to the combination of Alzheimer's disease and MID (Terry & Katzman, 1983b; Tomlinson et al., 1970). In a study of 175 patients with MID, Meyer and his colleagues (Meyer, McClintic, Rogers, Sims, & Mortel, 1988) confirmed previous reports of greater prevalence in males (61%) than in females. Meyer et al. also found that MID was strongly associated with risk factors for stroke (particularly hypertension and heart disease) and that the most frequently occurring lesions were multiple lacunar infarctions (seen alone in 43% of cases and with other lesions in an additional 21% of the cases).

To clinically differentiate MID from primary degenerative dementia (i.e., Alzheimer's disease), Hachinski and his colleagues (Hachinski et al., 1975) developed an "Ischemic Score" based on the distinguishing characteristics and associated risk factors of MID. A higher score reflects an increased probability of MID. Hachinski et al. (1975) found that the Ischemic Scores of twenty-four patients with comparable levels of dementia fell cleanly into two nonoverlapping groups and classified patients with scores of 4 or less as having primary degenerative dementia and patients with scores of 7 or more as having MID. Subsequent studies with pathological verification have confirmed that the Ischemic Score can correctly classify more than 70% of MID patients and almost 90% of AD patients (Molsa, Paljarvi, Rinne,

Rinne, & Sako, 1985; Rosen, Terry, Fuld, Katzman, & Peck, 1980).

If an adequate history is not available to determine a patient's Ischemic Score, however, differentiation between AD and MID can be extremely difficult. Several studies have shown that a significantly greater proportion of MID than normal controls has increased white matter lucency in the cerebral hemispheres on CT scan, but up to 55% of AD patients also demonstrate increased lucency (Aharon-Peretz, Cummings, & Hill, 1988; Erkinjuntti, Ketonen, Sulkava, Sipponen, Vuorialho, & Iivanainen, 1987; Steingart et al., 1987). Cerebral grey matter blood flow (CBF) is decreased bilaterally in both MID and AD patients, but this decrement is more regional in MID patients and more diffuse in AD patients (Tachibana, Meyer, Kitagawa, Rogers, Okayasu, & Mortel, 1984; Yamaguchi, Meyer, Yamamoto, Sakai, & Shaw, 1980). Meyer and his colleagues (Meyer, Rogers, Judd, Mortel, & Sims, 1988) also found that, although reductions in CBF correlate with the severity of dementia in both MID and AD patients, cognition and CBF fluctuate longitudinally more in MID patients than in AD patients.

Behaviorally, MID and AD patients are primarily distinguishable by their speech and language impairments (Bayles & Kaszniak, 1987). Powell, Cummings, Hills, and Benson (1988) found that AD patients were worse than MID patients in linguistic features (i.e., information content of spontaneous speech and confrontation naming), whereas MID patients were worse than AD patients in mechanical aspects of speech (i.e., pitch, melody, articulation, and rate). A stepwise discriminant function analysis revealed that information content and speech melody were the most effective distinguishing characteristics and correctly classified about 90% of the patients as either MID or AD.

Because the Hachinski Ischemia Scale was directed primarily toward vascular dementia from one cause (i.e., medium or large vessel cortical infarcts), specific research criteria for the diagnosis of broadly defined vascular dementia were recently proposed by an international workgroup supported by the Neuroepidemiology Branch of the National Institute of Neurological Disorders and Stroke (NINDS) and the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (AIREN) (Roman et al., 1993; see Chui, Victoroff, Margolin, Jagust, Shankle, &

Katzman, 1992, for similar diagnostic criteria). These criteria are intended to encompass dementia from all vascular causes, including infarction, ischemia, and hemorrhagic brain lesions. The NINDS-AIREN criteria include diagnoses of probable, possible, and definite vascular dementia, as well as a subcategorization of the specific types of vascular lesions (as determined by clinical, radiological, and neuropathological features). As with the NINCDS-ADRDA criteria for AD, the diagnosis of definite vascular dementia requires histopathological evidence of cerebrovascular disease. In addition, this evidence must occur in the absence of neurofibrillary tangles and neuritic plaques exceeding those expected for age and without clinical evidence of any other disorder capable of producing dementia (e.g., Pick's disease, diffuse Lewy bodies, etc.). Note also that the NINDS-AIREN criteria specify that the term "Alzheimer's disease with cerebrovascular disease" should be used to classify patients who meet the NINCDS-ADRDA criteria for possible AD and who also show clinical and/or brain imaging evidence of relevant cerebrovascular disease.

Huntington's Disease

Huntington's disease (HD) is an inherited, autosomal dominant disorder with clinical onset in the fourth or fifth decades of life and with an average duration of 17 years (Bruyn, 1968; Folstein, 1989; Hayden, 1981). A rare form of juvenile HD has also been noted, whose onset is before the age of 20 and has a shorter duration of illness than the adult form (Hayden, 1981). The genetic determinant of HD has been identified as an unstable expansion of trinucleotide repeats (cytosine-adenine-guanine; CAG) in the IT15 gene located on chromosome 4 (Huntington's Disease Collaborative Research Group, 1993). The prevalence of HD is much lower than that of AD; it occurs in roughly thirty-seventy individuals per million of the population (Hayden, 1981). Neuropathologically, the disease is characterized primarily by a progressive degeneration of the neostriatum (caudate nucleus and putamen), a selective loss of the small spiny neurons, and a relative sparing of aspiny interneurons (Bruyn, Bots, & Dom, 1979; Vonsattel, Myers, Stevens, Ferrante, Bird, & Richardson, 1985).

The onset of HD often begins with subtle changes in personality such as increased irri-

tability and moodiness, as well as with complaints of incoordination and clumsiness (Folstein, 1989; Hayden, 1981). As the disease progresses, most patients develop severe chorea and dysarthria (Folstein, 1989; Hayden, 1981; Petit & Milbled, 1973) and a dementia characterized by a moderate memory disturbance, attentional dysfunction, problem solving deficits, visuoperceptual and constructional deficits, and a deficiency in performing arithmetic (Brandt & Butters, 1986; Butters, Sax, Montgomery, & Tarlow, 1978). In this stage of the disease, little or no aphasia is apparent, although patients may be dysarthric due to the motor dysfunction inherent in the disease. Some patients may also develop gait and oculomotor disturbances. In the later stages, patients with HD become impaired in most tests of cognitive and memory ability, but still retain relatively intact naming ability (Butters et al., 1978).

Parkinson's Disease

Idiopathic Parkinson's disease (PD) is a neurodegenerative disorder characterized neuropathologically by a loss of pigmented cells in the substantia nigra pars compacta (Jellinger, 1987) and behaviorally by the classic motor symptom triad of resting tremor, rigidity, and bradykinesia (Jankovic, 1987). Alzheimer-like changes in the cerebral cortex, basal forebrain, and locus coeruleus have also been reported (Cash, Dennis, L'Heureux, Raisman, Javoy-Agid, & Scatton, 1987; Gaspar & Gray, 1984; Hakim & Mathieson, 1979; Perry et al., 1985; Whitehouse, Hedreen, White, & Price, 1983). The prevalence ratio of PD in the United States is roughly 150 per 100,000 (Marttila, 1987). The mean age at onset is around 60 years, and the disease rarely occurs before age 40.

Although not included in James Parkinson's original description of the disorder, dementia has been found more frequently than would be expected in a general population of the same age. Estimates of the prevalence of dementia in PD have ranged from less than 10% to more than 80% (see Brown & Marsden, 1984, for a review). This wide disparity of estimates is most likely due to differences in both the patient sampling methods and in the criteria used to diagnose dementia. More recent studies have found a roughly 30% prevalence rate of dementia in PD (Mindham, Ahmed, & Clough, 1982; Stroka, Elizan, Yahr,

Burger, & Mendoza, 1981). Thus, unlike AD and HD, dementia is *not* always associated with the presence of PD.

Despite the general agreement that dementia can be associated with PD, there is still considerable controversy concerning the underlying nature of this dementia. First, consensus has yet to be reached on which, if any, specific cognitive deficits are invariably seen in all PD patients, regardless of the presence or absence of dementia. Although visuospatial deficits have commonly been reported in patients with PD, these findings may be related more to their motoric and set-shifting difficulties than to impaired visuospatial processing *per se* (Brown & Marsden, 1986; Stelmach, Philips, & Chau, 1989).

Stronger support is found for a fundamental impairment in attentional mechanisms in PD patients. Wright and his colleagues (Wright, Burns, Geffen, & Geffen, 1990) have suggested that PD patients may be impaired in maintaining attention due to an increased tendency to disengage from the current object of focus. Such an attentional deficit may be involved in PD patients' set-shifting difficulties. Flowers and Robertson (1985) found that PD patients' impairment in an Odd-Man-Out test were due to an inability to *maintain* a cognitive set, rather than to increased *perseverative* behavior. Furthermore, Mayeux, Stern, Sano, Cote, & Williams (1987) suggest that impairments in attention and vigilance may also underlie the bradyphrenia (i.e., a slowing of mental processing) that has been observed in PD patients (Wilson Kaszniak, Klawans, & Garron, 1980).

Although demented patients with PD do display more *pervasive* cognitive impairments than their nondemented counterparts, their most *severe* impairments are in the same cognitive domains that are also impaired in nondemented patients. In characterizing the nature of the dementia seen in PD, several investigators (Albert, 1978; Huber et al., 1986; Mayeux, Stern, Rosen, & Benson, 1981) have stressed the features (e.g., preserved language) that it shares with the dementia of HD and other subcortical dementias. In contrast, other investigators (Alvord, Forno, Kusske, Kauffman, Rhodes, & Goetowski, 1974; Boller, Mizutani, Roessmann, & Gambetti, 1980) suggested that the dementia of PD may result from superimposition of Alzheimer-type changes on the primary subcortical pathology. Most likely, both groups are right:

The dementia of PD may reflect the coexistence of both cortical and subcortical features within the same disease.

Dementia with Lewy Bodies. A number of investigators recently described a neuropathological condition in demented patients that is characterized by typical subcortical changes in the substantia nigra, locus coeruleus, and dorsal vagal nucleus of PD; the typical cortical distribution of senile plaques and neurofibrillary tangles of AD; and in addition, Lewy bodies that are diffusely distributed throughout the neocortex (Hansen et al., 1990; Kosaka, Yoshimura, Ikeda, & Budka, 1984; Dickson et al., 1987; Gibb, Esiri, & Lees, 1985; Perry, Irving, Blessed, Fairbairn, & Perry, 1990; Lennox, Lowe, Landon, Byrne, Mayer, & Godwin-Austen, 1989). This neuropathological condition, designated the Lewy body variant (LBV) of AD by Hansen and colleagues (1990), is not rare and may occur in approximately 25% of all demented patients. The condition has been reported under a number of different names (e.g., senile dementia of the Lewy body type, diffuse Lewy body disease), and recently the more inclusive designation of Dementia with Lewy Bodies (DLB) has been proposed.

The clinical manifestation of DLB is similar to that of AD in many respects, and these patients are often diagnosed with probable or possible AD during life. This is not surprising, given that DLB often initially produces insidious and progressive cognitive decline without other significant neurological abnormalities. Patients with DLB do not always present with memory impairment as the earliest and most prominent feature, but this aspect of cognition is often affected early in the disorder's course. As in AD, the cognitive deficits that occur in DLB are widespread and progressive and have a significant impact on the patient's ability to engage in the normal activities of daily living. Patients with DLB often manifest a pattern of cognitive deficits similar to that of AD, and disproportionately severe deficits occur in verbal fluency, attention, and visuospatial abilities (Salmon & Galasko, 1996).

Despite the similarities in the clinical presentations of the two disorders, retrospective studies indicate that DLB may be clinically distinguishable from AD. Hansen and colleagues (1990), for example, found that DLB patients differed from patients with "pure" AD in that a greater propor-

tion had mild Parkinsonian or extrapyramidal motor findings (e.g., bradykinesia, rigidity, masked facies, but without a resting tremor). McKeith and colleagues (McKeith, Perry, Fairbairn, Jabeen, & Perry, 1992) also found that patients with DLB were significantly more likely than "pure" AD patients to manifest extrapyramidal motor features at some point during the course of the disease, as well as an increased likelihood of fluctuating cognitive impairment, visual or auditory hallucinations, and unexplained falls. In another study, Galasko and colleagues (Galasko, Katzman, Salmon, Thal, & Hansen, 1996) compared clinical and neuropathological features in thirty-eight autopsy-confirmed DLB and thirty-eight autopsy-confirmed "pure" AD patients. Significantly more DLB patients than AD patients exhibited rigidity, bradykinesia, masked facies, and Parkinsonian gait, and a significantly greater percentage of DLB (32%) than AD (11%) patients reported visual hallucinations. These general findings led to the recent development of clinical criteria for diagnosing DLB (McKeith et al., 1996) that include dementia, spontaneous motor features of Parkinsonism, recurrent and well-formed visual hallucinations, and fluctuating cognition with pronounced variations in attention or alertness. Probable DLB is diagnosed if two of these three features are present; possible DLB if only one is present. A recent examination of the performance of these consensus guidelines against autopsy verification of DLB demonstrated 83% sensitivity and 92% specificity. This was comparable to the 78% sensitivity and 87% specificity for AD (using NINCDS-ADRDA criteria) that was obtained in the same study (Ince, Jaros, Ballard, McKeith, & Perry, in press).

Memory Impairments in Dementia

Memory impairment is one of the earliest and most prominent symptoms of dementia. In fact, the DSM-IV (1992) requires that an impairment in memory be evident before the diagnosis of dementia can be made. Given the large significance attached to memory functions in identifying demented patients, the rather primitive nature of most clinical memory tests is quite remarkable. Standardized memory tests have traditionally

been constructed without any underlying theoretical rationale and often yield only a single score. Such tests may be useful in identifying the presence of a memory deficit but are notoriously ineffective in characterizing the underlying nature of the impairment. In contrast, experimental neuropsychological studies designed within the theoretical paradigms of cognitive psychology have yielded substantial insights into the processes involved in the memory deficits of different dementing illnesses. In the light of these successes, newer standardized memory tests such as the California Verbal Learning Test (Delis, Kramer, Kalan, & Ober, 1987) and, to some degree, the Wechsler Memory Scale-Revised (WMS-R; Wechsler, 1987) have been designed in terms of current cognitive models of memory.

In the next section, experimental neuropsychological investigations into the processes that underlie the memory deficits of patients with different dementing illnesses will be reviewed. Although the vast majority of these studies has been concerned with dementia of the Alzheimer type, several studies allow direct comparisons between patients with AD and patients with more "subcortical" dementias such as HD. As will be seen, two patient groups that superficially display equivalent memory impairments according to a standardized test can in fact have strikingly different processing deficits underlying their impairments. When possible, an effort will be made to illustrate how currently available standardized memory tests can be used to identify these distinct processing deficits. To make the distinction between AD and HD patients more intelligible, we shall also compare these patients' memory impairments to those found in patients with circumscribed amnesic syndromes, particularly patients with alcoholic Korsakoff's syndrome (Butters & Cermak, 1980). This comparison is particularly useful because the impairments seen for some aspects of memory in AD patients are strikingly similar to those seen in alcoholic Korsakoff patients.

A Taxonomy of Memory

One of the major contributions of cognitive psychology to the neuropsychology of memory is the recognition that memory is not a single, homogeneous entity (Butters, 1984). Rather, memory seems to be comprised of several distinct yet mutually interacting systems and subsystems; each

differs either in the type of information stored, the processes acting on that information, or both. Investigations of memory in impaired patient populations have validated this viewpoint and also helped to identify the neuroanatomical structures of different memory systems (Figure 1). Based on these studies, neuropsychological models of memory have been developed that provide a powerful conceptual framework for the clinical assessment and classification of the distinctive patterns of memory impairment observed in different neuropsychiatric disorders.

Within the taxonomy of memory that has emerged from this research, a fundamental distinction has been made between explicit (or declarative) memory and implicit (or nondeclarative) memory (Graf & Schacter, 1985; Squire, 1987). Explicit memory requires the conscious recollection of information acquired during prior study episodes, whereas implicit memory represents an unconscious change in task performance that is attributable simply to exposure to information during a previous study episode (Schacter, 1987). Classic tests of explicit memory include recall or recognition of a previously presented paragraph or list of words that a subject was told to try to remember. In tests of implicit memory, in contrast, subjects are never asked to remember a previous episode but instead are simply asked to perform a particular task that could be influenced by prior exposure to information. For example, classical conditioning, motor skill learning, and priming (i.e., a phenomenon in which the presentation of a stimulus influences subsequent processing of either the same or a related stimulus) all involve implicit memory.

Studies of patients with circumscribed amnesic syndromes suggest that explicit and implicit memory are mediated by distinct neuroanatomical substrates. Amnesic patients, it has been found, exhibit profound impairments in tests of explicit memory, yet generally show normal performance in tests of implicit memory (Cohen & Squire, 1980; Gardner, Boller, Moreines, & Butters, 1973; Graf, Squire, & Mandler, 1984; Warrington & Weiskrantz, 1970). These studies indicate that explicit, but not implicit, memory depends critically on the medial temporal and diencephalic brain regions that are damaged in amnesia. Implicit memory, in contrast, does not depend on a single neuroanatomical system. Rather, implicit memory reflects changes within the specific processing

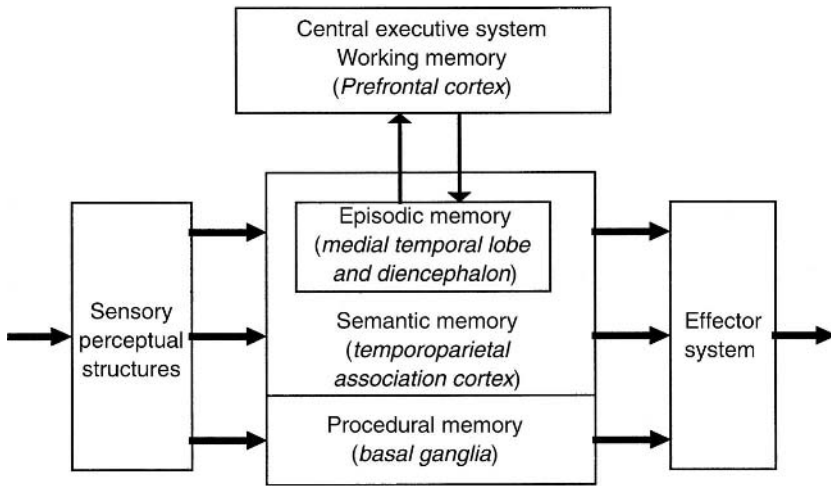

Figure 1. A schematic diagram showing the different forms of memory and their proposed neural substrates that are affected in various dementing disorders.

structures that are involved in performing different tasks. For example, skill learning may depend critically on a corticostriatal system involved in programming motor sequences, classical conditioning may involve changes within the cerebellum, and verbal priming may depend on the temporary activation of semantic representations stored in neocortical associative areas.

Explicit memory can be further subdivided into short-term or working memory, episodic memory, and semantic memory. Working memory (Baddeley, 1986) is viewed as a limited capacity system in which information is quickly (i.e., within 20 to 30 seconds) lost unless continuously rehearsed. With rehearsal, however, information can be maintained in working memory indefinitely. The capacities of patients' working memories are most frequently assessed using a digit span task in which subjects are asked to recall progressively longer sequences of numbers. Normal subjects can retain between five and nine digits in working memory with continual rehearsal (Miller, 1956). In contrast, long-term memory can essentially be considered virtually unlimited in capacity and can store experiences, factual knowledge, and skills over an entire lifetime (Klatzky, 1980).

Working memory can be thought of as the information that one is immediately attending to, or "working" on, and impairments in working memory capacity have been associated with underlying

deficits in attentional processes. The working memory model postulates a primary central executive system that is aided by two subsidiary buffer systems: a visuospatial scratch pad, responsible for holding visuospatial information and a phonological loop, responsible for holding speech-based information (such as the series of digits in the digit span test). The working memory system (in particular the central executive system) is critically responsible for the planning, organization, and other strategic aspects of memory that facilitate both encoding and retrieving information in long-term memory. Although the anatomical substrates of working memory are not fully known, recent evidence suggests that the frontal associative cortices are important for the normal functioning of this aspect of memory.

Episodic memory encompasses memories for personal experiences and events that depend on temporal and/or spatial cues to retrieve them (Tulving, 1983). For example, remembering what you had for breakfast this morning or when you last saw a physician would require retrieval from episodic memory. Most of the traditional verbal learning and memory techniques (e.g., list learning, paired-associate learning) used in cognitive psychology involve retrieval from episodic memory. For instance, when subjects are given a list of words and later asked to recall them, they must retrieve the words from a specific temporal (one

minute previously) and spatial (same examining room) context. Recalling any list of words encountered during their lifetimes would not be appropriate or correct.

Semantic memory, on the other hand, refers to memories of generic facts that are completely independent of contextual cues for retrieving them (Tulving, 1983). Knowledge of the meanings of words, the ability to name common objects, or to recollect well-known geographical, historical, and arithmetical facts are examples of semantic memory. In each case, the specific information can be retrieved without recalling the particular episode in which that information was acquired. It has been proposed that semantic information exists as a representation of knowledge based on an organized network of interrelated categories, concepts, and attributes.

As with the distinction between explicit and implicit memory, episodic and semantic memory can be neurobiologically and neuropsychologically distinguished by the differential impairment of these two forms of memory in patients with circumscribed amnesia. Patients with neurologically based amnesic syndromes are especially impaired in their attempts to acquire new episodic information (i.e., anterograde amnesia), whereas their semantic memory is relatively intact (for a review, see Squire, 1987). For instance, amnesic patients who cannot remember their physician's names for more than a few seconds or minutes usually retain knowledge of arithmetical, geographical, and historical facts. This pattern of spared and impaired abilities is consistent with the notion that episodic memory, but not semantic memory, critically depends on the medial temporal lobe and diencephalic structures that are damaged in amnesic patients. Semantic memory, in contrast, is likely to be mediated by the associative cortices in the temporal, frontal, and parietal lobes that are intact in patients with circumscribed amnesia.

The ability to remember autobiographical information from the distant past (i.e., remote memory) does not neatly fit into the episodic-semantic distinction but probably relies on both types of memory. Retrograde amnesia (i.e., a deficit in recalling information that was acquired before the onset of a memory deficit) is a common component of the amnesic syndrome, and in many cases, it is temporally graded with information from the distant past that is better recalled than information from the

more recent past (Butters & Cermak, 1980). One explanation for this temporal gradient is that information from the very remote past has passed from episodic to semantic memory, whereas events from the recent past remain in episodic memory (Butters & Cermak, 1986; Cermak, 1984). The elegance of this explanation is that it allows ready application of the episodic-semantic model to both of the major features (anterograde and retrograde amnesia) of the amnesic syndrome.

Working Memory

A number of recent studies indicate that damage to the prefrontal cortex can produce working memory impairments that are distinguishable from the episodic memory deficits classically observed following medial temporal lobe damage (Shimamura, Janowsky, & Squire, 1990). Patients with circumscribed amnesia are characterized by an inability to acquire and retain new episodic information; patients with frontal lobe damage can store new episodic information normally but have difficulty manipulating both new and old episodic memories in a strategic manner. Thus, like amnesics, frontal patients are impaired in free recall tests of memory for items previously presented. However, unlike amnesics, they can actually perform normally when tested by using a recognition memory format that places minimal demands on retrieval processes. Moreover, frontal patients display selective impairments in other strategic aspects of memory such as the ability to remember the temporal order in which items were previously presented, to make metamemory judgments about their ability to successfully identify items on a subsequent recognition test, and to remember where and when items were actually presented to them.

Despite their severe learning impairments, alcoholic Korsakoff patients demonstrate normal digit span performance (Butters & Cermak, 1980). Patients with AD have also exhibited normal digit span performance in some studies (Huber et al., 1986), but not in all (Kaszniak, Garron, & Fox, 1979; Kopelman, 1985). These discrepancies probably reflect differences in the severity of dementia of the AD patient groups used in the various studies (Berg et al., 1984). In contrast, digit span performance has been consistently impaired in all but the very earliest stages of HD (Butters et al., 1978; Caine, Ebert, & Weingartner, 1977), sug-

gesting that unlike patients with Korsakoff syndrome or AD, these patients suffer early deficits in working memory.

Studies using the revised version of the WMS-R further document the usefulness of attentional or working memory measures for differentiating AD from HD patients in both the early and middle stages of the diseases (Butters et al., 1988; Troster, Jacobs, Butters, Cullum, & Salmon, 1989). The WMS-R includes an Attention/Concentration Index that is derived from performance on tests of digit span (forward and backward), visual memory span (forward and backward), and mental control. Butters and colleagues (Butters et al., 1988; Troster et al., 1989) showed that mildly demented patients with AD earned near-normal scores on the Attention/Concentration Index, whereas equally demented patients with HD were impaired and performed significantly more poorly than the AD patients. As the disease progressed, Attention/Concentration scores declined in both groups, but HD patients continued to perform more poorly than their counterparts with AD (Troster et al., 1989). Similar clinical differentiation between AD and HD patients has been observed with the attention items of both the Mini-Mental State Exam (MMSE; Brandt et al., 1988; Folstein, Folstein, & McHugh, 1975) and the Dementia Rating Scale (DRS; Mattis, 1976; Salmon et al., 1989). The particularly severe attentional deficits exhibited by patients with HD are not surprising, given the extensive damage that the disease produces to frontostriatal circuits (for a review, see Cummings, 1990).

Although not as severe as in patients with HD, patients with AD do display progressive impairment to different components of working memory as the severity of the disease increases (Collette, Van der Linden, Bechet, & Salmon, 1999). Mildly demented AD patients primarily suffer disruption to the central executive along with relative sparing of the intact phonological loop. This results in a relatively intact span (i.e., working memory capacity) in the face of increased sensitivity to distraction. More severely demented patients, in contrast, have an additional impairment of the phonological loop itself which results in a diminished span and an actual decrease in working memory capacity.

Although alcoholic Korsakoff patients demonstrate normal working memory capacity when they are allowed to maintain information through rehearsal, their performance deteriorates rapidly if

even a few seconds of distractor activity intervenes between presentation and recall (i.e., the Brown-Peterson paradigm; Peterson & Peterson, 1959). For example, if Korsakoff patients are presented with three words (e.g., apple, bird, roof), and then are required to count backward from 100 by threes to prevent rehearsal (a distractor task), they will be impaired in recalling the three words after only 9 or 18 seconds of such counting activity (Butters & Cermak, 1980). Similar increased sensitivity to distraction has also been observed in patients with AD (Kopelman, 1985), HD (Butters et al., 1978; Caine et al., 1977), and PD (Tweedy, Langer, & McDowell, 1982).

Episodic Memory

The earliest demonstrations of selective impairment of only certain aspects of memory were provided by studies of episodic memory in patients with amnesia that arose from damage to the medial temporal lobe and related diencephalic brain structures. Despite preserved general intelligence, relatively normal performance in other cognitive domains, and intact semantic knowledge, these patients exhibit a strikingly severe inability to acquire new verbal and nonverbal episodic information (i.e., anterograde amnesia). Such long-term episodic memory deficits are exemplified experimentally by the poor performance these patients display in list learning tasks, paragraph recall tests, and tests of verbal paired-associate learning (for a review, see Squire, 1987).

Over the years, numerous studies with amnesic patients confirmed that acquiring and retaining episodic memories depend critically on the medial temporal lobe and midline diencephalic regions that are damaged in these patients (Squire, 1987). Although the actual episodic memory representations, it is thought, are stored within the neocortex, the medial temporal lobe system is responsible for consolidating the episodic memories within the neocortex by gradually binding together the multiple cortical regions that, together, store the memory for a particular event. This binding or integration is achieved through the reciprocal pathways that connect the hippocampus, via the entorhinal cortex, to the neocortex.

Experimental and clinical neuropsychological studies of memory in patients with various dementing disorders indicate that episodic memory impairment is also a ubiquitous feature of dementia.

However, the processes that underlie the episodic memory impairment associated with the various dementing disorders is quite variable and depends on the etiology and neuropathology of the particular disorder. In one of the first studies to directly compare the episodic memory deficit engendered by different amnesic and dementing disorders, Delis and colleagues examined the performance of patients with alcoholic Korsakoff syndrome, AD, and HD in a rigorous list-learning task, the California Verbal Learning Test (CVLT; Delis et al., 1987; Delis, Massman, Butters, Salmon, Cermak, & Kramer, 1991).

The CVLT is a standardized memory test that was developed to assess a variety of memory processes identified through cognitive psychological studies of normal memory. The CVLT assesses the rate of learning, retention after short- and long-delay intervals, semantic encoding ability, recognition (i.e., discriminability), intrusion and perseverative errors, and response biases. In the test, subjects are given five presentations/free recall trials for a list (List A) of sixteen items (four items in each of four semantic categories) and then are given a single interference trial using a second, different list (List B) of sixteen items. Immediately after the List B trial, subjects are given a free-recall and then a cued-recall (using the names of the four categories) test for the items on the initial list (List A). Twenty minutes later, the free-recall and cued-recall tests are repeated for List A, followed by a yes-no recognition test consisting of the sixteen List A items and twenty-eight randomly interspersed distractor items.

The results of the study by Delis and Colleagues (1991) showed that patients with AD, HD, and Korsakoff's syndrome were similarly impaired (compared to age- and gender-corrected normative data) on most measures from the CVLT, including the number of items recalled on the first and the fifth recall trials, the rate of learning across the five initial trials, and the number of items recalled on the free and cued long-delay recall trials. The groups did differ, however, in several crucial aspects of their performance.

One major difference was that patients with AD and Korsakoff's syndrome were just as impaired in the recognition discriminability trial as they were in the immediate and delayed-recall trials of the CVLT, whereas patients with HD were less impaired in the recognition discriminability trial than in the various recall trials. Furthermore, the

HD patients were significantly less impaired in the recognition discriminability trial than the AD and KS patients. Delis and colleagues viewed this result as evidence that the episodic memory impairments exhibited by patients with AD and HD may reflect different underlying deficits. The significant improvement shown by the HD patients when memory was tested with a recognition procedure rather than with a free-recall procedure suggests that deficient retrieval mechanisms may contribute significantly to their memory impairment (but see Brandt, Corwin, & Krafft, 1992). When the need for effortful retrieval was reduced by using a recognition format, the HD patients' memory impairment was somewhat ameliorated (also see Butters, Wolfe, Martone, Granholm, & Cermak, 1985). On the other hand, the failure of a recognition format to reduce the degree of episodic memory impairment exhibited by the AD and Korsakoff's syndrome patients suggests that these patients have a defect at the level of consolidation or storage (Butters, 1984; Delis et al., 1991; Martin, Brouwers, Cox, & Fedio, 1985). Regardless of the degree of retrieval support provided by the task, patients with AD and Korsakoff's syndrome could not effectively recall or recognize the items from the CVLT.

Further evidence that the episodic memory deficit of the AD patients reflects ineffective consolidation (or storage) was provided by the second major finding from the study by Delis and colleagues (1991). Patients with AD and Korsakoff's syndrome forgot information significantly faster during the 20-minute delay interval than the patients with HD. This difference was evident when savings scores were calculated that took into account the amount of information initially acquired (trial 5 List A recall) and the amount retained after the delay (long-delay, free-recall trial). Patients with HD retained approximately 72% of the initially acquired information during the delay interval, but patients with AD and Korsakoff's syndrome retained only 17 and 15%, respectively (see Figure 2).

A number of recent studies have shown that indexes of rapid forgetting have important clinical utility for early detection and differential diagnosis of AD (e.g., Butters et al., 1988; Locascio, Growdon, & Corkin, 1995; Welsh, Butters, Hughes, Mohs, & Heyman, 1991; but see Robinson-Whelan & Storandt, 1992). Welsh and colleagues (Welsh

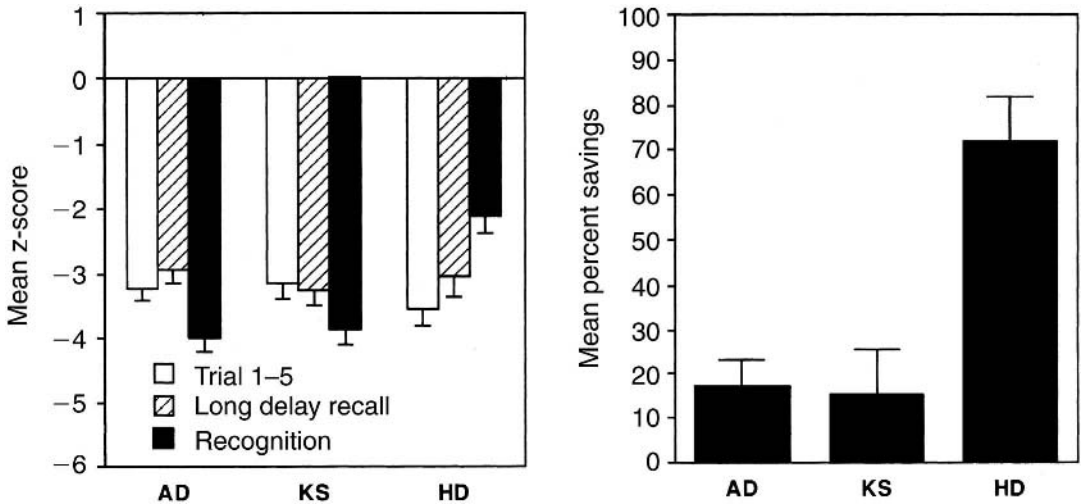

Figure 2. The mean z-scores achieved by patients with Alzheimer's disease (AD), amnesia due to Korsakoff's syndrome (KS), and Huntington's disease (HD) in key measures from the California Verbal Learning Test (left panel). The mean percentage of information retained over the 20-minute delay interval by each patient group is also shown (right panel). Adapted from Delis et al., 1991.

et al., 1991), for example, found that the amount of information recalled after a 10-minute delay differentiated very early AD patients from healthy elderly controls with better than 90% accuracy. This measure was superior in this regard to a number of other verbal memory measures such as immediate recall on each of three learning trials, recognition memory, and the number of intrusion errors produced throughout the test. A savings score (i.e., amount recalled after the delay divided by the amount recalled on the third learning trial) was the only measure that approached delayed recall in discriminative power, and it may have been less effective because analyses of savings were restricted to individuals who successfully learned two or more words by the third learning trial, thus eliminating the most severely amnesic individuals.

Butters and colleagues (1988) similarly found that delayed-recall scores and savings scores on the Logical Memory and Visual Reproduction tests of the WMS-R effectively differentiated between mildly demented patients with AD and normal elderly individuals. Furthermore, patients with AD had significantly lower scores on these measures than patients with HD who were similar in overall level of dementia. Thus, the patients with AD forgot verbal and figural materials more

quickly than the HD patients. Troster and colleagues (1993) examined the sensitivity and specificity of these savings scores for differentiating among AD patients, HD patients, and their respective age-matched normal control groups. Discriminant function analyses (DFAs) using Logical Memory and Visual Reproduction savings scores produced satisfactory to excellent overall classification accuracy with 94% of AD patients versus elderly control subjects correctly classified, 81% of HD patients versus middle-aged control subjects correctly classified, and 82% of AD patients versus HD patients correctly classified.

The particularly severe episodic memory deficit exhibited by patients with AD is not surprising, given the extensive evidence suggesting that neuropathological changes in the hippocampus and entorhinal cortex are the first and most severe to occur in the disease (Braak & Braak, 1991; Hyman, Van Hoesen, Damasio, & Barnes, 1984). Both human and animal studies have shown that these medial temporal lobe brain structures are critical for acquiring and retaining new information (for a review, see Squire, 1992), and a number of recent studies using magnetic resonance imaging (MRI) have confirmed a relationship between the degree of structural abnormality in these structures and the severity of episodic memory impair-

ment in patients with AD (Cahn et al., 1998; De-weer et al., 1995; Fama et al., 1997; Kohler et al., 1998; Pantel et al., 1997; Scheltens et al., 1992; Stout, Bondi, Jernigan, Archibald, Delis, & Salmon, 1999; Stout, Jernigan, Archibald, & Salmon, 1996; Wilson, Sullivan, deToledo-Morrell, Stebbins, Bennet, & Morrell, 1996).

Another prominent feature of the performance of patients with AD on episodic memory tests is the frequent occurrence of intrusion errors (i.e., when previously learned information is produced during the attempt to recall new material; Delis et al., 1991; Fuld, 1983; Fuld, Katzman, Davies, & Terry, 1982). Butters and colleagues, for example, found that when patients with AD were asked to recall a series of four short stories, facts from the first story intruded into their attempts to recall the second, third, and fourth stories (Butters, Granholm, Salmon, Grant, & Wolfe, 1987). In subsequent studies, Delis and colleagues found that patients with AD and amnesic patients with Korsakoff's syndrome produced significantly more intrusion errors than patients with HD in the various components of the CVLT (Delis et al., 1991). For example, nearly 70% of the total responses in the cued-recall condition were intrusion errors for both the AD and amnesic patient groups, whereas only 20% were intrusion errors for the HD group. Jacobs and colleagues (Jacobs, Troster, Butters, Salmon, & Cermak, 1990; Jacobs, Salmon, Troster, & Butters, 1990) obtained similar results when they compared the intrusion errors produced by patients with AD and patients with HD in the Visual Reproduction test from the WMS or WMS-R. Like normal control subjects, patients with HD only occasionally intruded components of a prior figure into their drawing of a subsequent figure. Patients with AD were much more likely to make these intrusion errors and produced significantly more than HD patients or normal control subjects.

Patients with AD and HD also exhibit strikingly different patterns of performance in memory tasks that employ an encoding specificity paradigm (Thomson & Tulving, 1970). In a study by Granholm and Butters (1988), patients with AD, like patients with alcoholic Korsakoff's syndrome (Cermak, Uhly, & Reale, 1980), performed better in a cued-recall task when strongly-related cues were present at retrieval, regardless of whether the same cue was present at encoding, than when a weakly related cue was present at both encoding and retrieval. This result indicates that patients

with AD are impaired in their ability to encode the semantic relationship between the two words during the study phase or cannot use the product of encoding at the time of retrieval. Patients with HD, in contrast, performed like control subjects (although their memory performance was impaired overall) by exhibiting better performance when the cue was identical during encoding and retrieval, regardless of the strength of its relationship to the target word, than when the cues differed at study and test. This result suggests that patients with HD could successfully encode the relationship between the cue and target words, but were generally impaired on the memory tasks due to an inability to initiate systematic retrieval strategies.

Although the studies described before indicate that different processing deficits underlie the episodic memory impairments of patients with AD, a "cortical" dementia, and patients with HD, a "subcortical" dementia, additional evidence indicates that not all so-called "subcortical" dementing disorders produce identical episodic memory deficits. Massman and colleagues (Massman, Delis, Butters, Leaven, & Salmon, 1990) directly compared the performance of PD and HD patients on the CVLT. Although these two groups performed similarly on many of the variables that distinguished HD from alcoholic Korsakoff's syndrome and AD patients (i.e., retention of information over delay periods, intrusion rates, and delayed recognition ability), there were also marked differences between the two groups. Specifically, the HD patients demonstrated a slower rate of acquisition, a larger regency effect, a higher preservation rate, and poorer free- and cued-recall performance than patients with PD. These differences between HD and PD patients suggest that somewhat different processing deficits may mediate the episodic memory impairments of these two patient groups and attests to the deficiencies of the cortical-subcortical distinction, even when it is used for heuristic purposes.

Semantic Memory

The studies described in the previous section indicate that the episodic memory capabilities of alcoholic Korsakoff patients are strikingly similar to those of AD patients, but quite different from those of patients with HD. The situation is somewhat reversed for semantic memory. Of the three patient groups, only patients with AD have a

marked disruption in the organization of semantic memory. In contrast, the performance of alcoholic Korsakoff and HD patients both reflect the superimposition of other cognitive deficits on an otherwise relatively intact semantic memory network.

The presence of an intact semantic memory in alcoholic Korsakoff patients is evidenced by their preserved ability to remember the meaning of words, the rules of syntax, and basic arithmetic skills (Kinsbourne & Wood, 1975), as well as by their normal performance in tests of verbal fluency. Weingartner and his colleagues (Weingartner, Grafman, Boutelle, Kaye, & Martin, 1983) demonstrated that, despite equivalent and severe episodic memory deficits, only patients with progressive degenerative dementia (presumably AD), *not* alcoholic Korsakoff patients, were impaired relative to normal controls in several tests of semantic memory, including verbal fluency. These results suggest that the demented patients possess an impairment in accessing knowledge in semantic memory that is not present in Korsakoff patients. Impaired verbal fluency has also been observed in both early and advanced HD patients (Butters et al., 1978, 1987), but the relatively normal confrontation naming ability of these patients suggests that their fluency deficit is not due to a general language dysfunction. Rather, the fluency deficit of patients with HD reflects their difficulty in retrieving information from long-term memory.

Butters et al. (1987) directly compared the performance of patients with alcoholic Korsakoff's syndrome, AD, and HD in letter and category verbal fluency tasks. In the letter fluency task (Benton, 1968; Borkowski, Benton, & Spreen, 1967), subjects were asked to generate orally as many words as possible that begin with the letters "F," "A," or "S." Subjects were allowed 60 seconds for each letter. In the category fluency task, subjects were allowed 60 seconds to generate orally as many animals as possible.

The HD patients were severely impaired in both the letter and category fluency tasks and produced fewer correct responses than any other subject group. The alcoholic Korsakoff's syndrome patients showed a mild-to-moderate impairment in both fluency tasks, and like the patients with HD, the severity of their fluency deficit was not related to the linguistic constraints (i.e., letter vs. category fluency) of the semantic memory task. The performance of the patients with AD, in contrast, was directly related to the linguistic demands of the

two fluency tests: AD patients performed normally in the letter fluency task but were severely impaired in the category fluency task.

Similar results were reported by Monsch and colleagues (Monsch et al., 1994) when comparing larger groups of AD and HD patients than in the study by Butters and colleagues (Butters et al., 1987). When the performances of the patient groups were expressed as fluency scores normalized to their respective normal control group scores, patients with AD were impaired in both tasks but demonstrated much greater impairment in the category fluency task than in the letter fluency task. Patients with HD, in contrast, were severely and equally impaired in both fluency tasks (see Figure 3).

The results of these studies support the notion that qualitatively different processes underlie the verbal fluency deficits of AD and HD patients. The greater impairment exhibited by patients with AD in the category than in the letter fluency tasks is consistent with the notion that they suffer a loss or breakdown in organizing semantic memory, rather than a general inability to retrieve or access semantic knowledge. Normal individuals can use their knowledge of the attributes, exemplars, and organization that define a particular semantic category to generate words efficiently from a small and highly related set of exemplars. The letter fluency task does not place great demands on the organization of semantic memory because it can be performed by using phonemic cues to search a very extensive set of appropriate exemplars within the lexicon. Therefore, a loss of semantic knowledge or a breakdown in the organization of semantic memory impacts performance in this task less than performance in the category fluency task. The fact that patients with AD are more impaired in the fluency task that places greater demands on the integrity of semantic memory suggests that they have deficient semantic knowledge.

Patients with HD, on the other hand, were equally impaired in the letter and category fluency tasks which suggests that their impairment reflects a general retrieval deficit rather than semantic memory dysfunction (Butters et al., 1985; Caine et al., 1978). Regardless of the demands that the fluency task placed on the semantic network, these patients had difficulty in retrieving successfully stored information. This interpretation is consistent with the general retrieval deficit that, it was postulated, underlies the impairment in episodic

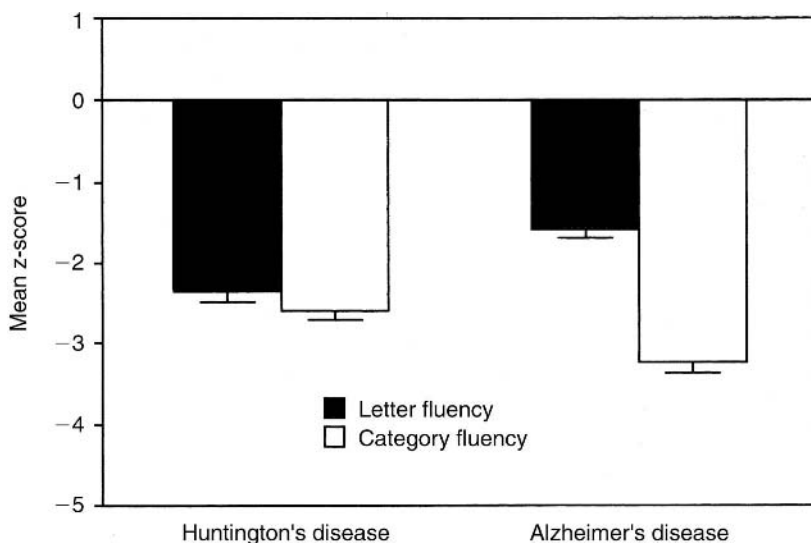

Figure 3. The mean z-scores of patients with Alzheimer's disease and Huntington's disease in the letter and category verbal fluency tasks. Patients with Alzheimer's disease were significantly more impaired in the category than in the letter fluency task, whereas patients with Huntington's disease were equally impaired in both tasks. Adapted from Monsch et al., 1994.

memory exhibited by patients with HD in recall and recognition memory tests (Butters et al., 1985, 1986; Delis et al., 1991).

Further evidence for a deterioration of the semantic network in patients with AD was provided by a recent study that examined the temporal dynamics of retrieval from semantic memory during verbal fluency tasks (Rohrer, Wixted, Salmon, & Butters, 1995). This study employed a mathematical model of exponential decline in retrieval from semantic memory as a function of time. The model assumed that the retrieval cue provided during the fluency task (e.g., farm animals) delimits a mental search set that contains the relevant exemplars (e.g., cow, horse, pig, etc.). According to well-known random search models (McGill, 1963), the exemplars are randomly sampled one at a time, at a constant rate, and each item has the same probability of being sampled. Each sampled exemplar is recognized as either a not-yet-sampled item (and reported) or as a previously-sampled item (and not reported). As the number of not-yet-sampled items decreases, the number of items retrieved correspondingly declines throughout the recall period and produces the exponential function. Thus, mean response latency (the average of the time intervals between the production of each response

and the onset of the recall period) increases when either the size of the search set increases or the duration of each sampling increases.

When applied to the verbal fluency performance of patients with AD, the measure of mean latency provides a direct test of the two proposed mechanisms of semantic memory deficits in these patients. If the set size for a particular semantic category is reduced in AD patients due to a loss of semantic knowledge, mean latency should *decrease* and be lower than normal. On the other hand, if the semantic set size remains intact but retrieval is slowed, mean latency should *increase* and be higher than normal. The results of this study showed that the mean response latency of patients with AD was significantly lower than that of the control subjects in the semantic category fluency task, but not in the letter fluency task. These results are consistent with the view that patients with AD suffer a true loss of semantic knowledge.

A subsequent study (Rohrer, Salmon, Wixted, & Paulsen, 1999) compared the mean response latencies of patients with HD in the semantic category fluency task to those produced by patients with AD in the previous study. The results revealed an opposite pattern of performance in the

two groups. Patients with HD exhibited a higher than normal mean response latency which is consistent with the view that the disease results in disrupting retrieval processes. As mentioned earlier, patients with AD exhibited a lower than normal mean latency consistent with a loss of semantic knowledge.

An examination of the qualitative nature of AD patients' performance in both an object naming and supermarket fluency test (Martin & Fedio, 1983) provide further support for the notion that these patients' verbal fluency deficits result from a disruption of the hierarchical organization of semantic memory. The supermarket fluency test is a component of the DRS and requires the subject to orally generate in 60 seconds as many items as possible that could be found in a supermarket. Martin and Fedio (1983) found that, despite normal performance on the Vocabulary and Similarities subtests of the WAIS-R, moderately demented AD patients were impaired both in the number of items correctly identified in the naming task and in the total number of words produced in the supermarket fluency task. In addition, the impairment in these two tasks were highly correlated with each other ($r = .80$).

Of more interest were the *types* of responses of AD patients in the naming and fluency tests. The AD patients' errors in the object naming task were primarily language-related rather than perceptual. A similar result was subsequently reported by Hodges and colleagues (Hodges, Salmon, & Butters, 1991) who found that patients with AD produced primarily semantically based errors (e.g., superordinate errors such as calling a "camel" an "animal") in an object naming task (also see, Huff, Corkin, & Growdon, 1986), whereas patients with HD tended predominantly to make perceptual errors (e.g., calling a "pretzel" a "snake"). In the supermarket fluency task, the AD patients produced significantly fewer specific items (e.g., "bananas") per general category (e.g., "fruits"), as well as a significantly larger ratio of category names to total words produced than normal control subjects.

These findings have been interpreted as reflecting a disruption in the organization of AD patients' semantic knowledge that is best characterized as a loss of specific attributes along with a relative preservation of general categories (Martin, 1987; Martin & Fedio, 1983), that is, if verbal representations of objects and categories are orga-

nized hierarchically with the most general aspects at the top and with more specific physical and functional features at the bottom, then the AD patients demonstrate a progressive *bottom-up* deterioration of the semantic network. Thus, AD patients may experience a loss of the defining attributes and exemplars of objects and categories but still retain general features and categories.

Troster and his colleagues (Troster, Salmon, McCullough, & Butters, 1989) extended the findings of Martin and Fedio (1983) by comparing the supermarket fluency performances of mildly and moderately demented patients with AD and HD. As expected, the moderately demented AD patients demonstrated a marked reduction in the number of specific exemplars generated per category and in addition, produced an increased percentage of category labels. The qualitatively similar (although less severe) pattern of performance that was also observed in the mildly demented patients with AD indicated that semantic knowledge is disrupted, even in the very early stages of the disease.

Surprisingly, the HD patients also exhibited a reduction in the number of exemplars generated per category that was similar to that of the mild AD patients, and this reduction worsened as the severity of the dementia increased (Troster et al., 1989). These results suggested that, in addition to their retrieval deficits, patients with HD may experience some disruption of the structure of semantic memory. A similar pattern of performance was observed in demented patients with PD (Troster, Heindel, Salmon, & Butters, 1989), that is, demented, but not nondemented, PD patients demonstrated both a decrease in the total number of words produced and in the number of exemplars per category label in the supermarket fluency test. Again, these results, along with those that demonstrated mild category naming impairments in patients with PD (Bayles & Tomoeda, 1983), indicate that these patients may also possess some semantic memory dysfunction.

Additional evidence for differences in the semantic memory deficits associated with various dementing disorders comes from a series of studies that addressed the issue within the framework of current cognitive psychological models of semantic memory (e.g., Collins & Loftus, 1975) that propose that our representations of knowledge are organized as a network of interrelated categories, concepts, and attributes (for a review, see

Salmon & Chan, 1994). In several recent studies, Chan and colleagues (Chan, Butters, Paulsen, Salmon, Swenson, & Maloney, 1993; Chan, Butters, Salmon, Johnson, Paulsen, & Swenson, 1995; Chan, Butters, Salmon, & McGuire, 1993) attempted to model the organization of semantic memory in AD and HD patients by using clustering and multidimensional scaling techniques (Romney, Shepard, & Nerlove, 1972; Shepard, Romney, & Nerlove, 1972; Tversky & Hutchinson, 1986). Multidimensional scaling provides a method for generating a spatial representation of the degree of association between concepts in semantic memory. The spatial representation, or cognitive map, generated in this manner clusters concepts along one or more dimensions according to their proximity, or degree of relatedness, in the patient's semantic network. The distance between concepts in the cognitive map reflects the strength of their association.

One study in this series compared the cognitive maps of AD, HD, and age-matched normal control subjects. The strength of association between concepts, or their proximity, was estimated using a triadic comparison task in which subjects chose, from among three concepts (i.e., among three animals), the two that are most alike. Every possible combination of three animals, from a total sample of twelve animals, was presented. This procedure produced a proximity score reflecting the strength of association for each pair of animals in relation to all other animal names, that is, how often those two animals were chosen as most alike. The proximity data derived in this manner for the three subject groups were subjected to multidimensional scaling analysis.

The results of this study showed that, although the semantic networks of both the AD and elderly control subjects generated in this analysis were best represented by three dimensions (domesticity, predation, and size), they differed significantly in a number of ways. First, AD patients focused primarily on concrete perceptual information (i.e., size) in categorizing animals, whereas control subjects stressed abstract conceptual knowledge (i.e., domesticity). Second, a number of animals that were highly associated and clustered together for control subjects were not strongly associated for patients with AD. Third, AD patients were less consistent than control subjects in using the various attributes of animals in categorization.

In contrast to the AD patients, the semantic networks of HD patients and their age-matched control subjects were best represented by two dimensions (domesticity and size). The cognitive maps of these two groups were virtually identical, and domesticity for both groups was the most salient dimension for categorizing animals. Furthermore, HD patients and their controls did not differ in the importance applied to the various dimensions or in their reliance on a particular dimension for categorization.

The results from these multidimensional scaling studies are consistent with the notion that AD patients suffer a breakdown in the structure and organization of semantic memory. Because of this semantic deterioration, AD patients tend to rely heavily on a concrete perceptual dimension (i.e., size) in categorizing animals rather than the more semantically demanding abstract conceptual dimension (i.e., domesticity) used by control subjects and patients with HD.

Converging evidence from studies of brain-damaged patients (e.g., McCarthy & Warrington, 1988; Warrington & McCarthy, 1987; Warrington & Shallice, 1984) and functional imaging in normal individuals (e.g., Demonet et al., 1992; Martin, Haxby, Lalonde, Wiggs, & Ungerleider, 1995; Martin, Wiggs, Ungerleider, & Haxby, 1996; Tulving, Markowitsch, Kapur, Habib, & Houle, 1994) suggests that semantic memory is mediated to a large extent by associative areas of the lateral and inferior temporal lobe cortex. These cortical regions are prominent sites of the neuropathological changes associated with AD (Terry & Katzman, 1983a,b). As the pathology of AD progressively spreads throughout the temporal lobe associative cortices, it is likely that the concepts and associations that comprise the semantic network gradually deteriorate and semantic knowledge is lost.

Consistent with this notion, several studies have provided evidence that semantic memory is actually lost relatively early in the course of AD and that this loss of semantic knowledge worsens as the disease progresses. Chertkow and Bub (1990), for example, found that patients with AD were significantly impaired in a wide variety of measures of semantic memory, regardless of the method of access or output required by the task, and showed remarkable item-to-item consistency across tasks. These investigators administered a picture naming test and a word-to-picture matching test, each comprised of the same 150 pictorial

stimuli, to patients with AD who were carefully screened to ensure that they had no visual perceptual deficits. In the matching test, subjects were shown each target with four distractor pictures from the same semantic category and were asked to point to the picture that corresponded to the verbal label. Alzheimer's disease patients were markedly impaired in the naming test (correctly identified only 72% of the pictures) and failed to derive any additional benefit in this test from semantic cueing (i.e., only 13% of the unnamed pictures were correctly named after presentation of the semantic cue). The patients with AD were also significantly impaired in the matching test, and showed remarkable consistency between the items failed in the matching test and the picture naming test, that is, 85% of the items correctly identified in the matching test were also correctly named, whereas only 21% of items incorrectly identified in the matching test were named correctly. Hodges and colleagues reported similar item-to-item consistency in the performance of patients with AD across various semantic memory tasks (Hodges, Salmon, & Butters, 1992).

The progressive loss of semantic knowledge by patients with AD has been demonstrated in several recent longitudinal studies. For example, when Chan, Butters, and Salmon (1997) examined the degree of deterioration of the semantic networks of patients with AD across time, they found that the semantic network for "animals" became more and more distorted as the disease progressed and that the patients focused less and less on the abstract dimension of domesticity when classifying animals. In another study, Norton and colleagues (Norton, Bondi, Salmon, & Goodglass, 1997) found that the performance of patients with AD in the Number Information Test (NIT; Goodglass, Biber, & Freedman, 1984), a test designed to assess generic semantic knowledge in a way that minimizes language demands, declined over three annual evaluations. Furthermore, the patients were highly consistent across evaluations in the individual items they missed. Finally, Salmon and colleagues (Salmon, Heindel, & Lange, 1999) found that the performance of patients with AD declined over four annual evaluations in both letter (i.e., FAS) and category fluency tasks, but the rate of decline was faster in the category than in the letter fluency task. Examination of individual responses across the annual evaluations revealed that when patients with AD failed to generate a

particular response in the category fluency task in a given year, they were unlikely to produce that item in a subsequent year. Taken together, the results of these studies are consistent with the notion that patients with AD suffer a gradual deterioration of the organization and content of semantic memory as the disease progresses.

Remote Memory

In addition to their severely impaired ability to learn and retain new information (i.e., anterograde amnesia), patients with AD exhibit a pronounced deficit in the ability to recollect information that was known before the onset of their dementing disorder (i.e., retrograde amnesia; Beatty, Salmon, Butters, Heindel, & Granholm, 1988; Hodges, Salmon, & Butters, 1993; Kopelman, 1989; Sagar, Cohen, Sullivan, Corkin, & Growdon, 1988; Wilson, Kaszniak, & Fox, 1981). This deficit was clearly demonstrated by Beatty and colleagues (Beatty et al., 1988) who found that even mildly demented patients with AD were strikingly impaired in Famous Faces and Public Events tests (Albert, Butters, & Levin, 1979) that required subjects to identify individuals or events that were widely known during the past decades of their life. Interestingly, the remote memory loss exhibited by the AD patients was temporally graded in that they recalled significantly more information from the 1940s and 1950s than from the 1960s, 1970s, or 1980s.

The temporal gradient in the remote memory loss of patients with AD is similar to the pattern of loss exhibited by patients with circumscribed amnesia associated with selective medial temporal lobe brain damage (Salmon, Lasker, Butters, & Beatty, 1988; Squire, Haist, & Shimamura, 1989) or diencephalic damage associated with Korsakoff's syndrome (Albert et al., 1979). These patients often have severe retrograde amnesia characterized by poorer memory for the more recent past (i.e., late adulthood) than for the more distant past (i.e., childhood and early adulthood). This gradient has been attributed to the interruption of a long-term consolidation process that depends critically on the hippocampal-diencephalic memory system (see Zola-Morgan & Squire, 1990 for a discussion of the role of consolidation and medial temporal lobe brain structures in temporally graded retrograde amnesia). When this process is interrupted by disease or trauma that affects the hippo-

campal system, older remote memories that have been more fully consolidated are better retained than more recent remote memories that have not been fully consolidated. In one version of this notion, Cermak (1984) suggested that consolidation may reflect the transfer of information from a time-limited, context-dependent form (i.e., episodic memory) to a relatively permanent, context-free form (i.e., semantic memory). According to this view, information that remains fully in episodic memory is lost when hippocampal damage occurs, and information that has become part of the diffusely distributed semantic knowledge system is retained.

To explore the possibility that the retrograde amnesia of AD is due to a retrieval deficit rather than an inability to adequately consolidate information over time, Hodges and colleagues (Hodges et al., 1993) examined the performance of patients with AD on an updated version of the Famous Faces test that employed recognition and cueing formats. These latter conditions allowed assessing remote memory across decades and greatly reduced the retrieval demands of the task. Patients were first shown four faces simultaneously and were asked simply to point out the one who was a famous person. Then, they were asked to name the person, then to identify the persons if they could not name them, and then to name the persons following the presentation of a semantic (e.g., an actor) or a phonemic (e.g., the person's initials) cue. The results demonstrated that patients with AD were impaired in the Famous Faces test, even when retrieval demands were minimized by using a recognition procedure. Furthermore, the retrograde amnesia that was evident in the recognition and phonemic cueing formats was temporally graded with information from the distant past that was retained better than information from the more recent past.

The severe, temporally graded retrograde amnesia exhibited by patients with AD is not a general feature of all dementia syndromes. In the study described before, Beatty and colleagues (1988) found that patients with HD exhibited a mild retrograde amnesia that was equally severe across all decades (also see, Albert, Butters, & Brandt, 1981). This divergent pattern was evident, even though the HD and AD patients were matched for overall severity of dementia, as measured by the DRS (see Figure 4).

A similar pattern of results was obtained when

patients with AD and patients with HD were compared in a test that assessed geographical knowledge for regions of the country in which subjects lived early and late in their lives (Beatty & Salmon, 1991). In this test, subjects were shown outline maps of regions of the country and had to identify the approximate locations of a number of cities or geographic features. Beatty (1988) had previously shown that the ability to perform this task is related to whether and how long an individual had lived in the targeted region. Subjects were tested with maps of regions in which they had spent their early lives and where they currently resided, and groups were carefully matched for the amount of time they had lived in each region. The results showed that both AD and HD patients were impaired, relative to their control subjects, in locating features in both regions. However, the AD patients, but not the HD patients, showed a temporally graded remote memory loss for this geographic knowledge, that is, their memory for the region of more recent residence was more impaired than their memory for the region of past residence.

When considered together, the results of the studies described suggest that the retrograde amnesia associated with various dementing disorders is likely to be mediated by different underlying abnormal processes. The severe, temporally graded retrograde amnesia of AD most likely arises from a loss of remote knowledge due to a consolidation deficit mediated by medial temporal lobe damage. The retrograde amnesia may be particularly severe, even for information from the distant past, because remote knowledge that has already been consolidated as semantic knowledge may also be lost as the structure and organization of semantic memory deteriorates. In contrast, the relatively mild and time-independent retrograde amnesia of HD may be another reflection of the general retrieval deficit that equally affects information from any decade of their lives.

Implicit Memory

As mentioned earlier, tests of explicit memory require the conscious recollection of previously learned information, whereas tests of implicit memory do not. Instead, implicit memory is manifested indirectly through changes in performance that can be attributed simply to previous exposure to the stimuli or procedures used in a particular

Figure 4. The mean percentage of correct responses given by patients with Alzheimer's disease (AD), patients with Huntington's disease (HD), elderly normal control (ENC) subjects, and middle-age normal control (NC) subjects in the remote memory battery (cues condition). Adapted from Beatty et al., 1988.

task. Despite their profound explicit memory impairments, amnesic patients often demonstrate essentially normal performance on implicit memory tests that involve priming and skill learning (for a review, see Squire, 1987). These findings have been instrumental in demonstrating that implicit memory does not depend critically on the medial temporal and diencephalic brain regions that, it is thought, mediate explicit memory, but they have shed little light on the neurological substrates that actually underlie implicit memory.

Unlike patients with circumscribed amnesia, demented patients often exhibit impaired performance in tests of implicit memory. What is more intriguing, however, are the results of studies that indicate that demented patients are not globally impaired in all implicit memory tests; rather, they evidence selective impairments in a subset of related tests, and different demented patient populations display distinct patterns of preserved and impaired ability across a variety of implicit tests.

These findings provide strong support for the notion that implicit memory is *not* a single entity, but instead a collection of independent systems mediated by distinct neuroanatomic structures. These results also suggest that implicit memory tests may ultimately have some diagnostic utility in distinguishing very mildly demented patients from both amnesic patients and neurologically intact subjects.

Skill Learning. One form of implicit memory that is preserved in amnesic patients is the ability to acquire and retain rule-based motor and cognitive skills. Specifically, alcoholic Korsakoff patients demonstrate normal learning on visuomotor tasks such as tracing two-dimensional line drawings while viewing the drawing as a mirror reflection (i.e., a mirror tracing task) and maintaining contact between a handheld stylus and a rotating metallic disk (i.e., a pursuit rotor task) (Brooks & Baddeley, 1976; Cermak, Lewis, Butters, & Goodglass, 1973). In addition, alcoholic Korsakoff pa-

tients have exhibited preserved learning ability in more cognitively loaded skills such as reading words that have been mirror-reversed (Cohen & Squire, 1980). In this task, amnesic patients could learn to read mirror-reversed words and retained this ability normally during a 3-month period, even though their ability to remember either the test sessions or the specific words read was significantly impaired.

Now, a number of studies indicate that demented patient populations can be differentiated by their performance in skill learning tasks that are performed normally by amnesic patients. Martone and her colleagues (Martone, Butters, Payne, Becker, & Sax, 1984) found that the ability of patients with HD to acquire the mirror reading skill in the task developed by Cohen and Squire was impaired (1980). On the other hand, Eslinger and Damasio (1986) reported that patients with AD demonstrate normal acquisition of the motor skills underlying a pursuit rotor task. Considered together, the results of these two studies provide evidence that the neostriatum (damaged in HD but preserved in the early stages of AD) may be critically involved in the acquisition of some visuo-motor skills.

This possibility was further examined in studies by Heindel and colleagues (Heindel, Butters, & Salmon, 1988; Heindel, Salmon, Shults, Walicke, & Butters, 1989) that directly compared the motor skill learning ability of amnesic patients, patients with AD, patients with HD, and both demented and nondemented PD patients. These investigations employed a pursuit rotor task in which subjects were required to maintain contact between a handheld stylus and a rotating metallic disk. The amount of time the stylus was kept in contact with the disk on each 20-second trial was measured across blocks of trials. To ensure that any observed group differences in skill acquisition could not be attributable to ceiling or floor effects, the initial levels of performance among the groups was equated by manipulating the difficulty (i.e., speed of rotation of the disk) of the task.

The results of these studies showed that AD patients and amnesic patients demonstrated systematic and extensive motor learning across trials that was equivalent to that of normal control subjects. The preserved motor learning of these groups has been replicated (Bondi, Kaszniak, Bayles, & Vance, 1993) and extended to the learning of the visuo-motor skills necessary to trace a

pattern seen in a mirror-reversed view (Gabrieli, Corkin, Mickel, & Growdon, 1993), and it provides further evidence that this form of implicit memory is not mediated by the medial temporal lobe structures damaged in these two patient populations. Patients with HD, in contrast, were impaired in learning the motor skill underlying pursuit rotor task performance, and the little learning they did exhibit was significantly correlated with their overall level of dementia (as measured by the DRS) but not with the severity of their choreiform movements. Based on these findings, Heindel et al. (1989) concluded that HD patients have a true motor learning deficit that may be an integral part of their dementia, rather than simply a reflection of their primary motor impairment. In conjunction with the findings of Martone et al. (1984) and Eslinger and Damasio (1986), these results also support the notion that the neostriatum is indeed involved in the acquisition of motor skills and particularly in the acquisition and generation of motor programs (see Figure 5).

The analysis of human performance in tracking tasks suggests that the motor system is hierarchically organized into different levels of motor control (Pew, 1974; Summers, 1981). In learning a motor skill, a performer must combine the appropriate movements into both the correct serial order and the correct temporal pattern within that order. The awkward performance seen in the early stages of learning a motor task can be adequately described by an elementary closed-loop negative feedback system that relies directly on visually perceived errors to generate new motor commands. However, the smoother, more coordinated movements seen after much practice are due to the acquisition and modification of motor programs that allow the performer to organize a sequence of movements in advance of their performance. Skill learning, then, involves the development of increasingly more accurate motor programs.

From this point of view, the impaired performance of the patients with HD in the pursuit rotor task may be attributable to their reliance on the visual error-correction mode of motor performance. Although these patients could demonstrate some improvement during the first few blocks of trials by improving their error-correction strategy, their inability to generate new motor programs would prevent them from adopting the more effective, predictive mode of performance used by patients with AD, amnesic patients, and control subjects.

Figure 5. Performance of Huntington's disease (HD) patients, demented (DPD) and nondemented (NPD) Parkinson's disease patients, with dementia of the Alzheimer type (DAT), and middle-aged (MNC) and elderly (ENC) normal control subjects in the pursuit rotor motor learning task. From Heindel et al., 1989.

Heindel et al. (1989) also found that, although nondemented patients with PD exhibited normal learning on the pursuit rotor task, the learning of the demented PD patients was as impaired as that of the HD patients (see Figure 5). Similarly, the residual motor skill learning ability of the patients with PD was significantly correlated with their overall level of dementia but not with the severity of their motor symptoms (i.e., tremor, rigidity, bradykinesia). Although early studies (e.g., Flowers, 1978) initially suggested that nondemented PD patients may have open-loop motor control deficits, the results of the study by Heindel and colleagues are consistent with subsequent studies (Bloxxham, Mindel, & Frith, 1984; Bondi & Kaszniak, 1991; Day, Dick, & Marsden, 1984) that showed that nondemented PD patients can in fact employ predictive motor strategies in tracking tasks. These studies and others that demonstrate the ability of PD patients to use advance information effectively in preparing for movement (Rafal, Inhoff, Friedman, & Bernstein, 1987; Stelmach, Worringham, & Strand, 1986) suggest that motor programs are intact in nondemented PD patients. This is not the case for demented PD patients, however, because they exhibit a motor learning deficit, perhaps due to the presence of greater corticostriatal damage in these patients than in

their nondemented counterparts (Agid, Ruberg, Dubois, & Pillon, 1987).

To examine more directly whether HD patients' skill learning impairments are related to a motor programming deficit, Heindel, Salmon, and Butters (1991) administered a modification of Helson's (1948) classic adaptation-level task, which involves biasing weight judgments, to HD patients, AD patients, and control subjects. In this task, subjects first lift a series of weights and judge whether each weight is heavier or lighter than the immediately preceding weight. Twenty minutes later, these subjects are asked to judge the heaviness of a standard set of ten weights on a nine-point scale. Benzing and Squire (1989) previously found that both amnesic patients and control subjects tended to rate the standard set of weights heavier, when they had been exposed initially to a relatively light series of weights (light bias condition), and lighter when they had initially been exposed to a relatively heavy set of weights (heavy bias condition). In the case of the amnesic patients, this effect occurred despite impaired recall for the earlier biasing session.

The weight biasing task, like motor skill learning, may involve modifying programmed movement parameters. A number of studies (see Jones, 1986, for a review) indicate that weight perception

is normally mediated by centrally generated motor commands and that sensations of heaviness can be influenced by discrepancies between the intended, or programmed, force, and the actual force needed to lift objects. Prior experience with relatively heavy or light weights during the initial biasing trials may result in an increase or decrease in the amount of force programmed for lifting the weights, which would then lead to an illusory decrease or increase in the perceived heaviness of the standard set of weights. Because the task requires little overt movement, a demonstration that HD patients are less likely than patients with AD to manifest normal weight biasing would further strengthen the probability that their motor learning deficits are due to a failure in skill acquisition, not to some basic motor dysfunction.

The results of the study by Heindel et al. (1991) showed that AD and HD patients did indeed differ in the extent to which their judgments of heaviness were biased by prior experience. Although unable to explicitly remember the initial biasing trials, both mildly and moderately demented patients with AD, like normal control subjects, perceived that the standard set of weights was heavier after previous exposure to the series of light weights than after previous exposure to the series of heavy weights. In contrast, only mildly demented patients with HD exhibited the same biasing effect. Moderately demented patients with HD showed no evidence that their ratings of the standard weights were influenced by the prior biasing trials. This difference in performance in the weight biasing task occurred despite the fact that both patient groups could discriminate easily among the different weights, indicating that the weight judgments were not limited by any sensory or motor deficit.

A related study compared the performance of AD and HD patients in a task that assessed their ability to develop a new perceptual-motor response required by the use of laterally displaced vision (Paulsen, Butters, Salmon, Heindel, & Swenson, 1993). In this task, subjects were required to point to a target while wearing distorting prisms that shifted the perceived location of objects 20° to the right or left. The groups demonstrated comparable ability to perform the basic pointing task, as assessed by baseline pointing accuracy without prisms or visual feedback regarding accuracy. After thirty trials of training while wearing the prisms, patients with AD displayed a new perceptual-motor response that al-

lowed them to point accurately to the target with laterally displaced vision. In addition, the AD patients displayed normal negative aftereffects in the pointing task, when the prisms were removed. Patients with HD, in contrast, failed to exhibit normal adaptation or negative aftereffects in this task. Given that perceptual-motor adaptation to this lateral spatial distortion, it is thought, is mediated by the modification of central motor programs through visual feedback regarding the accuracy of intended movements, these results are consistent with motor skill learning deficits displayed by HD patients in the pursuit rotor and weight biasing tasks.

The results from the pursuit rotor, weight biasing, and prism adaptation studies, in conjunction with studies showing that patients with HD (Knopman & Nissen, 1991; Willingham & Koroshetz, 1993) or PD (Ferraro, Balota, & Connor, 1993; Pascual-Leone et al., 1993) but not patients with AD (Knopman & Nissen, 1987; Grafman et al., 1990; but see Ferraro et al., 1993) have deficits in implicitly learning sequences of movements in a serial reaction task (Nissen & Bullemer, 1987), suggest that the motor learning deficits of patients with HD may result from an inability to generate central motor programs. Such of a programming deficit is certainly consistent with the neuropathology of the disease. A number of studies (for a review, see Alexander, DeLong, & Strick, 1986) demonstrated the presence of several anatomically and functionally distinct circuits that link the cortex and basal ganglia. One such circuit, dubbed the motor circuit by Alexander et al., is critically involved in programming movements. The motor circuit consists of inputs to the putamen from the motor, premotor, and sensorimotor cortical regions. This information is subsequently integrated through the pallidum and thalamus and is returned to the supplementary motor area (SMA). A number of studies provided evidence that this circuit is critically involved in programming and executing motor movements. For example, DeLong and colleagues (DeLong, Alexander, Georgopoulos, Mitchell, & Richardson, 1984) demonstrated that cells in the basal ganglia respond to the direction, amplitude, and amount of force required by a movement. Neurons in the SMA it has been shown, discharge during actual limb movement and during preparation for limb movement (Brinkman & Porter, 1979; Tanji, Taniguchi, & Saga, 1980). Regional cerebral blood flow studies have shown that

the SMA is activated when a subject rehearses and prepares for complex limb movements (Orgogozo & Larsen, 1979; Roland, 1984; Roland, Larsen, Lassen, & Skinhoj, 1980). It has been found that lesions to the SMA (Watson, Fleet, Gonzalez-Rothi, & Heilman, 1986) or basal ganglia (De Renzi, Faglioni, Scarpa, & Crisi, 1986) cause apraxia (i.e., an impairment in executing skilled movements). Taken together, these studies suggest that damage to the motor circuit in patients with HD creates a motor programming deficit that most likely mediates the deficits in motor skill learning, weight biasing, and prism adaptation displayed by these patients.

Alexander et al. (1986) described several other corticostriatal loops that pass through the basal ganglia and follow the same general pattern of organization as in the "motor" circuit. In each of these "complex" circuits, inputs from functionally related cortical associative areas project primarily to the caudate nucleus and ultimately project back to a specific region of the prefrontal cortex. Given the parallel organization of these circuits, it is likely that they are all performing similar operations, even though the information transmitted through individual circuits might differ considerably. In particular, if the "motor" circuit is involved in programming external actions (i.e., movements), then it is possible that the "complex" circuits may be involved in programming internal actions (i.e., cognitive processes). Because these "complex" loops are compromised in HD and PD, they may represent the neurological substrate that underlies the reported deficits of these patients in acquiring the visuomotor skills necessary to read mirror-reversed text (Martone et al., 1984), in acquiring the cognitive skills necessary to solve complex puzzles efficiently (Butters et al., 1985; Saint-Cyr, Taylor, & Lang, 1988), and the inability to acquire the cognitive skill necessary to perform a probabilistic classification task (Knowlton, Mangels, & Squire, 1996). In addition, these complex loops might also be associated with the retrieval deficits that patients with Huntington's disease exhibit in tests of explicit memory (Butters et al., 1985; Caine et al., 1978).

Priming. In addition to normal skill learning, patients with circumscribed amnesia perform normally in a wide variety of priming tasks that involve temporary and unconscious facilitation of performance simply from prior exposure to stimuli (Shimamura, 1986). For example, amnesic pa-

tients and normal control subjects have an equivalently strong tendency (relative to chance) to complete three-letter word stems (e.g., MOT) with previously presented words (e.g., MOTEL), despite the failure of the amnesic patients to recall or recognize these words in standard memory tests (Graf et al., 1984; Warrington & Weiskrantz, 1968, 1970). Similar normal priming effects have been reported in severely amnesic patients with alcoholic Korsakoff's syndrome in tasks that require generating exemplars from particular semantic categories (Gardner et al., 1973; Shimamura & Squire, 1984), identifying words flashed for very short durations (e.g., 35 ms) on a computer screen (Cermak, Talbot, Chandler, & Wolbarst, 1985), or identifying incomplete (i.e., "fragmented") line drawings of animate and inanimate objects (Warrington & Weiskrantz, 1968, 1970).

Although the effects of previous exposure to stimuli (i.e., priming) can arise from a variety of processes, some investigators have made a theoretical distinction between perceptual (or data-driven) priming and conceptual priming (Blaxton, 1989; Roediger & Blaxton, 1987). Perceptual priming, it is thought, involves processes that operate at the level of the visual or auditory form of a target stimulus, and it is not affected by the particular meaning or content of the stimulus. It can, however, be influenced by manipulations of the surface features of the stimulus (e.g., changes in modality or typeface). Conceptual priming, in contrast, it is thought, involves processes that operate at the level of the meaning or content of a target stimulus, and it is influenced by manipulations of the depth of conceptual analysis of the stimulus.

Gabrieli and colleagues recently suggested that the distinction between perceptual and conceptual priming may have a neurological as well as a psychological basis (Fleishman et al., 1995; Gabrieli, Fleischman, Keane, Reminger, & Morrell, 1995). It is important to point out, however, that tasks used to assess priming often do not exclusively engage either conceptual or perceptual processes. Rather, both types of processing may contribute to normal priming performance, and the relative contribution of each depends on the specific features of the task. Priming effects in normal individuals and in amnesic patients in the widely used word-stem completion task, for example, are greater following elaborative processing of a semantic, rather than a physical, feature of the stim-

Figure 6. Percentage of word stems completed with previously presented words in the lexical priming task by Alzheimer's disease (AD), Huntington's disease (HD), alcoholic Korsakoff (AK) patients, and their age-matched normal control (NC) subjects. The shaded portion of the bar indicated the baseline guessing rate for each subject group. Adapted from Salmon et al., 1988.

ulus during study (indicating a conceptual processing component) and also as well as when the stimulus is presented in the same modality, rather than in different modalities, in study and test (indicating a perceptual processing component) (Carlesimo, 1994).

Some of the first studies to examine conceptual priming in patients with dementia (Salmon, Shimamura, Butters, & Smith, 1988; Shimamura, Salmon, Squire, & Butters, 1987) compared the performance of AD, HD, and alcoholic Korsakoff's syndrome patients in the word-stem completion task previously used by Graf et al. (1984). In this task, subjects were shown ten words (e.g., MOTEL, ABSTAIN), one at a time, and were asked to rate how much they liked each word on a five-point scale. Following these presentation trials, the subject were shown twenty three-letter word stems (e.g., MOT, ABS) and were asked to complete each stem with the first word that came to mind. Ten of the stems could be completed using study words, and the other ten stems were used to assess baseline guessing rates.

As expected, the alcoholic Korsakoff patients and control subjects displayed equivalent and significant increases (relative to baseline guessing rates) in the number of stems completed with previously presented words, despite the profound explicit memory impairments of the alcoholic Korsakoff patients. Although both groups of de-

mented patients were also severely impaired in explicit memory and did not differ in baseline guessing rates, they performed quite differently on the priming test. Patients with HD, like the alcoholic Korsakoff patients, displayed normal lexical priming, whereas the patients with AD showed little tendency to complete the word stems with the previously presented words (see Figure 6). This deficit in the stem-completion priming performance of AD patients has now been replicated in numerous studies (Heindel et al., 1989; Keane et al., 1991; Randolph, 1991; Bondi & Kaszniak, 1991; Perani et al., 1993; but see Deweer et al., 1994; Huberman, Moscovitch, & Freedman, 1994).

Subsequent studies examined the stem-completion priming performance of patients with PD. Heindel et al. (1989) and Bondi and Kaszniak (1991) observed normal stem-completion priming effects in nondemented patients with PD. However, demented patients with PD, like patients with AD, exhibited impaired priming in this task (Heindel et al., 1989).

Another study that examined conceptual priming in demented patients (Salmon et al., 1988) compared the performance of AD, HD, and control subjects in a semantic priming task that employed a paired-associate procedure. In this task, subjects were asked to judge categorically or functionally related word pairs (e.g., BIRD-ROBIN, NEEDLE-THREAD) and later to say the first

word that came to mind when presented with the first word (e.g., BIRD, NEEDLE) of a pair. The subjects' semantic priming abilities are reflected by their tendencies to produce the second word of the functionally or categorically related word pairs. As in the lexical priming task, HD patients demonstrated normal levels of semantic priming. Patients with AD, in contrast, primed significantly less than HD patients and control subjects and actually failed to prime above baseline guessing rates. Using a somewhat different free-association procedure, Brandt et al. (1988) also found significantly impaired priming in patients with AD.

The deficits exhibited by patients with AD in conceptually based priming tasks has been extended in several studies to priming of meaningful pictorial stimuli (Bondi & Kaszniak, 1991; Bondi, Kaszniak, Rapcsak, & Butters, 1993; Corkin, 1982; Heindel, Salmon, & Butters, 1990; but see Gabrieli et al., 1994). Heindel et al. (1990), for example, developed a picture priming task that was designed to be directly comparable to the stem-completion test of verbal priming. In this task, subjects were first shown complete, realistic line drawings of common animate and inanimate objects (e.g., tree, bicycle) and were simply asked to name the object depicted. Then, subjects were given the pictorial priming test in which they were asked to say the first thing they thought of when shown incompletely drawn (i.e., fragmented) pictures, half of which were previously shown to the subject in the naming task. Priming effects were reflected in the enhanced identification of objects previously seen in the naming task relative to the novel objects. Although all subjects performed well in the initial naming task, patients with AD exhibited significantly less facilitation in identifying fragmented pictures from this prior exposure than the HD patients or control subjects. The patients with HD were not impaired in this pictorial priming task, and they actually demonstrated significantly greater facilitation than the control subjects.

Although the pictorial priming task appears, at first glance, to evoke perceptually based processes, some investigators suggest that pictures and words simply have differential access to different features within a common semantic store (Nelson, Reed, & McEvoy, 1977), that is, pictures may access the semantic features of a concept more directly than words, whereas words may access phonemic features more directly than pic-

tures. To the extent that words and pictures are indeed represented by a single, shared semantic representation, a common conceptual processing deficit could underlie the impaired performance of patients with AD on the stem-completion, paired-associates, and pictorial priming tasks.

One possible explanation of AD patients' deficits in the various conceptual priming tasks is rooted in their previously described deficiencies in semantic knowledge, that is, the hierarchic associative network that forms the skeletal structure of semantic knowledge may have deteriorated sufficiently to greatly limit the capacity of available cues to activate traces of previously presented stimuli. For example, the cue BIRD may not have evoked an unconscious activation of the categorical associate ROBIN in the semantic priming task because the association between the two words has been greatly weakened. Similarly, the association in semantic memory between the word stem MOT and the word MOTEL in the lexical priming task may have been sufficiently disrupted to negate the facilitating effect of the word's presentation. In the pictorial priming tasks, the initial presentation of the intact picture of an object may not have sufficiently activated the semantic representation of that object to aid in identifying it, when it was presented in a fragmented form.

In contrast to the studies described before, some studies indicate that patients with AD can, under certain conditions, demonstrate intact long-term semantic priming. One such study examined verbal priming in AD patients using a homophone spelling bias task (Fennema-Notestine, Butters, Heindel, & Salmon, 1994). In this study, subjects were asked to spell series of homophonic words (to establish the initial spelling preference) and then to spell these words again a few minutes later after they had been biased against their preference by presenting the homophone within a semantic context. For example, depending on whether subjects' preferred spelling had initially been either "son" or "sun," they were then asked in the second phase to spell this word immediately after having heard either "moon and stars" or "father and daughter," respectively. After the biasing trials, AD patients and normal control subjects displayed comparable and significant increases in their tendency to shift to their nonpreferred spelling of the target words.

In a similar study, patients with AD displayed a normal biasing effect of verbal labels on memory

for ambiguous figures (Ostergaard, Heindel, & Paulsen, 1995). In this task, ambiguous figures were presented to the subjects along with a verbal label corresponding to one of two possible interpretations of the figure. Biasing was reflected in a subject's tendency to produce responses and response latencies on a subsequent recognition test that were consistent with these verbal labels. Alzheimer's disease patients displayed a normal biasing effect despite their chance performance on the recognition test.

The normal priming exhibited by patients with AD in these two semantic biasing tasks casts some doubt on the notion that these patients' priming impairments can be attributed simply to a disruption in the organization of their semantic memory. It is still possible, however, to accommodate these findings within the semantic memory framework by assuming that different verbal priming tasks place different demands on the capacity of AD patients' compromised semantic structure. In this view, prior exposure to stimulus may be sufficient to activate the general contextual or superordinate semantic information that remains relatively intact in patients with AD to a level that can support normal priming in the homophone and ambiguous figures biasing tasks. However, prior exposure may not prove sufficient to activate the specific semantic associates or exemplars that are particularly disrupted in patients with AD, and this leads to impaired priming in the stem-completion, paired-associates, and pictorial priming tasks.

In contrast to their impairments in more conceptually driven priming tasks, patients with AD consistently perform normally in more perceptually driven priming tasks, including lexical decision (Ober & Shenalt, 1988), simple reading (Balota & Duchek, 1991), reading geometrically transformed script (Deweert, Pillon, Michon, & Dubois, 1993; Grober, Ausubel, Sliwinski, & Growdon, 1992; Moscovitch, Winocur, & MacLachlan, 1986), and identifying briefly presented words and nonwords (Keane et al., 1991, 1994; but see Ostergaard, 1994). A recent study (Heindel, Salmon, Fennema-Notestine, & Chan, 1998) examined the repetition priming ability of AD patients using novel, non-verbal stimuli that do not have preexisting lexical or semantic representations. In this task, subjects discriminated perceptually between geometric designs that had either a continuous ("closed") or discontinuous ("open") perimeter. With the open

stimuli, AD patients and control subjects displayed significant and equivalent levels of priming after immediate repetition of the stimuli.

This demonstration provides strong support for the claim that perceptual priming is normal in patients with AD and suggests that this form of priming is mediated by brain regions different from those that support conceptual priming and that are damaged in AD. Consistent with this suggestion, Gabrieli and colleagues (Fleischman et al., 1995; Gabrieli et al., 1995) presented evidence that perceptual priming may be mediated by a putative visual memory mechanism in the right occipital cortex, a brain area not prominently affected by AD. These investigators examined explicit memory and perceptual identification priming in a patient (M.S.) with a left homonymous hemianopsia due to a right-hemisphere temporal lobectomy performed as treatment for pharmacologically intractable epilepsy. Despite normal performance in a visually based explicit recognition memory test, patient M.S. was impaired in a perceptual identification priming test.

Although the pattern of impaired conceptual priming and intact perceptual priming exhibited by patients with AD is consistent with the possibility that their priming deficit is mediated by deterioration of semantic memory, other evidence suggests that a more general factor may be at fault. Several studies, for example, demonstrated that patients with AD exhibit normal priming of semantic relationships when on-line tasks that require very short-term effects are employed. In one study, for example, Nebes and colleagues (Nebes, Martin, & Horn, 1984) tested patients with AD in a task in which a given word was preceded (by approximately 500 ms) either by a semantically related word (primed trials) or by an unrelated word (unprimed trials), and priming was measured by the difference in naming latencies between primed and unprimed trials. Patients with AD and control subjects displayed a slight and equivalent facilitation in naming latency when a word was preceded by a semantic associate (i.e., semantic priming). From these and similar results, Nebes et al. (1984) concluded that semantic memory is unimpaired in patients with AD when it is assessed by techniques that rely solely on automatic information processing. According to Nebes and colleagues, the deficits that these patients display on other implicit and explicit tests of seman-

tic memory are due to the heavy attentional demands of these tasks, rather than to an impairment in semantic memory *per se*. Ober, Shenaut, Jagust, and Stillman (1991) reached a similar conclusion.

Another general factor that may contribute to the priming deficit of patients with AD is a deficiency in the level of steady-state cortical activation, or "cortical tonus" (Sara, 1985), that modulates the efficiency of cortical information processing (Salmon & Heindel, 1992). This steady-state cortical activation, it is thought, is maintained by the noradrenergic projection system (i.e., the locus coeruleus; Sara, 1985) that is often damaged in patients with AD (Bondareff et al., 1982). It may be that poor cortical tonus leads to insufficient levels of activation or inadequate maintenance of activation of representations required to support long-term priming. Representations may still be sufficiently activated, however, to manifest intact priming over the very short (e.g., 500 ms) delay intervals used in the Nebes et al. (1984) paradigm. This explanation might also account for the observations that, though patients with AD display intact immediate priming in the homophone (Fennema-Notestine et al., 1994) and nonverbal perceptual (Heindel et al., 1998) priming tasks, they also display abnormally rapid dissipation of the priming effect in both tasks. Although these explanations remain tentative, future investigations into the processes that underlie the priming deficits of patients with AD should provide information about the necessary and sufficient conditions for priming phenomena and about the nature of the neuropsychological deficits of the disease.

Summary

The goals of this chapter have been twofold: (1) to demonstrate the diagnostic, theoretical, and neurological value of applying concepts derived from cognitive psychology to the severe memory impairments of demented patients and (2) to stress the heterogeneity of the memory and underlying cognitive disorders of different types of dementia.

It is evident that, though patients with so-called "cortical" and "subcortical" dementias may generate quantitatively similar scores in some standardized tests of memory and mental status, the cognitive processes that underlie their performance are often quite distinct. Patients with AD

(i.e., a "cortical" dementia) cannot store new information, are highly sensitive to proactive interference, and rapidly forget what little information they can acquire initially. Qualitative analyses of AD patients' performance in semantic memory tasks indicate that they have endured some breakdown of the hierarchical structure of semantic knowledge. In tests of implicit memory, AD patients have an intact ability to acquire and retain motor and visuomotor skills but their ability to manifest lexical, semantic, and pictorial priming is often severely impaired. Although the role of semantic, perceptual, attentional, and arousal factors in these priming deficits remains uncertain, the available evidence suggests that the association cortices are involved in mediating this type of implicit memory task.

When similar analyses are applied to the memory disorder associated with HD (i.e., a "subcortical" dementia), a different profile of cognitive deficiencies becomes apparent. Huntington's disease patients' episodic and semantic memory impairments are characterized by an inability to initiate retrieval of stored information. In comparison to AD patients, patients with HD demonstrate less sensitivity to proactive interference and better retention of information over time. In tests of implicit memory, the pattern of impairments is the opposite of that seen in patients with AD. Although HD patients exhibit normal lexical, semantic, and pictorial priming, their learning of motor skills is severely impaired, and they perform poorly in other tasks that require the acquisition of central motor programs. Given these data and existing neuroanatomical knowledge, the notion that motor skill learning depends on the integrity of the striatum and complex corticostriatal circuits has substantial support.

Finally, it is important to stress that not all forms of dementia can be assumed under an *Alzheimer-type* or *Huntington-type* profile of memory and cognitive deficits. Studies with demented PD patients, for example, suggest that their memory deficiencies may reflect a combination of the features associated with AD and HD. Rather, the investigations reviewed in this chapter should be seen as prototypical analyses that can provide novel insights into the nature of the memory disorders of *all* forms of dementia and perhaps even contribute new clues to the neurological bases of various memory systems.

ACKNOWLEDGMENTS. The preparation of this chapter was supported, in part, by NIH grants AG15375 to Brown University and AG05131 to the University of California, San Diego.

PART VI

Disorders Arising in Specific Life Stages

This page intentionally left blank.

Psychopathology in Children

Paul J. Frick and Persephanie Silverthorn

Introduction

A significant number of children and adolescents are affected by psychopathological conditions. Prevalence estimates vary widely, depending on the age group, type of disorder, and method of assessment. However, epidemiological studies conducted in the United States (Cohen et al., 1993; Costello, 1989; Costello et al., 1988, 1996, 1997; Kashani et al., 1987; Lewinsohn et al., 1993; Shaffer et al., 1996; Simonoff et al., 1997), New Zealand (Anderson, Williams, McGee, & Silva, 1987; McGee, Feehan, Williams, & Anderson, 1992), Canada (Offord et al., 1987), Puerto Rico (Bird et al., 1988; Shaffer et al., 1996), and the Netherlands (Verhulst et al., 1997) suggest that from 9–22% of children and from 18–22% of adolescents have significant emotional or behavioral problems at any given time. Rates of disorders in preschoolers have been less extensively studied, although a similar range of problems (9–21%) has been found in this age group (Lavigne et al., 1996).

These overall rates of childhood disorders obscure important differences in boys and girls. Regardless of the specific diagnosis, in preschool age children, boys are diagnosed with disorders at a greater rate than girls (e.g., Lavigne et al., 1996). During childhood, this pattern is maintained, and

most studies indicate that boys are more often diagnosed with disorders than girls (e.g., Anderson et al., 1987; Cohen et al., 1993; Costello et al., 1996, 1997; McGee et al., 1992). In adolescence, the male predominance for most forms of psychopathology disappears; some studies find that boys and girls are equally diagnosed (e.g., Simonoff et al., 1997; Verhulst et al., 1997), and other studies find that girls are more often diagnosed than boys (e.g., Cohen et al., 1993; Lewinsohn et al., 1993; McGee et al., 1992). These changes in prevalence rates for boys and girls are more pronounced for some forms of psychopathology (e.g., depression, conduct disorders) than for others, and these diagnosis-specific changes are discussed in more detail later in the chapter.

When classifying and studying childhood disorders, two major paradigms have generally been used. The first paradigm has been variously labeled as the multivariate, empirical, or psychometric approach. There are two key aspects to this approach. First, this approach typically relies on statistical techniques (e.g., factor analyses) to isolate interrelated patterns of behavior that are usually assessed by using standardized behavior rating scales (Achenbach, 1995; Quay, 1986). Reviews of studies that use such multivariate techniques have consistently identified two major dimensions of psychopathology (Achenbach, 1995; Achenbach & Edelbrock, 1978; Quay, 1986). One dimension has been labeled undercontrolled or externalizing and includes various acting out, disruptive, delinquent, hyperactive, and aggressive behaviors. The second broad dimension of childhood behavior problems has been labeled overcontrolled or internalizing and includes such be-

Comprehensive Handbook of Psychopathology (Third Edition), edited by Patricia B. Sutker and Henry E. Adams. Kluwer Academic/Plenum Publishers, New York, 2001.

haviors as social withdrawal, anxiety, and depression. Second, this approach to classification views emotional and behavior problems as a continuum from normal to deviant. Abnormality or “psychopathology” is defined by comparing a child’s functioning to those of children in a normative sample. For example, children are considered to have disorders when their behavior exceeds some set level of deviance from the general population (e.g., the 95th percentile).

The second major paradigm for conceptualizing childhood psychopathology is the clinical paradigm, and it is exemplified by the 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), the classification system promulgated by the American Psychiatric Association (1994). Rather than relying solely on multivariate statistical approaches to define psychopathology, this approach places a greater emphasis on clinical observations of disordered individuals or on theoretical models of abnormal behavior to define psychopathological conditions. Although there is less emphasis on patterns of behavioral covariation that result from multivariate analyses, such patterns are often considered in defining a psychopathological category in this approach (e.g., Carlson, Lahey, & Frick, 1997). A more dramatic point of divergence between these two approaches, however, is the focus of the clinical paradigm on functional impairment to define breaks with normality, rather than a focus on deviations from a normative sample, that is, clinical approaches to defining psychopathology, such as the DSM-IV, focus on behaviors that lead to significant levels of impairment in a child or adolescent’s everyday functioning as at home, at school, or with peers (see Lahey et al., 1994, for an example). This determination is made whether or not the level or severity of symptomatology is rare in the general population.

Despite the strong opinions concerning the value of one method of classifying psychopathological conditions over another (e.g., Achenbach, 1995), there is often great correspondence with respect to which children are identified as having psychopathological conditions using these two approaches (see Jensen et al., 1996). Furthermore, for most clinical and research applications, it is unnecessary to “choose” one approach over another. The two approaches simply provide different perspectives from which to understand a child or adolescent’s behavior. Assessments that inte-

grate both types of information typically provide the best way to understand a child’s psychosocial functioning (Kamphaus & Frick, 1996). Due to the large-scale use of the DSM-IV for both research and clinical practice, the organization and terminology of this chapter are heavily guided by this classification system. However, we do not limit the discussion only to this view of psychopathological conditions, especially when there is clear evidence to support alternative ways of conceptualizing a specific disorder.

Attention Deficit Hyperactivity Disorder

Overview

ADHD is one of the most common reasons in the United States for referring children to mental health clinics, it accounts for as many as 50% of all child referrals to outpatient mental health clinics (Cantwell, 1996). The essential features of this disorder focus on two symptom clusters: developmentally inappropriate degrees of inattention-disorganization (e.g., difficulty sustaining attention, failure to finish tasks, difficulty organizing tasks) and developmentally inappropriate degrees of impulsivity-overactivity (e.g., difficulty sitting still, talking excessively, difficulty awaiting a turn). Although the hyperactive child syndrome has long been recognized as a psychopathological condition, there has been great debate over the core symptoms of the disorder. Some authors emphasize the importance of deficits in attention and impulse control (Douglas, 1972; Douglas & Peters, 1979) and others focus on motor hyperactivity (Porrino, Rapoport, Behar, Sceery, Ismond, & Bunney, 1983). However, the DSM-IV decision to define ADHD along the two symptom domains was based on a substantial amount of research that showed that factor analyses in both clinical and community samples have consistently isolated these two correlated dimensions of behavior (Carlson et al., 1997; Frick & Lahey, 1991).

ADHD is generally considered a lifelong disorder that is not solely a function of a single environmental stressor. As a result, the DSM-IV specifies that the ADHD symptoms must be present early in childhood, must continue for an extensive period of time, and must be displayed in more than one setting (American Psychiatric Associa-

tion, 1994). Also critical in the classification of ADHD is the presence of several subtypes. Based on the two core symptom clusters, the DSM-IV defines three subtypes of ADHD: a primarily hyperactive-impulsive type (approximately 18% of ADHD children), a primarily inattentive type (approximately 27%), and a combined type (approximately 55%) (Lahey et al., 1994). There is little research on the primarily hyperactive-impulsive subtype of ADHD. However, rather extensive research documents important differences between the primarily inattentive subtype (which was formerly called Attention Deficit Disorder without Hyperactivity, American Psychiatric Association, 1980) and the combined subtype. Specifically, those children with the problems of inattention without high rates of impulsivity and hyperactivity (i.e., the primarily inattentive subtype) tend to show fewer conduct problems, less peer rejection, and are more anxious and shy than those children who are also impulsive and hyperactive (see Carlson et al., 1997; Frick & Lahey, 1991 for reviews). The two subtypes may also show differences in the types of attentional processes that are deficient (Barkley, DuPaul, & McMurray, 1991; Carlson et al., 1997; Pliska, 1998), and the inattentive type shows a different response curve to stimulant medication (Barkley et al., 1991). These latter two findings clearly illustrate both the theoretical and clinical importance of distinguishing between these two subtypes of ADHD.

Epidemiology

The DSM-IV reported estimates that ADHD is present in from 3–5% of school-age children (American Psychiatric Association, 1994), and recent epidemiological studies reported prevalence rates from 2–9% in childhood (Anderson et al., 1987; Cohen et al., 1993; Costello et al., 1996, 1997; Offord et al., 1989; Verhulst et al., 1997) and from 2–4.5% in adolescence (Kashani et al., 1987; Lewinsohn et al., 1993; McGee et al., 1990). In general, ADHD affects more boys than girls; ratios range from 4:1 in community samples and are as high as 9:1 in clinical samples (American Psychiatric Association, 1994; Cantwell, 1996).

Although there is a clear and dramatic difference in the prevalence of ADHD in boys and girls, whether there are other gender-specific manifestations of the disorder is less conclusive. Recent data

from the DSM-IV field trials showed that girls are more likely to have ADHD Primarily Inattentive Type (Lahey et al., 1994). Some early studies also reported that girls with ADHD had more severe cognitive deficits (Berry et al., 1985; Brown et al., 1991), more language deficits (Brown et al., 1991; James & Taylor, 1990), and a higher rate of ADHD in their relatives (James & Taylor, 1990; Mannuzza & Gittelman, 1984) than boys. However, more recent studies using more stringent criteria to diagnose ADHD failed to find such differences between boys and girls with ADHD (Farone et al., 1991; Silverthorn et al., 1996) or have found that girls with ADHD had *fewer* cognitive and executive functioning deficits than boys with ADHD (Seidman et al., 1997).

Comorbid Disorders

In addition to the primary symptoms of ADHD, children with this disorder often show other adjustment problems. One such problem is poor school performance: ADHD children are at risk of grade retention, being placed in special education classes, and dropping out of school (Barkley, 1981; Semrud-Clikeman et al., 1992; Weiss & Hechtman, 1993). Furthermore, about a third to a half of children with ADHD meet criteria for a learning disability (Frick et al., 1991; Jensen et al., 1997; Pliska, 1998; Semrud-Clikeman et al., 1992). There is no conclusive evidence that any of the subtypes of ADHD are more strongly associated with learning disabilities (Carlson et al. 1997). It is also not clear what accounts for this correlation between academic difficulties and ADHD (Hinshaw, 1992). It may be that the symptoms of ADHD (i.e., inattention, impulsivity, and overactivity) impair children's abilities to learn up to their potentials. It is also possible that the same mechanisms that cause ADHD also place children at risk for having a learning disability.

Children with ADHD are also likely to have peer difficulties; children with ADHD Combined Type are more likely to be unpopular or rejected by peers, and those with ADHD Primarily Inattentive Type are more likely to be shy and withdrawn (Cantwell & Baker, 1992; Carlson, Lahey, & Neepner, 1986; Lahey et al., 1984, 1987). Children with ADHD also have high rates of emotional disorders. As many as 20–50% of ADHD children have comorbid anxiety disorder, and from 9–38% have comorbid depressive disorder (Jensen et al., 1997; Pliska, 1998). Children with ADHD Primar-

ily Inattentive Type are more likely to exhibit depression and anxiety than children with the Combined Type (Pliska, 1998).

The most significant correlate of ADHD is conduct problems/aggression; estimates of children that have a codiagnosis of ADHD and Conduct Disorder range from 30–90% (Hinshaw, 1987; Loney & Milich, 1982; Sandberg, Weiselberg, & Shaffer, 1980; Stewart, Cummings, Singer, & deBlois, 1981). In the past, this high degree of overlap led to considerable debate whether these two behavior domains were in fact separate entities (see Hinshaw, 1987; Quay, 1986; Rutter, 1983). However, there is now substantial evidence that these disorders are separate conditions. For example, a seminal review of the literature by Hinshaw (1987) showed several lines of evidence to support the distinction between these two disorders, including factor analytic support and findings of different correlates to the two disorders. Studies show that conduct disorder, but not ADHD, is related to low self-esteem (SES)(Loney, Langhorne, & Paternite, 1978), parental psychopathology (Frick, Lahey, Christ, Loeber, & Green, 1991; Lahey, Piacentini et al., 1988; Lahey, Russo, Walker, & Piacentini, 1989; Stewart, deBlois, & Cummings, 1980), dysfunctional parenting practices (Frick, 1994), and marital instability (August & Stewart, 1983). All of these studies suggest that ADHD and conduct disorder are correlated but meaningfully distinct syndromes.

Etiology

Most current causal theories of the etiology of ADHD focus on neurobiological mechanisms (see Zametkin & Liotta, 1998, for a review). In support of this biological focus, several studies using magnetic resonance imaging (MRI) have found abnormalities in the basal ganglia (the caudate nucleus and putamen, globus pallidus, and substantia nigra) and corpus callosum of children with ADHD (Hynd et al., 1993; Lou et al., 1984, 1989; Tannock, 1998). In addition, studies using positron emission tomography (PET) have also implicated the basal ganglia (McCracken, 1998; Zametkin et al., 1990, 1993). Investigations into potential neurochemical correlates to ADHD have been less conclusive (Barkley, 1998; Zametkin & Liotta, 1998), although the potential role of catecholamines in the etiology of ADHD has been proposed (Zametkin & Rapoport, 1986).

A number of other possible etiologies have been

proposed for ADHD, such as exposure to environmental toxins (e.g., lead exposure) and dietary factors (e.g., food allergies, increased sugar sensitivity). However, most of the research into these factors suggest that they could account for only a very small percentage of children with ADHD, if any at all (e.g., Wolraich et al., 1994). Although children with ADHD often come from families in which parents use less than optimal child-rearing techniques, it also appears that this is largely due to difficulties and stressors involved in raising a child with ADHD (Barkley, 1998). Although these familial factors do not play a causal role in the development of ADHD symptoms, they can increase the severity of the ADHD symptoms and they can lead to the development of conduct problems in children with ADHD (Frick, 1994), both of which can affect the severity and course of the disorder.

Despite the focus on neurobiological mechanisms in the causes of ADHD, it is not clear what leads to the neurological deficits exhibited by ADHD children. There is evidence that both genetic factors and environmental trauma (e.g., pre- and perinatal traumas) could play a role (Pliska, 1998). As a result, the same neurological deficit can result from multiple causal pathways. It is also unclear what the core deficit is that results from the neurological dysfunction and underlies the behavioral symptomatology associated with ADHD. In one of the best articulated theories to date, Barkley (1997) posits that ADHD Combined Type is the result of deficits in behavioral inhibition. Impairments in delayed response lead to difficulties with self-regulation, which lead to the symptoms of hyperactivity, impulsivity, distractibility, and secondary symptoms of inattention and executive dysfunctions. In addition, Barkley (1997) contends that ADHD Primarily Hyperactive-Impulsive Type is the preschool and early elementary school version of ADHD Combined Type and that accompanying symptoms of inattention emerge only later in school. In contrast, ADHD Primarily Inattentive is considered a completely separate disorder that is less related to response inhibition and more related to primary problems in regulating attention (Barkley, 1998).

Prognosis and Treatment

The outcome of children with ADHD has been the focus of several follow-up studies that have largely dispelled the myth that children with

ADHD outgrow their disorder in adolescence and adulthood. Initial studies suggested that approximately 31% of hyperactive children continue to show the full syndrome as adolescents (Gittelman, Mannuzza, Shenker, & Bonegura, 1985). However, more recent research suggests that as many as 50–80% of children diagnosed with ADHD in childhood will continue to show symptoms into adolescence and 30–50% will show symptoms into adulthood (Barkley, 1998; Biederman, 1998). It has been argued that the primary symptoms of ADHD tend to become less debilitating in adolescence and that overt hyperactivity becomes manifested as an internal sense of restlessness (Barkley, 1990; Cantwell, 1996). However, more recent studies have shown that children and adolescents referred to clinics present with similar symptom profiles (Biederman et al., 1998). In addition, Barkley (1998) argues that the apparent decrease of symptomatology and the reduced prevalence of ADHD in adolescence may be related to problems with the diagnostic criteria, rather than to actual changes in the prevalence of the disorder.

Regardless of whether the actual symptomatology decreases or changes over development, several studies have shown that adolescents and adults with ADHD continue to exhibit a number of adjustment problems (Hechtman, 1996), including academic and occupational difficulties, difficulties in relationships, low self-esteem, and higher rates of psychopathology (Weiss & Hechtman, 1993). Antisocial and delinquent behavior is one type of adjustment problem that is especially prevalent in adolescents and young adults with ADHD; from 23–45% are diagnosed with antisocial personality disorder (Gittelman et al., 1985; Loney et al., 1983; Weiss, Hechtman, Milroy, & Perlman, 1985), and 40% have been arrested (Mannuzza et al., 1989). There is some evidence that the risk for antisocial behaviors in adolescence and adulthood may be more related to the frequent presence of conduct problems or aggressiveness in these children (August, Stewart, & Holmes, 1983; Hechtman, 1996; Gittelman et al., 1985; Loney et al., 1978).

The most common form of intervention for children with ADHD is the use of medication, typically a central nervous system (CNS) stimulant such as methylphenidate (Ritalin), dextroamphetamine (Dexedrine), Pemoline (Cylert), methamphetamine (Desoxyn), or amphetamine salts (Adderall) (Pelham, 1987, Sallee & Gill, 1998). These drugs decrease the rate of many of the disruptive

behaviors associated with ADHD; positive effects are most marked in measures of attention and activity and, to a lesser extent, in conduct problems (Barkley & Cunningham, 1979; Sallee & Gill, 1998; Solanto & Conners, 1982). Furthermore, stimulants increase in-task classroom behavior, improve peer status, and improve performance in academic tasks in some children with ADHD (Pelham, Bender, Caddell, Booth, & Moorer, 1985; Whalen et al., 1989). Stimulants show an immediate beneficial response in approximately 70% of ADHD children. However, they have not proven effective in altering the long-term prognosis of ADHD children (Conners & Werry, 1979; Findling & Dogin, 1998; Pelham et al., 1998; Riddle & Rapoport, 1976).

In addition to stimulant medication, clinical researchers have investigated several psychosocial treatments for ADHD. One of the most promising of these treatments is behavioral parent training and classroom behavior management (see Pelham et al., 1998). These programs focus on helping parents and teachers design and implement very structured and consistent behavioral management programs that (1) set clear behavioral goals for the child, (2) have a clear monitoring system to assess progress toward these goals, and (3) have a structured set of consequences designed to encourage behavioral goals and discourage negative behaviors (e.g., Barkley, 1997; Pfiffner & O'Leary, 1993). Cognitive-behavioral techniques have also been tested as treatment for children with ADHD, based on the assumption that ADHD children have failed to develop age-appropriate cognitive strategies that help to regulate their behavior. Unfortunately, controlled outcome studies on the effects of cognitive-behavioral techniques with ADHD children have found significant effects on laboratory measures of attention and impulsivity but little generalization to either home or school behavior (Abikoff, 1985; Richters et al., 1995).

Although both stimulant medication and behavioral programs have proven effective in treating ADHD, a multimodal treatment approach combining treatment approaches may be the most effective approach to intervention. Several investigators have shown that children with ADHD who receive multimodal treatment strategies do not differ from normal classmates following treatments (Gittelman-Klein et al., 1980), require lower doses of psychostimulants (Horn & Ialongo, 1988), and may show a lower rate of teenage arrest than those treated only with medication (Satterfield,

Satterfield, & Schell, 1987). However, more data are needed on the potential synergistic effects of different treatments for ADHD to determine the optimal combination of treatment approaches (Arnold et al., 1997; Richters et al., 1995).

Disruptive Behavior Disorders

Overview

Antisocial and aggressive behavior is another common reason that children and adolescents are referred to mental health clinics (Kazdin, Siegel, & Bass, 1990). One of the most critical aspects to understanding these behaviors is the recognition that children who show these behaviors can differ dramatically in the causes, course, and response to treatment. As a result, a significant amount of research has focused on defining meaningful subgroups of children with Disruptive Behavior Disorders. One of the main distinctions made in the DSM-IV is between Oppositional Defiant Disorder (ODD) and Conduct Disorder (CD) (American Psychiatric Association, 1994). ODD is defined as a pattern of negativistic, hostile, and defiant behavior, whereas CD is a persistent pattern of behavior in which the basic rights of others and/or major societal norms or rules are violated. These CD symptoms fall into four categories: aggression to people or animals, destruction of property, deceitfulness or theft, and serious violation of rules.

The distinction between ODD and CD is not based simply on severity, but there is also a developmental and hierarchical relation between these disorders, that is, ODD symptoms often precede the development of CD in prepubertal boys. For example, in a 4-year longitudinal study of boys (ages 6 to 13) who developed CD, the vast majority (82%) had a diagnosis of ODD in the previous year (Lahey et al., 1995). Importantly, there is an asymmetry to this relation. Although most children who develop CD show ODD in previous years, less than half of children with ODD (47%) progress to the more serious CD (Lahey et al., 1995). The link between ODD and CD also holds only for children who develop CD prior to adolescence; those who show a later onset to their CD are less likely to show this progression of conduct problems from ODD to CD (Hinshaw, Lahey, & Hart, 1993).

This difference in development progression between childhood and adolescent-onset patterns of CD was a major consideration in the adoption of a further subtyping of CD by the DSM-IV. The DSM-IV recognizes a childhood-onset type of CD in which the serious symptoms of CD onset before age 10, usually as a culmination of a process that began early in life in which the child progresses into more and more severe types of conduct problems over time (Lahey & Loeber, 1994). The adolescent-onset type of CD, in contrast, is defined by a later development of CD symptoms (on or after age 10) without clear signs of dysfunction before puberty.

In addition to the DSM-IV approach, there have been several other methods for dividing children with CD into more homogeneous subtypes. For example, a distinction has been made based on whether the child (1) can sustain social relationships and tends to commit antisocial behavior with other deviant peers (socialized or group type) or (2) cannot sustain social relationships and commits antisocial acts alone (undersocialized or solitary type) (Quay, 1986). Distinctions have also been made as to whether the child shows primarily aggressive or primarily nonaggressive symptoms of CD (Hinshaw et al., 1993). Some approaches to subtyping children with CD also have been based on the co-occurrence of other disorders. For example, Lynam (1996) suggested that the presence of ADHD with CD results in a distinct subtype of CD, and others have suggested that the presence or absence of anxiety disorders may designate important subtypes of children with CD (McBurnett et al., 1991; Walker et al., 1991).

Another promising approach to dividing children with CD into subtypes is based on the presence of a callous and unemotional interpersonal style that has been used to designate psychopathy in adults. Psychopathic traits are characterized by pathological egocentricity, an absence of empathy, an absence of guilt, superficial charm, shallow emotions, an absence of anxiety, and the inability to form and sustain lasting and meaningful relationships (Cleckley, 1976; Hare, 1994; McCord & McCord, 1964). These traits are only moderately correlated with ODD and CD symptoms in children (Frick, O'Brien, Wootton, & McBurnett, 1994), and more importantly, designate a very severely disordered group of children within the childhood-onset type of CD. For example, children with CD and callous and unemotional traits

tend to show a greater number and variety of antisocial behaviors (including aggression), they have a higher rate of police contacts at a young age, and they have a stronger family history of criminal and antisocial behavior than other children with CD (Christian, Frick, Hill, Tyler, & Frazer, 1997). Furthermore, the most severe and violent juvenile offenders (i.e., violent sex offenders) tend to show high rates of these callous and unemotional traits (Caputo, Frick, & Brodsky, *in press*).

Epidemiology

The prevalence of antisocial and aggressive behavior depends on a number of factors, including the number and severity of problem behaviors, the age group studied, and the sex of the child. To illustrate the relation with severity, a longitudinal study conducted in Dunedin, New Zealand, reported that almost all (94%) of the adolescents who participated in the study admitted engaging in some illegal behavior (e.g., underage drinking, using fake ID's), but only 6% showed severe enough antisocial behavior to be arrested by the police, and only about 7.3% met criteria for a disruptive behavior disorder (McGee et al., 1992; Moffitt, 1993).

To illustrate changes across different age groups, it has been estimated that the prevalence of serious oppositional conduct problems in preschoolers is from 4–9% (Cohen et al., 1987). In elementary school-aged children, the prevalence of ODD is within a similar range of 6–12% (Anderson et al., 1987; Bird et al., 1988; Cohen et al., 1993; Costello et al., 1988; Shaffer et al., 1996), but it is estimated that more severe conduct disorders are present in only about 2–4% of school-age children (Anderson et al., 1987; Costello et al., 1988; Shaffer et al., 1996). In adolescence, the rates of both ODD and CD show a dramatic rise; estimated rates of ODD are as high as 15% (Cohen et al., 1993), and the rate of CD is estimated at from 6–12% (McGee et al., 1992).

The final factor that influences the prevalence of these disorders is gender. Overall, boys tend to show more conduct problems than girls. However, this is moderated somewhat by age. For example, school-age boys outnumber girls with CD at a ratio of about 4:1 (Anderson et al., 1987; Cohen et al., 1993; Offord et al., 1987). Estimates in adolescent samples also show male predominance, but

the ratio drops to about 2:1 (Cohen et al., 1993; Offord, Adler, & Boyle, 1986). Some studies have even found an equal sex ratio of CD in adolescence (McGee et al., 1992). It is also clear that the male predominance of CD is much greater for aggressive and violent antisocial behavior and much less for nonaggressive behaviors (McGee et al., 1992) or for relational aggressive behaviors (e.g., excluding children from play groups, spreading rumors about children so that they are rejected by others) (Crick & Grotpeter, 1995).

Comorbid Disorders

ADHD is by far the most common comorbid diagnosis for children with ODD or CD; rates of ADHD range from 65% (Stewart, Cummings, Singer, & deBlois, 1981; Trites & Laprade, 1983) to 90% (Abikoff & Klein, 1992) for clinic-referred children diagnosed with these disorders. Although there is no widely accepted explanation to account for this overlap between these disorders, their comorbidity is quite important for several reasons. First, the presence of ADHD in children with ODD or CD leads to more severe behavior problems. Children with CD who also show ADHD have a greater number of conduct problem symptoms, have an earlier age of onset of severe conduct problems, show more aggressive conduct problems, and show earlier and greater substance use than children with CD who do not have ADHD (Loeber, Brinthaup, & Green, 1990; Thompson, Riggs, Mikulich, & Crowley, 1996; Walker, Lahey, Hynd, & Frame, 1987). Second, the presence of ADHD in children with CD predicts greater risk of poor adjustment in adolescence and adulthood. Specifically, children with CD and ADHD carry out a greater variety of delinquent acts in adolescence, show more severe aggression in adolescence, and show more violent offending in adulthood than children with CD but without ADHD (Klinterberg, Andersen, Magnusson, & Stattin, 1993; Loeber et al., 1990; Moffitt, 1993).

Learning disabilities are another frequent comorbidity in children with severe conduct problems (Cantwell & Baker, 1992; Rutter, Tizard, Yule, Graham, & Whitmore, 1976). There are many explanations for this link, and there is some evidence that the learning problems are more related to the ADHD which is frequently comorbid with conduct problems, rather than to the conduct problems themselves (Frick et al., 1991; Maughan,

Pickles, Hagell, Rutter, & Yule, 1996). However, this explanation applies largely to children in the childhood-onset group; some children with learning disabilities develop conduct problems in adolescence without an early history of ADHD or other behavior problems (Hinshaw, 1992).

Children with severe conduct problems also show high rates of emotional disorders, such as depression and anxiety. From 15–31% of children with CD have comorbid depression and from 22–33% of children in community samples and between 60–75% in clinic samples have comorbid anxiety disorder (Russo & Biedel, 1994; Zoccolillo, 1993). One important issue in this comorbidity between conduct problems and emotional disorders is that children with CD and depression are at increased risk of suicidal ideation. For example, in a community sample of seventh and eighth grade students, 31% of the children with CD and depression reported suicidal ideation compared to only 12% of the students with CD only (Capaldi, 1992). Also, for many children with CD, the presence of anxiety and depression largely results from interpersonal conflicts (e.g., with peers, teachers, and police) and other stressors (e.g., family dysfunction, school failure) that are often experienced by children with CD (Capaldi, 1992; Panak & Garber, 1992). As a result, the anxiety and depression experienced by these children is often best conceptualized as emotional distress or negative affectivity that results from their impaired psychosocial functioning (Frick, 1998a).

CD is also associated with alcohol and drug use. The comorbidity between CD and substance abuse is important because, when children with CD also abuse substances, they tend to show an early onset of substance use and they are more likely to abuse multiple substances (Lynskey & Fergusson, 1995). Although most of the research on the association between CD and substance abuse before adulthood has been conducted with adolescents, the association between conduct problems and substance use may begin very early in development. In an urban community sample ($n = 2573$) of children in the first, fourth, and seventh grades, substance use was fairly rare in first and fourth grade children (Van Kammen, Loeber, & Stouthamer-Loeber, 1991). When it did occur in these early grades, however, it was usually associated with the presence of significant conduct problems. In the seventh grade, substance use became more

common, especially the use of milder substances like alcohol. However, the use of harder drugs and the use of multiple drugs were associated with CD. Therefore, CD is associated with *nonnormative substance use* throughout childhood and adolescence.

Etiology

A number of different factors, both within children and within their psychosocial contexts, have been associated with conduct problems in research (see Frick, 1998b for a review). For example, several aspects of a child's family environment have been consistently associated with CD and ODD (see Frick, 1994; Loeber & Stouthamer-Loeber, 1986 for reviews). These include higher rates of parental psychopathology, especially substance abuse and antisocial disorders, higher rates of divorce and marital conflict, and dysfunctional parenting practices (e.g., low parental involvement, poor monitoring and supervision, and harsh or inconsistent discipline practices). Children with CD also tend to be rejected and isolated by peers (Coie, Dodge, & Kupersmidt, 1990). As a result of this peer rejection, the child does not experience the socialization of prosocial peers in developing nonaggressive and nonaversive means of interacting with others. It also places a child at risk of associating with other antisocial and rejected peers (Keenan, Loeber, Zhang, Stouthamer-Loeber, & Van Kammen, 1995). Another aspect of a child's psychosocial context that has been related to conduct problems is living in economically impoverished circumstances that limit a child's chances of advancing educationally, occupationally, or socially (Wilson, 1987).

In addition to these aspects of a child's psychosocial context, there are individual vulnerabilities within the child that have been associated with ODD and CD. For example, research has documented a number of neurological correlates to CD. Antisocial children have lower levels of serotonin (Kreusi et al., 1990), lower levels of epinephrine (Magnusson, 1988; Olweus, Mattesson, Schalling, & Low, 1988), and higher levels of testosterone (Olweus et al., 1988; Scerbo & Kolko, 1994) than other children. In addition, studies have found abnormalities in the central nervous system functioning of children with CD by using skin conductance measures (Schmidt, Solanto, & Bridget, 1985), heart rate measures (Raine, Venables, &

Williams, 1990), and event-related electroencephalographic potentials (Raine et al., 1990). In their summary of this literature, Lahey, McBurnett, Loeber, and Hart (1995) concluded that most of these biological correlates are interrelated and may reflect a small number of physiological processes related to abnormalities in the sympathetic arm of the autonomic nervous system.

These autonomic irregularities may underlie some of the unique temperamental features found in children with conduct problems. As already mentioned, children with ODD and CD are more likely to have significant problems in impulse control and response inhibition, as reflected by the high rate of ADHD. They also are more likely to show a preference for thrill- and adventure-seeking activities (Frick et al., 1994) and to show a reward-dominant response style in which their behavior is more responsive to cues of reward than to punishment (O'Brien & Frick, 1996; O'Brien, Frick, & Lyman, 1994). Children with CD are also more likely to show a number of neurocognitive deficits, including lowered overall IQ and other more specific cognitive deficits, such as deficits in their verbal abilities and in their executive functioning (Lynam, 1996; Moffitt, 1993). Finally, children and adolescents with severe conduct problems often show social information-processing deficits that make them more likely to respond aggressively in interpersonal contexts. Social information processing is the sequential steps that are involved in interpreting social information and choosing appropriate responses based on this interpretation (see Crick & Dodge, 1996; Dodge & Frame, 1982).

In much of the past research, there has been little attempt to go beyond the documentation of these many factors in children and in their psychosocial environments that are associated with ODD and CD. The most common model for viewing these correlates has been from a "cumulative risk" perspective in which the development of ODD and CD is seen as a function of the number of risk factors to which a child is exposed. In recent years, however, there has been an attempt to develop more sophisticated developmental models for the causes of ODD and CD that consider the potential for different causal pathways underlying these disorders. For example, research has illustrated that childhood-onset and adolescent-onset patterns of CD have very different correlates that could suggest the operation of different causal

mechanisms (see Frick, 1998b; Moffitt, 1993). Specifically, the childhood-onset group exhibits higher rates of cognitive and neuropsychological dysfunction and family dysfunction than the adolescent-onset group. As a result, the childhood-onset group has a more characterological disorder that involves the "juxtaposition of a vulnerable and difficult infant with an adverse rearing context that initiates ... a transactional process in which the challenge of coping with a difficult child evokes a chain of failed parent-child encounters" (Moffitt, 1993, p. 682). In contrast, the adolescent-onset group is viewed as more of an exaggeration of the normative developmental process of separation and individuation that characterizes adolescence (Moffitt, 1993).

There is evidence to suggest that there may even be another pathway that can be identified within the childhood-onset category, based on the presence or absence of callous and unemotional traits (see Frick, 1998b for a review), that is, children with callous and unemotional traits show a more severe pattern of behavior, as mentioned previously, and they also show several other characteristics that differentiate them from other children with CD. For example, children in this group are more likely to show autonomic irregularities (Lahey et al., 1991), a thrill- and adventure-seeking or fearless temperament (Frick et al., 1994), and a reward-dominant response style (O'Brien & Frick, 1996) than other children with CD. However, they are *less* likely to be impaired intellectually (Christian et al., 1997), and their behavior is less strongly associated with dysfunctional parenting practices (Wootton et al., 1997). Therefore, this group shows a temperament defined by low behavioral inhibition that is characterized physiologically by a higher threshold of reactivity in their autonomic nervous system functioning and behaviorally by low fearfulness to novel or threatening situations and poor responsiveness to cues to punishment (Kagan & Snidman, 1991; Rothbart, 1989). This temperament can influence the development of guilt and empathy in children (see Kochanska, 1993, for seven different theories to account for this link) and may make these children less susceptible to parental attempts at socialization.

Using callous and unemotional traits to designate a distinct group of children with conduct disorders could explain some of the diversity within the childhood-onset pattern of conduct disorders. However, all of these models have substan-

tial limitations when attempting to account for the development of severe antisocial behavior in girls (Silverthorn & Frick, 1999). As was evident from the age and sex trends in the prevalence of CD, girls with CD often show an adolescent-onset to their antisocial behavior, as reflected by the decrease in the male predominance of the disorder in adolescence. However, despite the later onset, girls with CD have many characteristics that make them similar to boys with childhood-onset CD, such as a chronic course with poor adult outcomes, high rates of neuropsychological and cognitive deficits, and high rates of family dysfunction. As a result, Silverthorn and Frick (1999) described the developmental pattern in girls as a "delayed-onset" trajectory to illustrate that these girls are likely to show temperamental and environmental vulnerabilities throughout most of their lives, but they do not manifest overt antisocial and aggressive behavior until adolescence.

Prognosis and Treatment

Recently, Frick and Loney (in press) reviewed twenty-one prospective longitudinal studies that documented both the short term ($n = 12$; more than 8 months to 6 years) and long term ($n = 9$; 7 to 30 years) stability of CD in children and adolescents. From these studies, there is evidence for substantial stability across many types of samples, many different definitions of CD, and many different methods for estimating stability. For example, during a 4-year period, from 45–50% of children with CD can be rediagnosed with the disorder (Lahey et al., 1995; Offord et al., 1992). Longitudinal studies that followed children with CD into adulthood found that from 43–64% of boys and approximately 17% of girls with CD were arrested for criminal behavior by adulthood and about 31% of boys and 17% of girls were diagnosed with antisocial personalities as adults (Krazter & Hodgins, 1997; Robins, 1966).

Frick and Loney (in press) provided evidence that even these substantial stability estimates may underestimate the true level of stability of severe conduct problems due to a number of methodological factors, such as a failure to use measures that capture varying manifestations of CD across development, reliance on single follow-up assessments that do not capture the fluctuating severity of symptoms over time, and failure to control for measurement error in the estimates of

stability. More importantly, a substantial degree of stability is accounted for by a small proportion of childhood CD. For example, about 5% of the most persistent juvenile offenders account for about 50% of reported crimes (Farrington, Ohlin, & Wilson, 1986), and the stability of CD is dramatically reduced when the most persistent 5% of children with CD are excluded from the estimates (Moffitt, 1993). Variables that predict persistence in children with CD are displaying a large number and multiple types of CD symptoms in multiple settings, developing CD symptoms at an early age (prior to adolescence), and having a comorbid diagnosis of ADHD (Frick & Loney, in press).

Given the stability of CD, the development of effective prevention and treatment programs becomes quite important. Four interventions have proven effective in treating children with ODD and CD in controlled outcome studies (Frick, 1998b). These include structured contingency management programs based on operant principles, parent management training (PMT) programs that teach parents how to develop and implement very structured contingency management programs in the home and that teach them how to change other family processes (e.g., poor supervision) related to conduct problems, and cognitive-behavioral interventions that help children with CD to overcome deficits in social cognition and deficits in social problem-solving that can lead to their behavior problems. In addition, because a substantial proportion of clinic-referred children with CD also show ADHD and because the impulsivity associated with ADHD may directly lead to some of the aggressive and other poorly regulated behaviors of children with CD, the use of stimulant medication in reducing the ADHD symptoms also leads to a reduction in the rate and severity of conduct problems in children with both ADHD and CD (Hinshaw, 1991; Hinshaw, Heller, & McHale, 1992; Pelham et al., 1993).

Although each of the four treatment approaches has proven effective in controlled outcome studies, research has also documented substantial limitations in their effectiveness for older children, who have more severe conduct problems and are from more dysfunctional family environments (Frick, 1998b). Furthermore, the treatment gains made by these interventions have not always been sustained over time. As a result, some of the more promising approaches to treatment use more comprehensive interventions that simultaneously tar-

get multiple processes that could lead to conduct disorders, such as the Families and Schools Together (FAST Track) Program (Conduct Problems Prevention Research Group, 1992). Many of these comprehensive approaches, such as Multi-Systemic Therapy (MST) (Henggeler & Borduin, 1990), are also designed to be flexible in their implementation, in which the comprehensive intervention is tailored to the needs of the individual children and their families. The success of MST (see Borduin et al., 1995; Henggeler, Melton, & Smith, 1992; Henggeler, Schoenwald, & Pickrel, 1995) illustrates that successful treatment of CD does not involve simply selecting one "best" intervention and implementing it for all children and adolescents with the disorder. Rather, it illustrates that successful intervention must address the various factors that contribute to the child's antisocial behavior and it must be tailored to the needs of the individual child (see Frick, 1998b, for a general intervention framework).

Anxiety Disorders

Overview

The DSM-IV (American Psychiatric Association, 1994) has child-specific criteria for only one anxiety disorder, Separation Anxiety Disorder. Several other anxiety disorders are frequently diagnosed in childhood and adolescence, including Generalized Anxiety Disorder, Social Phobia, Specific Phobia, Obsessive-Compulsive Disorder, Panic Disorder, Agoraphobia, Posttraumatic Stress Disorder, and Acute Stress Disorder. However, children are diagnosed for these disorders using the same criteria as those used for adults. This is a major change from past versions of the DSM (DSM-III and DSM-III-R; American Psychiatric Association, 1980, 1987) in which there were two additional anxiety disorders with child-specific criteria. The first was Avoidant Disorder which focused on excessive shrinking from contact with unfamiliar persons or extreme shyness. The second diagnosis was Overanxious Disorder which focused on a chronic and generalized pattern of anxious behavior across a number of situations. These diagnoses were eliminated because it was thought that the constructs were adequately captured by the adult Social Phobia criteria (Avoidant Disorder) and the criteria for Generalized Anxiety

Disorder (Overanxious Disorder) (American Psychiatric Association, 1994).

Separation Anxiety Disorder (SAD), the one anxiety disorder with child-specific criteria, is characterized by anxiety for at least 2 weeks over separation from a major attachment figure. During the course of development, there are changes in the way this anxiety is expressed. For example, Francis, Last, and Strauss (1987) found that young children (ages 5–8) with SAD were more likely to report nightmares that involved separation, worry about attachment figures, and worry about calamitous events happening to themselves. Older children (ages 9–12) with SAD were more likely to report excessive distress upon separation from major attachment figures, including withdrawal, apathy, sadness, and poor concentration. Adolescents (ages 12–19) with SAD often presented with refusal to attend school and physical symptoms when confronted with separation.

From this description of the symptoms of SAD, it is evident that some children and adolescents with SAD can express their concerns about separation through refusal to attend school. For these children, the refusal to attend school is precipitated by fear of leaving the caretaker or home. Other children with school phobia refuse to attend school because of an actual fear of school or some aspect of the school situation. In both cases, the child or adolescent expresses specific or vague fears associated with school or presents with somatic complaints as an explanation for avoiding school (Kearney, 1995). However, when children who refuse to attend school as a result of SAD are compared to children who refuse to attend school due to a school phobia, those with SAD tend to be younger, female, from lower socioeconomic families, from single parent families, have another comorbid disorder, and have mothers with a history of an anxiety or affective disorder (Last, Francis, Hersen, Kazdin, & Strauss, 1987; Last & Strauss, 1990).

Unlike SAD in which the anxiety is somewhat circumscribed around a common theme (e.g., separation from a major attachment figure), Generalized Anxiety Disorder (GAD) is characterized by anxiety around a large number of different events, such as worry about future events (e.g., upcoming tests), anxiety about being criticized or making mistakes, worry about social activities, and worry about school performance (Last, Francis, & Strauss, 1989). Children with GAD are also

perfectionistic and self-conscious and report a high rate of somatic complaints (e.g., heart palpitations, feelings of shakiness) (Biedel, Christ, & Long, 1991). Given the diversity of anxiety symptoms that they exhibit, it is not surprising that one-half of the children with GAD also exhibit another anxiety disorder (Last, Hersen, Kazdin, Finkelshtein, & Strauss, 1987).

Social Phobia is another common anxiety disorder in children that is characterized by extreme performance anxiety or evaluative anxiety in social situations. Children with Social Phobia fear that they will be humiliated or embarrassed in these situations. In recent years, it has been recognized that children with Social Phobia can have more generalized forms of social anxiety in which their anxiety is shown in most social situations or more circumscribed social fears are displayed only in discrete situations (e.g., at parties) (American Psychiatric Association, 1994). Like children with GAD, children with Social Phobia often also have somatic complaints. In fact, Biedel et al. (1991) reported that 50% of their sample of children (ages 6–13) with School Phobia endorsed feelings of nausea, shakiness, heart palpitations, sweating, flushes and chills, and feelings of going crazy.

As the name implies, Specific Phobia refers to a discrete fear focused on a specific stimulus. For example, the DSM-IV recognizes five types of specific phobias that involve (1) fears of animals; (2) environmental fears (e.g., heights, storms, darkness, water); (3) fears of blood, shots, or bodily injury; (4) fears that involve specific situations (e.g., airplanes, cars, elevators); and (5) miscellaneous fears (e.g., loud noises, costumed figures). An important consideration in viewing phobias in children is that mild fears are relatively common in childhood years. In fact, most children experience some fears (Campbell, 1986; Muris, Meesters, Merckelbach, Sermon, & Zwakhalen, 1998), and the most common types of fears change over development in a predictable manner related to the tasks of a given developmental stage (Bauer, 1976). However, phobias, which by definition have to be severe enough to cause significant impairments for the child, are not normative in children and can be quite stable over time (Ollendick & King, 1994).

There has recently been increased awareness that children may respond acutely to exposure to traumatic and life-threatening events, similar to adults who experience Acute Stress Disorder

(ASD) or Posttraumatic Stress Disorder (PTSD; Eth & Pynoos, 1985). For example, one study investigated elementary school-age children's reaction to a sniper attack on their school yard in which a child and passerby were killed and 13 other children were injured (Pynoos et al., 1987). These authors reported finding three classes of responses exhibited by children. One (intrusiveness/numbing/avoidance) involved intrusive thoughts, a wish to avoid feelings and anhedonia; a second (fear/anxiety) involved fears of reoccurrence and being jumpy or easily startled; and a third class (disturbances in sleep/concentration) involved bad dreams, difficulty paying attention, and sleep disturbance. The most significant variable that influenced the occurrence of a posttraumatic stress reaction was the level of exposure to the traumatic event (e.g., being in the school yard at the time of the shooting vs. being home from school and hearing about the shooting). Knowledge of the victims was also associated with a stress reaction, whereas sex, age, ethnicity, exposure to recent previous trauma, and worry about a sibling were not significantly associated with the severity of the reaction.

Epidemiology

Silverman and Ginsburg (1998) provide an excellent review of the prevalence of anxiety disorders in children across ten epidemiological studies conducted from 1987–1993. Overall, rates of anxiety disorders ranged from 6–18% across the samples; the most common disorders were SAD (3–12%) and GAD (3–12%). Interestingly, there is little evidence for consistent relations between anxiety disorders and sociodemographic variables, such as socioeconomic status, ethnicity, and gender. To illustrate the inconsistency of the findings, Cohen et al. (1993) found an almost equal gender ratio in the prevalence of SAD and GAD in a large community sample of children, whereas Anderson, Williams, McGee, and Silva (1987) found a female predominance for SAD (0.4:1) but a male predominance for GAD (1.7:1). The failure to find consistent gender differences is still somewhat striking, however, given the clear female predominance of anxiety disorders in adults.

Comorbidity

In the previous sections, we reviewed the literature on the comorbidity between anxiety disorders and ADHD and between anxiety disorders and

CD/ODD. Similar to the high rates of comorbidity between the externalizing disorders (i.e., ADHD, CD, and ODD), there is also a high rate of comorbidity within the internalizing disorders of anxiety and depression. Studies of clinic-referred children have reported that between one-third and one-half of children diagnosed with an anxiety disorder also have a depressive disorder (Bernstein & Garfinkel, 1986; Strauss, Last, Hersen, & Kazdin, 1988). As for externalizing disorders, this high rate of comorbidity has led some researchers to question the utility of distinguishing between these emotional disorders and to consider the possibility of a single category of "negative affectivity" or internalizing disorders (see Finch, Lipovsky, & Casat, 1989). Also similar to the research on the comorbidity among externalizing disorders, there are some important differences in children with both anxiety and depression: these children tend to be older, tend to exhibit a more severe disturbance, and tend to be more socially impaired than children with anxiety disorders alone (Mitchell, McCauley, Burke, & Moss, 1988; Strauss, Last et al., 1988).

Anxious children may have difficulties in two other areas, school achievement and social interactions. For example, Strauss, Frame, and Forehand (1987) reported that teachers rated children with anxiety disorders as having more deficits in performance than nonanxious children, and Reeves, Werry, Elkind, and Zimetkin (1987) reported that children with anxiety disorders were somewhat more likely to underachieve on achievement test scores (20–29%), compared to nonanxious controls (5–10%). Anxious children are also neglected by their peers, signifying difficulties in their ability to make friends (Strauss, Lahey, Frick, Frame, & Hynd, 1988), and are described by parents and teachers as lonely, lacking appropriate social skills, shy, and socially withdrawn (Strauss, Lease, Kazdin, Dulcan, & Last, 1989).

Etiology

For many decades, behavioral and social learning conceptualizations dominated etiological theories of anxiety disorders (see Menzies and Clark, 1995 for a review). Many of these theories were developed from basic classical conditioning paradigms that focused on a child who acquires a feared response to a stimulus that is consistently paired with a noxious and aversive event. Many of these basic paradigms were extended to consider

cognitive expectancies involved in the pairing of an unconditioned stimulus to a noxious event (e.g., a child expects a stimulus to lead to an aversive outcome) (see Reiss, 1991) and to consider the reinforcing aspects of avoiding the anxiety-producing stimulus to enhance and maintain the anxious behavior (Mowrer, 1939). In addition to models based on classical conditioning, other models focused on operant conditioning have been proposed and are supported by research that shows that parents often deliver positive reinforcement for anxious behavior, such as providing special considerations for their children's anxious behavior, that could serve to maintain this maladaptive behavior (Ayllon, Smith, & Rogers, 1970; Kennedy, 1965). Finally, social learning theorists have provided evidence that modeling can be a powerful influence in developing and maintaining anxious behavior (Bandura & Menlove, 1968).

Although these social learning theories remain influential in explaining the development of anxiety disorders, more recent models have begun to integrate genetic/biological and cognitive factors. The role of heredity has been supported by a number of family history studies that show that mothers of children with anxiety disorders also tend to have histories of anxiety disorders (Last, Hersen, Kazdin, Francis, & Grubb, 1987; Reeves et al., 1987). Although these studies do not indicate whether the transmission across generations is by genetic or environmental mechanisms, some evidence from behavioral genetic studies indicates that there is a heritable component in at least the more severe types of anxiety disorders in children (Rutter, 1976). This leads to the logical question of how this transmission takes place.

The work of Kagan and colleagues on the temperamental style called "behavioral inhibition to the unfamiliar" could provide some clues to this transmission (Kagan, Reznick, Clarke, Snidman, & Garcia-Coll, 1984). These authors found that children as young as 21 months could be classified as either behaviorally inhibited or behaviorally uninhibited; inhibited children show a tendency to avoid novel and unfamiliar stimuli and situations (e.g., new toys, new children, strange adults). This is the opposite end of the continuum of the thrill- and adventure-seeking tendencies or behaviorally *uninhibited* styles of the callous and unemotional children with CD, described previously. Importantly, this behaviorally inhibited temperament has been associated with distinct biological markers related to a lower threshold of response or higher

“reactivity” of the sympathetic arm of the autonomic nervous system (Kagan, Reznick, & Snidman, 1987), and these physiological markers can be identified as early as 2 months of age (Kagan & Snidman, 1991).

Theoretically, this temperamental style could explain why some children are more easily “conditioned” to anxiety than others. Specifically, behaviorally inhibited children could become aroused to more stimuli and become more strongly aroused to these stimuli than other children, making them more likely to develop conditioned anxiety responses and making the avoidance of anxiety-producing stimuli more reinforcing. It also could explain the mechanism that is passed from parent to child in family history studies. In support of both these possibilities, children that are behaviorally inhibited to the unfamiliar during three assessment periods are at a higher risk of an anxiety disorder (Hirshfeld et al., 1992) and children of parents with anxiety disorders are at higher risk of being behaviorally inhibited (Rosenbaum et al., 1988).

The second trend for explaining anxiety disorders in children is to focus on cognitive factors that can relate to the development and maintenance of anxious behavior. For example, anxious children in general tend to interpret ambiguous information as threatening, are more likely to express avoidant plans when confronted with ambiguity, and show a tendency to assign higher probabilities to the potential occurrence of threatening events (Chorpita, Albano, & Barlow, 1996). Taken together, these findings suggest that anxious children tend to show a bias for interpreting events as threatening. Anxious children also use less positive self-statements in a large number of situations (Treadwell & Kendall, 1996). Many of these anxiety-related cognitive styles specifically relate to anxiety-producing stimuli, for example, test-anxious children anticipate more negative performance outcomes in testing situations (Prins, Groot, & Hanewald, 1994), and social phobic children are more likely to view social situations as threatening (Bell-Dolan, 1995). Although these negative cognitive styles are often viewed as predisposing a child to act anxiously to certain situations, the correlational nature of these studies make it impossible to determine the direction of influence. Therefore, it is also possible that these cognitive styles result from the child’s anxiety. It also appears that these cognitive styles can be influenced by processes within the family that encourage biased ways of processing information (Dadds, Barrett, Rapee, & Ryan, 1996).

Prognosis and Treatment

In discussing the prognosis of children with anxiety disorders, it is important to note that there is not nearly the same amount of longitudinal research conducted with anxious children as there has been for children with externalizing disorders like ADHD and CD. In addition, when follow-up studies are conducted, typically they do not provide stability estimates that are separate for anxiety and depression but provide estimates for internalizing behaviors in general (e.g., Verhulst & Ende, 1992) or for emotional disorders that combine both anxiety and depression (Offord et al., 1992). The follow-up periods for these disorders also tend to be relatively short; virtually no data are available on the adult outcome of children with anxiety disorders. Therefore, conclusions about the stability of anxiety disorders must be quite tentative (see Ollendick & King, 1998). However, the limited evidence available suggests that anxiety disorders may be more chronic than was once thought (Agras, Chapin, & Oliveau, 1972; Kohlberg, LaCrosse, & Ricks, 1972; Rutter, 1976).

This contention is based on several research findings. First, retrospective reports of adults with anxiety disorders suggest that many of these adults report an onset of their anxiety in childhood (Last et al., 1987). Second, although Verhulst, Koot, and Berden (1990) reported the stability coefficients only for internalizing behaviors or for a combined anxiety/depression scale for a 4-year period, they did report that the most stable symptom within these broader composites was the symptom, “Acts nervous or high strung.” Third, in the few studies that did report stability estimates for anxiety disorders separate from other emotional disturbances, the disorders tend to be fairly stable, especially for more generalized anxiety disorders like GAD. For example, in a sample of 151 children (ages 2–15) referred to a speech and hearing clinic, 50% of those children with a GAD diagnosis at initial testing were rediagnosed during a 4- to 5-year follow-up period. Similarly, Cohen, Cohen, and Brook (1993) reported that 47% of the children with GAD in a community sample of 734 children (ages 9–18) were rediagnosed with the disorder during a 2½-year follow-up period. Therefore, although these stability estimates are based on a limited amount of research, they suggest that anxiety disorders, especially GAD, are not as transient as was once thought.

A recent review of the literature on published treatment outcome studies of children with anxi-

ety disorders reported that the most successful treatments tended to be those based on behavioral and social learning conceptualizations of anxiety (Ollendick & King, 1998). Specifically, use of participant modeling and reinforced practice, use of *in vivo* and imaginal desensitization procedures, and use of various types of modeling approaches have proven effective for treating a large number of children with anxiety disorders. Unfortunately, these techniques have proven most effective in treating discrete forms of anxiety such as fears and phobias (Ollendick & King, 1998). One approach to enhancing the treatment for more generalized anxiety disorders has been the use of anxiolytic and other pharmacological medications. However, except for the treatment of childhood OCD (see Allen, Leonard, & Swedo, 1995), literature on the effectiveness of these treatments consists largely of uncontrolled clinical reports that make firm conclusions about the effectiveness of these interventions impossible.

One promising approach to the treatment of GAD is the cognitive-behavioral approach tested by Kendall and colleagues in two controlled outcome studies (Kendall, 1994; Kendall et al., 1997). The treatment specifically addresses the cognitive distortions that are often displayed by children with anxiety disorders combined with an exposure-based component that addresses the avoidance behavior that often maintains and reinforces anxious behavior. Specifically, the first sessions involve establishing a hierarchy of anxiety-producing events for the child and teaching the child a relaxation technique to use when exposed to these events. The next several sessions focus on teaching the child to recognize anxious feelings and somatic reactions to anxiety, to recognize cognitions leading to anxiety, to develop methods for modifying anxious self-statements (e.g., "I am going to fail this test"), to develop ways of evaluating performance in anxiety-producing situations, and to administer self-reinforcement for adaptive coping. Finally, both imaginal and *in vivo* exposure trials are conducted with the child, beginning with low anxiety-producing situations and progressing to high anxiety-producing situations, and the child is encouraged to use the skills taught in early sessions. In the two studies that tested the effectiveness of this intervention, 53–66% of the children (ages 9–13) did not meet criteria for a diagnosis of their pretreatment anxiety disorder at the end of the program, and these gains were maintained at a 1-year follow-up (Kendall et al., 1997).

These gains are impressive, given the past difficulties in treating generalized anxiety in children, but it is obvious that there is room to improve the effectiveness of this intervention. As mentioned previously, there is evidence that parents can play a role in reinforcing children's anxious behavior and in maintaining an anxious cognitive processing style. As a result, Dadds and colleagues attempted to enhance a cognitive-behavioral approach to treatment by adding a family component to the intervention that includes teaching parents (1) child management skills, (2) anxiety management skills, and (3) communication/problem-solving skills (Barrett, Dadds, & Rapee, 1996). These authors reported that a larger percentage of children who received the family intervention combined with the cognitive-behavioral intervention were free from an anxiety disorder at post-treatment (84 versus 57%) and at a 1-year post-treatment follow-up (96 versus 70%). A later study suggested that the critical component of this family intervention was the parent training in anxiety management techniques (Cobham, Dadds, & Spence, 1998).

Depressive Disorders

Overview

Today, there is little debate that clinical depression can be manifested in prepubertal children in ways similar to those of adults (Cantwell, 1983a; Quay, Routh, & Shapiro, 1987). However, this is a relatively new consensus (e.g., Lefkowitz & Burton, 1978; Rie, 1966). The DSM-IV (American Psychiatric Association, 1994) includes two types of major affective disorders, major depression and bipolar disorder. Because bipolar disorder rarely has onsets before puberty and because this disorder was discussed elsewhere in this book, our focus will be on Major Depression. In the DSM-IV, major depression is defined as a change from previous functioning that lasts at least 2 weeks and is characterized by either depressed mood (or irritable mood in children and adolescents) or anhedonia (loss of interest in usual activities) and at least four other vegetative symptoms (e.g., change in appetite, change in sleep patterns, psychomotor agitation or retardation, fatigue, feelings of worthlessness, diminished ability to concentrate, and suicidal ideation). In addition to episodic major depression, the DSM-IV also specifies a chronic mood disturbance labeled Dysthymic Disorder

and a category of adjustment disorder with depressed mood in which there is a reaction to an identifiable psychosocial stressor(s) and the primary manifestation is in the form of depressed mood, tearfulness, and feelings of hopelessness.

Despite the use of the adult criteria to diagnose depression in children and adolescents, there are some unique features of depression in youth. For example, depressed prepubertal children are more likely to show somatic complaints, psychomotor retardation, and depressive hallucinations, whereas depressed adolescents are more likely to show high levels of hopelessness, hypersomnia, and weight changes (Birmaher et al., 1996; Ryan et al., 1987). The overlap between anxiety and depression that was discussed previously is also greater for children than for adolescents and adults (e.g., Cole, Truglio, & Peeke, 1997; Hinden, Compas, Howell, & Achenbach, 1997).

Despite these developmental variations, the symptomatology exhibited by depressed children and adolescents is quite similar to that of adults with major depression. For example, in a study of ninety-five prepubertal children and ninety-two postpubertal adolescents with major depression, the most common symptoms for both groups were depressed mood (97%), anhedonia/lack of interest (88%), decreased concentration (86%), irritability and anger (83%), fatigue (81%), negative self-esteem (79%), insomnia (74%), social withdrawal (68%), psychomotor retardation (65%), suicidal ideation (60%), excessive or inappropriate guilt (52%), and anorexia (51%) (Ryan et al., 1987). Although it is quite rare, there are reports of depressive disorders in preschool children, and the symptomatology in this group is also relative consistent with that found in depressed adults. For example, in a small study of eight children ages 2–6 years diagnosed with major depression or dysthymic disorder, the most common symptoms were sadness/irritability (100%), concentration problems (100%), poor appetite (87.5%), low self-esteem (87.5%), sleep problems (75%), and fatigue (75%) (Kashani, Allen, Beck, Bledsoe, & Reid, 1997).

Epidemiology

Although changes in manifesting major depression are somewhat minor across development, there are dramatic changes in the prevalence of depressive disorders from preschoolers to adoles-

cents (Quay et al., 1987). Prevalence rates in community samples of preschool children are reportedly below 1%, whereas the rates in elementary school age children range from 2–4% (Anderson et al., 1987; Angold & Costello, 1993; Costello et al., 1997; McGee et al., 1992; Verhulst et al., 1997). In contrast, the prevalence of depressive disorders increases dramatically in adolescence to a rate of about 7% (Angold & Costello, 1993; McGee et al., 1992).

In addition to this clear jump in prevalence in depressive disorders in adolescence, there are two additional trends in the epidemiology of depressive disorders. First, there is considerable evidence of a cohort effect that operates for both adults and children; persons born more recently are significantly more likely to experience major depression than persons in older cohorts (Lewinsohn, Rohde, Seeley, & Fischer, 1993). Second, there are dramatic changes in the sex ratio of depressive disorders that coincide with the onset of puberty. In childhood, boys experience more depression than girls at about a 2:1 ratio (Angold & Costello, 1993; Angold, Costello, & Worthman, 1998; Rutter, 1990). In adolescence, however, this sex ratio changes; more girls report depression than boys at about a 2:1 ratio, and this ratio continues into adulthood. The shift in prevalence is due to an increased rate of depression in girls once they reach mid-puberty (Tanner stage 3) and a decreased rate of depression in boys once they reach puberty (Angold et al., 1998). One explanation for this change in the sex ratio of depression at adolescence suggests that girls have predisposing characteristics and risk factors that make them vulnerable to developing depression, and after the onset of puberty, depression develops in vulnerable individuals (Nolen-Hoeksema & Girgus, 1994).

Comorbidity

Like other childhood disorders, childhood depression tends to co-occur with other forms of psychological disturbance (Hammen & Compas, 1994), most often with anxiety disorders and conduct disorder. From 37–75% of children with depression also exhibit an anxiety disorder (Angold & Costello, 1993), although some estimates have been as high as 100% (Mitchell et al., 1988; PuigAntich, Blau, Marx, Greenhill, & Chambers, 1978; Ryan et al., 1987). Similarly, from 22–84% of children with depression also exhibit ODD or

CD (Angold & Costello, 1993). These rates of comorbidity depend somewhat on the type of depressive disorder. For example, children diagnosed with adjustment disorder with depressed mood show the least amount of overlap with other diagnostic groups; only 45% have an additional diagnosis (Kovacs, Feinberg, Crouse-Novak, Paulauskas, & Finkelstein, 1984a,b). In contrast, 79% of children with major depression had an additional diagnosis (38% with dysthymia, 33% with an anxiety disorder, and 7% with conduct disorder), and 93% of children with dysthymia had an additional diagnosis (57% with major depression, 36% with an anxiety disorder, 14% with an attention-deficit disorder, and 11% with conduct disorder).

Etiology

Evidence is strong that genetic factors play an important etiological role in primary affective disorders in adults (Cantwell, 1983b). However, this has not been well studied for childhood depression, and most of this research has relied on family history studies. For example, children with major depression are more likely to have higher rates of major depression, alcoholism, and other psychiatric disorders (mostly anxiety disorders) in both first- and second-degree relatives compared to control children (Puig-Antich et al., 1989). Although it is possible that the link between parent and child depression is through a genetic predisposition, it is also possible that the link is mediated by other forms of familial dysfunction (Puig-Antich et al., 1978). In addition, children of depressed parents have higher rates of many types of emotional and behavior disturbances (e.g., anxiety, conduct problems), suggesting that the link may be through a "nonspecific" vulnerability to problems in adjustment, not through a mechanism that is specific to depression (Birmaher et al., 1996).

The search for biological correlates to childhood and adolescent depression have typically yielded negative or inconclusive results. For example, there are often reports that depressed children and adolescents have higher rates of sleep problems and various neurochemical abnormalities than other children (e.g., Ryan et al., 1987). However, these neurochemical abnormalities are not consistently found across studies (see Birmaher et al., 1996 and Emslie, Weinberg, & Kowatch, 1998

for reviews). One of the more promising avenues of biological research focuses on differences in the brain activity of infants of depressed mothers. These infants show abnormalities in their frontal lobe activation which could underlie problems in their ability to regulate emotion and predispose them to affective disorders (e.g., Dawson, Frey, Panagiotides, Osterling, & Hessl, 1997).

One of the more consistent psychosocial correlates to depression in children is the presence of a high number of stressful life events ranging from severe stressors, such as parental death or divorce or the suicide of a friend, to milder stressful events such as a poor grade on a test, an argument with a parent or teacher, or a broken date (Birmaher et al., 1996). Although the presence of more stressful events are consistently found in depressed children, the reason for this association is not clear. It is possible that children who experience chronic uncontrollable stressors or who at least perceive that the stressors are uncontrollable, develop a "learned helplessness" attributional style that leads to depression (Seligman, 1975). This is a compelling model for explaining the correlation between stressful life events and depression, but it is also still possible that, possibly due to their problems in emotional regulation, depressed children put themselves at risk of experiencing more stressful life events than other children (Garber, Braafladt, & Zeman, 1991).

As in adult depression, however, many models to explain the development of depression in children focus on cognitive factors. Children who develop depression often show a negative cognitive style that involves low self-esteem, cognitive distortions (e.g., perfectionistic standards), a negative attributional style (e.g., attributing failures to internal, global, and stable factors), hopelessness, and excessive self-criticism (Dixon & Ahrens, 1992). However, there are two important issues that involve the association between these cognitive factors and depression in children. First, rather than leading directly to depression in children, these cognitions may form a predisposing way of interpreting information (i.e., a cognitive diathesis) that makes a child less likely to cope competently with life stressors (Garber, 1992). Second, the cognitive diathesis may not emerge until later childhood and adolescence, and therefore, it may not play as prominent a role in the development of depression in younger children (Turner & Cole, 1994).

Prognosis and Treatment

Despite early views that childhood depression is a transitory developmental phenomenon, current research suggests that major depressive disorders in children are as chronic as adult depression. For example, studies have shown that the average length of a major depressive episode in prepubertal children is 7–9 months, and it is approximately 2 years before 90% of children can expect to have complete remission of their symptoms (Kovacs et al., 1984a; Kovacs, Feinberg, Crouse-Novak, Paulauskas, Pollock, & Finkelstein, 1984b). In addition, the likelihood of a relapse is high; 40% of children relapse within 2 years, and 70% relapse within 5 years (Flemming et al., 1993; Lewinsohn et al., 1994). As one would expect, Dysthymic Disorder is even more chronic; the average duration is 3 years, and 69% of children develop a superimposed major depressive episode within a 5-year period (Kovacs et al., 1984a,b). Children with an adjustment disorder have the best prognosis; 90% recover within 9 months, and none develop a major depressive episode within a 5-year period (Kovacs et al., 1984a,b). Unfortunately, given this chronicity over a short period of time, data on the long-term outcome of children with a depressive disorder are limited.

Because pharmacological intervention for adult depression has had well-documented effectiveness, it is not surprising that this has been the focus of initial attempts to treat childhood depression. The most common treatment for children with major depression has been the use of tricyclic antidepressants and, more recently, selective serotonin re-uptake inhibitors (SSRI) (Emslie et al., 1998). Despite this widespread practice, most well-controlled studies have failed to find that either form of medication is more effective than placebo in double-blind medication trials (Puig-Antich et al., 1987). For example, a recent meta-analysis of all available placebo-controlled trials showed that the effectiveness of tricyclic antidepressant medications was too low to be clinically significant (Emslie et al., 1998), and similar results were reported for the newer SSRIs (Simeon et al., 1995). Much of the failure to document medication effectiveness in these controlled studies has not been due to the fact that children treated with medication do not show symptomatic improvement; it is more due to the fact that children in the placebo condition also show dramatic im-

provement although they are not on an active dose of medication (Emslie et al., 1997).

These findings suggest that expectancies for treatment success may play a major role in the treatment of childhood depression which has led to the development of cognitive-behavioral interventions that attempt to increase positive expectancies in depressed children and adolescents. For example, most of the psychosocial interventions focus on increasing the positive events experienced by children, directly altering negative cognitive styles, and teaching the children skills necessary to increase positive events in their lives (see Kaslow & Thompson, 1998). As an example of an intervention that combines all of these components, Lewinsohn, Clarke, Hops, and Andrews (1990) reported on a fourteen-session cognitive behavioral intervention for adolescents that involved increasing pleasant activities, training in relaxation exercises to cope with stressors, controlling depressive thoughts, improving social interactions, and developing conflict resolution skills.

All of these cognitive-behavioral interventions appear promising in that they have brought about positive changes in children's depressive symptomatology that have been maintained at follow-up intervals of 1–2 years (Kaslow & Thompson, 1998). However, most studies were conducted with nonreferred children and adolescents. Therefore, their effectiveness with clinic-referred children who are likely to experience more severe disturbances remains untested. Furthermore, there have been few studies comparing the effectiveness of interventions to determine the *relative* efficacy of various treatment approaches to childhood depression or whether a combination of treatments (e.g., medication combined with cognitive-behavioral interventions) lead to even greater treatment success than either intervention alone.

Autistic Disorder and Other Pervasive Developmental Disorders

Overview

Autistic disorder is a pervasive, stable disorder whose onset is prior to age 3 and is characterized by conspicuously abnormal or impaired social interactions, marked deficits in or absence of communication skills, and participation in an ex-

tremely restricted and repetitive range of activities and interests (American Psychiatric Association, 1994). Impaired development in social interest is characterized by severe deficits in reciprocal social interactions, including failure to use nonverbal behaviors (e.g., eye-to-eye gaze), failure to establish developmentally appropriate peer relationships, an inability to share experiences verbally or nonverbally (e.g., pointing to show an object), and a lack of reciprocal social or emotional interactions. Communication deficits include abnormal speech (e.g., echolalia, pronoun reversal), an inability to initiate or sustain conversations, or complete lack of communicative speech. Restrictive patterns of behaviors or interests include preoccupation with certain interests or activities, stereotypical motor movements (hand flapping), and rigid adherence to routines (American Psychiatric Association, 1994). In the DSM-IV, Autistic Disorder is one of five diagnoses listed under the heading of Pervasive Developmental Disorders. The others include Rhett's Disorder, Asperger's Disorder, Childhood Disintegration Disorder, and Pervasive Developmental Disorder Not Otherwise Specified.

Autism was first described in 1943 by Kanner who differentiated children with childhood-onset schizophrenia (Mesibov, Adams, & Klinger, 1997). One of the critical distinctions between autism and schizophrenia is the very early onset of autism; some studies show evidence of the disorder as early as 12 months (Osterling & Dawson, 1994) to 18 months of age (Baron-Cohen et al., 1996), and clear impairments are evident in the third year of life (Mesibov et al., 1997). Children with autism are often significantly impaired in many aspects of functioning; up to 77% of autistic children have IQ scores in the mentally retarded range of intellectual functioning (Gillberg, 1984), and proportionally more females than males are in the lowest range of intellectual functioning (American Psychiatric Association, 1994; Eme, 1992; Lord & Schopler, 1987). Children with autism often have better developed visual-spatial skills compared to their verbal skills (Mesibov et al., 1997). In fact, up to 50% of children with autism never develop communicative speech or language skills (Werry, 1996b). Both the general cognitive delay and the delay in verbal abilities are the key points in differentiating between Autistic Disorder and Asperger's Disorder which first appeared in the DSM-IV. Asperger's Disorders are defined by the presence of significant social impairments and a se-

verely restricted range of activities and interests, but no delay in language or cognitive development (American Psychiatric Association, 1994).

Other associated characteristics of autism include a variety of externalizing behaviors, such as aggressiveness, self-injurious behaviors, temper tantrums, hyperactivity, attention deficits, and impulsive behaviors (Mesibov et al., 1997). In addition, children with autism often exhibit sleep disturbances, eating problems, and severe anxiety to common household items, such as vacuum cleaners and blenders (Klinger & Dawson, 1996). Furthermore, sensory abnormalities, including overresponsiveness to some sounds and an intolerance to some tactile stimuli but extreme tolerance to pain, are also evident in many children diagnosed with autism (Schreibman & Charlop-Christy, 1998). Finally, approximately 20–30% of children eventually develop seizure disorders, typically in adolescence (Gillberg, 1991; Werry, 1996b).

In addition to Autistic Disorder and Asperger's Disorder, the DSM-IV lists three other pervasive developmental disorders. Considerable argument exists whether all of these disorders should be considered different diagnoses or variants of an autistic spectrum (e.g., Szatmari, 1997). As mentioned previously, Autistic Disorder and Asperger Disorders share many features that could support a relationship based on the severity of impairment between the two disorders. However, the other pervasive developmental disorders show quite distinct characteristics. For example, Rhett's Disorder is found only in females and is characterized by normal development for the first 5 months, followed by significant deterioration of previously acquired skills (language skills, hand movements, trunk movements), deceleration of head growth beginning between the ages of 5 and 48 months, and subsequent development of stereotypical hand movements (American Psychiatric Association, 1994). Childhood Disintegration Disorder, or Heller's Disorder, is characterized by normal development for the first 2 years of life, followed by a significant loss of skills before age 10 in at least two of five areas: language, social skills, elimination functions, play, and/or motor skills (American Psychiatric Association, 1994). Therefore, unlike Autistic Disorder, both Rhett's Disorder and Childhood Disintegration Disorder occur after a clear period of normal development (Mesibov et al., 1997; Volkmar & Rutter, 1995). The remaining disorder in this category, Pervasive Developmen-

tal Disorder Not Otherwise Specified, is an ill-defined category that captures children with pervasive developmental delays who do not fall into any of the other four diagnostic categories.

Epidemiology

Given the relative recent division of the Pervasive Developmental Disorders into more discrete categories, most of what we know about the epidemiology and etiology of these disorders has focused on children with autism, some of whom were high functioning intellectually and who would, as a result, most likely meet current criteria for Asperger's Disorder. Even with the broader definition of autism, it is still quite a rare form of psychopathology, and estimates of prevalence range from 2–5 per 10,000 (American Psychiatric Association, 1994) up to 11.6 per 10,000 (Gillberg et al., 1991). Recent estimates have yielded higher prevalence rates of autism, in part due to improved methods of identifying the disorder. However, more accurate diagnosis does not fully account for the increase in prevalence. It is possible that the increased survival rate of children with severe perinatal complications (Ornitz, 1989), coupled with the fact that higher functioning autistic individuals marry and have children (Ciaranello, 1995) also contributes to the increased rate of autistic disorder (Mesibov et al., 1997).

Epidemiological studies also suggest that more males than females are diagnosed with autism; ratios are 3:1 to 4:1 (Eme, 1992; Lord & Schopler, 1987). Early reports suggested that children with Autistic Disorder were more likely to come from high SES homes (Volkmar et al., 1996). However, several studies have shown that the apparent high SES level found for children with autism is based on patterns of referral, not on the disorder itself (Tsai, Stewart, Faust, & Shook, 1982; Wing, 1980). In addition, most studies that found more autistic children in higher social classes were conducted before 1970, and few SES differences have been found in studies conducted after that (Mesibov et al., 1997; Tsai et al., 1982).

Etiology

Several biological factors have been linked to autism, including genetic, neurochemical, and neuroanatomical factors. Numerous studies have found strong evidence that genetic factors are

likely to play a role in the development of autism. For example, siblings of autistic children are at increased risk of autism and other developmental disorders (Smalley, Asarnow, & Spence, 1988; Szatmari et al., 1993). Studies have found a high rate of concordance for autism in monozygotic twins that ranges from 36–91%, whereas the same studies failed to find any significant concordance in dizygotic twins (Klinger & Dawson, 1996; Mesibov et al., 1997). In addition, other developmental problems, including learning disabilities, language delays, and mental retardation, have been found in up to 25% of siblings of autistic children; this suggests that Autistic Disorder may be on a continuum with other cognitive deficits (Klinger & Dawson, 1996; Schreibman & Charlop-Christy, 1998).

There is also evidence that the genetic causes of autism may be varied and complex. For example, certain single gene abnormalities are found in a subset (10–20%) of autistic individuals (Mesibov et al., 1997; Smalley, Levitt, & Bauman, 1998). It is also estimated that 5% of autistic males have Fragile X Syndrome and that 1–3% of individuals with autism have tuberous sclerosis (Smalley et al., 1998). In addition to genetic factors, prenatal and perinatal complications have been implicated in the development of autism, including maternal bleeding after the first trimester and an excessive gestational period (Mesibov et al., 1997). There is also evidence to suggest that immune factors, such as maternal viral infections, may play a role in the development of Autistic Disorder in some children (Smalley et al., 1998).

The focus on genetic factors and early types of neurological trauma illustrates the current view of Autistic Disorder as a neurobiological disorder. This conceptualization is supported by a number of studies that documented several neurochemical abnormalities associated with Autistic Disorder. For example, more than twenty-five published investigations have found elevated platelet serotonin (5-HT) levels in individuals with Autistic Disorder, compared to nonautistic individuals (McBride et al., 1998), although this may be present in only 33% of autistic individuals (Smalley et al., 1998; Volkmar et al., 1996). Other investigators have attempted to implicate other neurochemicals, including opioid system functions, noradrenergic functions, and dopaminergic functions, but the results of these studies are less consistent (Smalley et al., 1998). Neuroanatomical

abnormalities have also been found in children with autism, most often in the areas of the cerebellum, limbic system, cerebral cortex (parietal lobe, frontal lobe), and overall brain size (see Mesibov et al., 1997, for a review).

Prognosis and Treatment

In general, individuals with Autistic Disorder have poor outcomes, and the vast majority continue to manifest significant impairments into adulthood. Less than 10% of children with Autistic Disorder recover from their symptoms, and more than 90% exhibit social and intellectual deficits over their life-spans (Werry, 1996b). Worse prognosis is associated with lower IQ (<50) and/or lack of communication skills at age 5. Therefore, children with Asperger's Disorder may have better prognoses than other children with autism (Gillberg, 1991; Werry, 1996b). Nevertheless, even these individuals without cognitive and language impairments often show a number of social deficits and interpersonal rigidity throughout their lives that can significantly impair their educations and occupational and social functioning (Werry, 1996b; Wing, 1981).

Given the view of Autistic Disorder as a neurobiological disorder, it is not surprising that a number of medications have been used to treat children with this disorder. Unfortunately, none of the medications that have been tested in controlled outcome studies have proven very effective, although some of the SSRI's (clomipramine, fluoxetine, fluvoxamine) have led to a reduction of the stereotypies and aggression in children with autism (Smalley et al., 1998).

Given the poor response to medication, behavioral treatments have also been developed for treating Autistic Disorder. In general, these behavioral interventions usually fall within one of two broad categories: focal treatments directed toward ameliorating specific symptoms and comprehensive programs directed toward an overall increase in functioning (Rogers, 1998). Examples of comprehensive programs include Division TEACCH (e.g., Mesibov, 1997) and the Lovaas approach (Lovaas, 1987). The Lovaas (1987) approach is based on operant training techniques that include positive reinforcement and punishment to help a child develop more appropriate social and adaptive skills. Early results provided by Lovaas (1987) suggested that intensive, one-on-one training for

30–40 hours per week resulted in significant gains in IQ and reductions in symptomatology for many children with autism (Rogers, 1998). Interventions such as Division TEACCH are based on cognitive-behavioral principles and are designed to help the child with autism understand expectations and relationships in the environment (see Mesibov et al., 1997). For example, through structured teaching, the environment of the autistic child is simplified, schedules and routines are used to enhance predictability, and work systems are developed so that the child knows the length of time required to complete a task.

Childhood Schizophrenia

Overview

The typical onset to schizophrenia is in late adolescence or early adulthood, but there is a growing consensus that, while quite rare, prepubertal onset of schizophrenia does occur (Werry, 1997). In addition, there is considerable evidence that schizophrenia which has onsets in childhood is similar to the adult form of the disorder (e.g., Jacobsen & Rapoport, 1998; Volkmar, 1996; Werry, 1996a; Werry & McClellan, 1992). For example, the DSM-IV uses the same criteria for diagnosing schizophrenia in both adults and children. This diagnosis requires the presence of at least two of five characteristic symptoms, including delusions, hallucinations, disorganized speech, disorganized or catatonic behavior, and/or negative symptoms (flat affect, alogia), for at least 1 month, some signs of the disorder for at least 6 months, and the symptoms must significantly interfere with social or occupational functioning (American Psychiatric Association, 1994).

Although the criteria presented for a diagnosis of schizophrenia appear appropriate for both children and adults, children are more likely to experience some symptoms of schizophrenia in the course of other disorders (e.g., hallucinations as part of a mood disorder) and are less likely than adults to experience certain symptoms during the course of schizophrenia (e.g., poverty of thinking, well-formed delusions) (Werry, 1997). When these factors are combined with the low base rate of the disorder, it makes the diagnosis of schizophrenia much more difficult in children. Thus, it is not surprising that the validity and reliability of

childhood-onset schizophrenia is often low (Werry, 1996a). Upon reassessment, children diagnosed with schizophrenia often receive different diagnoses, including psychotic depression, bipolar disorder, schizoaffective disorder, and personality disorders (Jacobsen & Rapoport, 1998; Werry & McClellan, 1992; Werry, 1996a).

Epidemiology

Actual estimates of prevalence of childhood-onset schizophrenia are difficult to obtain, given its low prevalence. However, it is estimated that the onset of schizophrenia before age 13 occurs with less frequency than autism (Volkmar, 1996). In adulthood, schizophrenia is generally considered to affect males and females equally, particularly when community-based estimates are used (American Psychiatric Association, 1994). However, several investigations of early-onset schizophrenia suggested that the disorder was found more commonly in males than females (Asarnow & Asarnow, 1996; Green et al., 1984, 1992), although this is not a consistent finding (Galdos et al., 1993).

Etiology

Like the presence of schizophrenia in adults, genetic factors, it is thought, influence childhood-onset schizophrenia. In fact, it has been noted that the earlier the age of onset, the more likely that family members have the disorder (Asarnow & Asarnow, 1996; Werry, 1996a). Also consistent with research on adults, a number of studies have suggested that neurological abnormalities are associated with childhood schizophrenia (Rapoport et al., 1997). For example, studies have found differences between schizophrenic children and normal controls in measures of autonomic activity and reactivity (Zahn et al., 1997), cerebral and ventricle volume (Rapoport et al., 1997), and basal ganglia structures (Rapoport et al., 1997). The temporal and frontal lobes of the cerebral cortex are other structural areas that may be involved in childhood schizophrenia (Werry, 1996a). Neurotransmitters implicated include dopamine, noradrenaline, and serotonin, although recent research suggests that negative symptoms and cognitive deficits are less related to dopamine than positive symptoms (Asarnow & Karatekin, 1998).

Prognosis and Treatment

Early-onset schizophrenia generally has an insidious or gradual onset which is associated with a worse prognosis, so it is not surprising that the course of the disorder is often chronic and stable when its onset is in childhood (Jacobsen & Rapoport, 1998). More than half of children who receive a diagnosis of schizophrenia continue to show significant symptomatology during follow-up assessments, regardless of the time elapsed from diagnosis to follow-up (Gillberg, Hellgren, & Gillberg, 1993; Green et al., 1992; Jacobsen & Rapoport, 1998; Werry et al., 1991). Even those who are not diagnosed at follow-up often show significant symptomatology. For example, only 13% (Gillberg et al., 1993) to 17% (Werry et al., 1991) of children with schizophrenia had full recoveries. Jacobsen and Rapoport (1998) reported that, similarly to adults, children show intellectual declines after the onset of schizophrenia. However, unlike adults, children continued to show declines nearly 2 years after the onset of their symptoms.

The primary treatment for adult-onset schizophrenia is neuroleptic treatment, and similar medications have been used with children. Double-blind studies have found that haloperidol is more effective than placebo, particularly for positive symptoms, although there were significant adverse side effects associated with the medication, including extrapyramidal symptoms (Spencer et al., 1992). A recent double-blind study revealed that clozapine is superior to haloperidol for treating both positive and negative symptoms in children. However, the side effects of clozapine were even more significant, and 38% of children required discontinuation of treatment (Kumra et al., 1997).

Psychosocial treatments are often advocated in combination with medication. However, none of these treatments has been subjected to controlled trials in children, and the utility of these treatments for enhancing the effects of medication has not been conclusively shown. Generally, behavioral family treatment that emphasizes having a parent teach their children communication skills, problem-solving skills, and social skills through intensive instruction and practice is recommended (Asarnow & Asarnow, 1996). Many of these interventions also support parents in coping with a child with a severe and impairing psychiatric disorder,

and they help parents to obtain needed educational and rehabilitation services (Asarnow & Asarnow, 1996).

Learning Disorders

Overview

A learning disorder, or learning disability, is a disorder in one or more of the basic psychological processes involved in understanding or in using language (spoken and written) that may manifest itself in an impaired ability to listen, speak, read, write, spell, or perform mathematical calculations. Although there is general agreement about this definition of learning disorders, there is a great deal of confusion how best to classify children using it (Beitchman & Young, 1997; Culbertson, 1998). For example, some definitions of learning disorders classify children according to the cognitive processes that interfere with acquiring basic academic skills. Using this approach, a broad distinction can be made between language-based or verbal disorders and perceptual-organizational or nonverbal disorders. However, many other distinctions can be made, depending on the cognitive processes assessed (Beitchman & Young, 1997; Swanson, Carson, & Saches-Lee, 1996). In contrast, other classification systems, like the DSM-IV, focus on the academic skills that are deficient in a child. The DSM-IV recognizes four learning disorders: Reading Disorder, Mathematics Disorder, Disorder of Written Expression, and Learning Disorder Not Otherwise Specified (American Psychiatric Association, 1994). These two different approaches to classification identify very different children because different processing deficits (e.g., visual-perceptual deficit or deficient verbal comprehension) can lead to delays in the same academic subject (e.g., reading) (Beitchman & Young, 1997).

Another difficulty involved in classifying learning disorders is the practice in many school systems of using a significant discrepancy between a child's intellectual abilities and academic achievement to diagnose a learning disorder. The rationale for this method is that the child's intelligence test score represents the child's "academic potential," and performance on a standardized test of achievement below this potential reveals the presence of a learning disorder. However, this method is flawed

for a number of reasons (See Culbertson, 1998; Kamphaus, Frick, & Lahey, 1991). First, it assumes that the child's score on an intelligence test would not be influenced by the processing deficit that caused the learning disorder and thereby provides a "pure" measure of the child's academic potential. Intelligence tests are designed to assess cognitive processes, so this assumption is tenuous. For example, a child with a verbal processing deficit is likely to have a lower score on an intelligence test due to this processing weakness. Second, scores on intelligence tests are correlated with scores on achievement tests. As a result, there are regressive effects at more extreme levels of intelligence that make larger discrepancies less meaningful at higher intelligence levels than at lower levels of intelligence and make smaller discrepancies more meaningful at lower intellectual levels. As a result of this, corrections have been developed to calculate differences between intelligence test scores and academic achievement to adjust for these regressive effects (e.g., Kamphaus et al., 1991).

Epidemiology

These conceptual issues are critical for interpreting all of the research on learning disorders because the way learning disorders are defined can affect prevalence rates, comorbid disorders, and the causes of the disorder. This confusion is the reason that estimates of learning disorders range from 2–10% (American Psychiatric Association, 1994; Beitchman & Young, 1997), and some estimates are as high as 15% (Gaddes & Edgell, 1993). Although boys exhibit a higher incidence of learning disabilities than girls, this difference could be due to the fact that boys with learning disorders are more likely to exhibit comorbid behavior problems, which increases the likelihood that they will be referred for evaluation and treatment (Beitchman & Young, 1997; Culbertson, 1998).

Comorbid Disorders

Several psychological disorders occur at higher rates in children with learning disorders than in normal children; these include hyperactivity, depression, social withdrawal, anxiety, language disorders, and somatic complaints (Beitchman & Young, 1997; Culbertson, 1998; Frick et al., 1991; Fuerst, Fisk, & Rourke, 1989; Porter & Rourke,

1985). For example, from 20–30% of children with learning disorders also have ADHD and between 10–50% of children with ADHD have learning disabilities (Hinshaw, 1992). However, it is important to note that a large number of children with learning disabilities (30–55%) do not show significant emotional or behavioral problems and there is no specific pattern of behavioral or emotional disturbance that is distinctive for children with learning disabilities (Fuerst, Fisk, & Rourke, 1989; Porter & Rourke, 1985; Speece, McKinney, & Appelbaum, 1995). One possible exception is the finding that children with nonverbal learning disabilities often have more social problems and difficulties interpreting social cues than children with language-based learning disorders (Rourke, 1988).

Etiology

It is clear that learning disorders run in families. In a review of the literature, Pennington (1990; Pennington & Smith, 1988) found that from 35–40% of sons of learning-disordered parents were affected; the risk to daughters was approximately 18%. There is also mounting evidence of a genetic component in this transmission, at least for certain types of learning disorders. For example, twin and adoption studies in combination with genetic linkage studies have suggested that deficits in phonological awareness leading to one type of reading disability may be linked to chromosome 6 and deficits with single-word reading may be linked to chromosome 15 (Pennington, 1990).

One of the most popular etiological theories for learning disorders is the neuropsychological approach which proposes that learning disorders result from neuroanatomical and/or neurofunctional deficits. The location of the dysfunction determines the specific cognitive processing problems that affect a child's abilities to learn (e.g., visual-perceptual problems, perceptual-motor problems, sequencing deficits) (Beitchman & Young, 1997; Hynd & Willis, 1988). A second common theory views learning disorders as a consequence of deficits in psycholinguistic functioning (e.g., impaired phonological processing skills or deficits in manipulating individual speech sounds) (e.g., Torgesen, 1986). However, advances in our understanding of learning disorders have been limited by the lack of agreement on classifying children with these disorders.

Prognosis and Treatment

In general, learning disorders persist though late adolescence and adulthood (Maughan & Hagell, 1996). Specific academic deficits, such as deficits in reading comprehension, word recognition skills, phonological coding, and reading speed, continue to be present for a number of adults previously diagnosed as learning disordered (see Beitchman & Young, 1997, for a review). In addition, there is some evidence that psychosocial functioning may also be impaired in adulthood; learning disordered individuals are at risk of educational failure, poorer occupational achievement, and emotional disturbances (e.g., anxiety and depression) (Spreen, 1988). A summary of these longitudinal studies estimated that about one-third of individuals who experienced reading disorders as children experienced adult psychosocial problems and those affected as adults often had the most severe forms of learning disorders (Beitchman & Young, 1997; Maughan & Hagell, 1996). Unfortunately, these longitudinal studies have yet to document any consistent relationship between intervention for the learning disorder in childhood and improved adult outcome.

Intervention strategies for children with learning disabilities vary greatly and heavily depend on the way these disorders are conceptualized (Ingersol & Goldstein, 1993). For example, treatment strategies that originate from neuropsychological theories advocate using instruction designed to emphasize intact processing capabilities to bypass processing weaknesses. Treatment approaches based on the psycholinguistic model of learning disabilities involve including a language-based curriculum that teaches children specific linguistic skills that are components of general reading skills (e.g., analyzing phonological structure of words, use of sound-symbol relations; Lyon & Moats, 1988; Torgesen, 1986). A recent meta-analysis by Swanson et al. (1996) found that cognitive interventions (e.g., problem-solving skills, solution strategies, self-monitoring) show some of the greatest effects of treatment ($d = 1.07$) for children with learning disorders, followed by direct instruction (e.g., structured learning, corrective feedback; $d = .91$) and remedial instruction (e.g., phonic, letter-sound associations; $d = .68$) (see also Lloyd, Hallahan, Kaufmann, & Keller, 1998, for a description of other treatment options).

Elimination Disorders

Enuresis

Enuresis is urinary incontinence that occurs in a child after an age at which urinary control is typically attained and in the absence of organic pathology. The DSM-IV requires repeated voiding of urine at least twice a week for at least three months in children age 5 years or older for a diagnosis (American Psychiatric Association, 1994). Enuresis can be diurnal, which is daytime wetting, or the more common nocturnal form, which is wetting the bed at night. Reviews of the literature indicate that approximately 15–20% of 5-year-olds, 7–15% of 7-year-olds, 5–7% of 9- to 10-year-olds, and 2–4% of 12- to 14-year-olds suffer from nocturnal enuresis (Costello et al., 1996; Doleys, 1977; Shaffer et al., 1996; Walker, Milling, & Bonner, 1988). In contrast, diurnal enuresis is much less prevalent; approximately 6% of 6-year-olds and 1% of children between the ages of 7–17 show this type of enuresis (Walker et al., 1988). A distinction is also made between primary enuresis, in which a significant period of bladder control has never been achieved, and secondary enuresis, in which urinary incontinence occurs after a period of bladder control. Primary enuresis accounts for approximately 85% of all cases of enuresis (de Jonge, 1973). In general, boys suffer from enuresis approximately twice as often as girls (Costello et al., 1997; Mellon & Stern, 1998).

A number of organic factors, such as neurological pathology, structural abnormalities, urinary or bladder infections, and diabetes can cause urinary incontinence (Walker et al., 1988; Werry, 1986). For this reason, children with enuresis, especially secondary diurnal enuresis, should have a physical evaluation to rule out physical causes for the incontinence. By definition, however, enuresis occurs in the absence of such an organic dysfunction. Nevertheless, there is a fairly strong genetic component in enuresis (Bakwin, 1973), and this may be related to a smaller functional bladder capacity that is transmitted across generations (Muellner, 1960). Although some have speculated that children with enuresis may have differences in their sleep patterns such as “heavy sleeping” that lead them to miss bodily cues to use the bathroom, research has not consistently shown differences in the sleep architecture of enuretic children (Ondersma & Walker, 1998).

In addition to biological theories of enuresis, some authors have focused on learning mechanisms such as the failure of the child to learn to control the urination reflex adequately and to discriminate cues necessary to inhibit urination to reach the bathroom (Walker et al., 1988). One psychological theory that has not been supported by research is the role of an emotional disturbance in causing enuresis. Well-controlled studies have indicated that, although enuretic children show a higher rate of anxiety, family disruption, and other stressful events than nonenuretic children, the vast majority of enuretic children do not suffer from emotional disturbance (Ondersma & Walker, 1998; Walker et al., 1988; Werry, 1986).

Although approximately 15% of untreated enuretic children attain bladder control each year (de Jong, 1973; Forsyth & Redmond, 1974; Lyman, Schierberl, & Roberts, 1992), a large proportion of children with this problem continues to exhibit enuresis for extended periods of time, and they experience increasing impairment in social functioning as they get older. Several psychopharmacological interventions have been tested with children; the most common is the tricyclic antidepressant, imipramine. Controlled studies suggest that 85% of enuretic children treated with imipramine improve within 2 weeks. Unfortunately, there are a number of side effects, and there is a very high relapse rate after discontinuing the medication (Ondersma & Walker, 1998).

Given the potential for side effects and the high relapse rate with medication, behavioral interventions have been very popular for treating enuresis. The urine alarm technique, introduced by Mowrer and Mowrer (1938), involves using a urine sensitive pad, placed in the child's bed or sewn into his or her pajamas, that activates an alarm or buzzer when wet. When the alarm is activated, the child is awakened and is instructed to go to the bathroom to finish voiding. Over time, the child begins to awaken before wetting and before activating the alarm. The urine alarm has an effectiveness rate that ranges from 60–90%, and although the initial relapse rate is rather high (41%), a short reintroduction of the alarm leads to rapid and sustained remission of the enuresis (Ondersma & Walker, 1998). A controlled study that compared treatment with imipramine to treatment with the urine alarm reported that use of the urine alarm produced a larger percentage of children who reached the cure criterion (e.g., fourteen dry nights), showed bene-

ficial effects sooner, and resulted in children who were less likely to relapse (Wagner, Johnson, Walker, Carter, & Witmer, 1982).

Encopresis

Encopresis is the second elimination disorder found in children. This is defined as fecal incontinence in a child past the age at which bowel control is expected and where no organic pathology can be found. According to the DSM-IV, a child age 4 years or older must show fecal incontinence at least once a month for at least three months to meet the criteria for encopresis (American Psychiatric Association, 1994). Like enuresis, encopresis can be diurnal or nocturnal and primary (continuous) or secondary (discontinuous). For encopresis, however, nocturnal soiling appears to be much less common than diurnal encopresis (Levine, 1975).

Research suggests that there are at least three major types of encopresis (Schroder & Gordon, 1991; Walker et al., 1988). Manipulative soiling involves a pattern of soiling that results in successful manipulation of the environment, such as avoiding school, avoiding parental punishment, or expressing anger. Irritable bowel syndrome involves expulsion of feces diarrhetically as a reaction to stress and emotional upset. Retentive encopresis, the third category, accounts for the vast majority of cases of encopresis (80–95%). In such cases, children become constipated for some reason (e.g., poor learning of toileting skills, poor diet, previous painful bowel movement, toilet phobia), and fecal material becomes impacted in the intestine, preventing full evacuation of fecal material. Fluid material from stomach and intestine seep around the blockage out of the anus leaving a stain in the child's clothing. Because of the extension of the intestine by the impacted fecal material, the child typically is unaware of the need to defecate.

It is estimated that encopresis occurs in approximately 0.3–0.8% of children (Costello et al., 1996; Lyman et al., 1992; Walker et al., 1989). The proportion of child referrals to psychiatric clinics who are encopretic ranges from 6–10% (Walker et al., 1988), whereas approximately 3% of referrals to pediatric clinics (Abrahamian & Lloyd-Still, 1984; Levine, 1975) and 25% of referrals to pediatric gastroenterology clinics (Taitz, Wales, Urwin, & Molnar, 1986) are for encopresis. Males are

predominant in encopretic samples, and male to female ratios range from 2:1 to 5:1 (Abrahamian & Lloyd-Still, 1984; American Psychiatric Association, 1994; Costello et al., 1996; Levine, 1975).

Early studies based on referrals to psychiatric clinics suggested that children with encopresis tended to show a typical personality style characterized by immaturity, excessive dependence, spitefulness, vindictiveness, and lack of creativity, and had families with an overcontrolling and rejecting mother and a weak, uninvolved, and ineffective father (Bemporad, Pfeifer, Gibbs, Cortner, & Bloom, 1971). Such characteristics are related to the fact that these were referrals to psychiatric clinics. Studies of children referred to general pediatric clinics have failed to find a typical personality style related to encopresis (Abrahamian & Lloyd-Still, 1984; Levine, 1975). These studies reported that only 20–30% of encopretic children show significant psychological disturbance. Thus, the general conclusion is that the data do not support a causal relationship between psychological disturbance and encopresis for many children (Walker et al., 1988).

In contrast to the large literature of well-controlled studies that document the effective treatment of enuresis, there are few such studies that tested the treatment of encopresis. This is unfortunate, given the very distressful circumstances confronting the encopretic child. Appropriate treatment for encopresis depends on the type of encopresis exhibited, which necessitates a thorough assessment of the child and family. Manipulative soiling is best treated by teaching parents how to eliminate reinforcers to the soiling, to reinforce appropriate toileting, and to teach the child more appropriate ways of controlling his or her environment (Walker et al., 1988). Irritable bowel syndrome or chronic diarrhea is related to stress and anxiety experienced by the child, and so treatment should focus on altering environmental sources of stress or teaching the child anxiety-reduction techniques (Walker et al., 1988). The most promising treatment for retentive encopresis is a combination of medical and behavioral approaches. Fireman and Koplewicz (1992) and Wright and Walker (1976) reported successful results using a two-stage treatment; stage one involves evacuating the impacted colon by using cathartics. In stage two, the child relearns control over bowel movements and appropriate toileting through the use of reinforcement and punishment. A complete program using

such a two-stage approach can be found in Walker et al. (1988) and Schroder and Gordon (1991).

Tic Disorders

Tics are involuntary, sudden, rapid, repetitive, nonrhythmic, unexpected, and purposeless muscular movements or vocal utterances (Evans, King, & Lechman, 1996). Tics can often be suppressed for brief periods and may be exacerbated by stress and fatigue (Evans et al., 1996). Tic disorders are commonly divided into four general categories: Tourette's Disorder, Chronic Motor or Vocal Tic Disorder, Transient Tic Disorder, and Tic Disorder Not Otherwise Specified (DSM-IV; American Psychiatric Association, 1994). Current research suggests that all four tic disorders can best be considered as a continuum, where Transient Tic Disorder is on the mild end and Tourette's Disorder is at the more severe end (Leckman & Cohen, 1991). Estimates of the prevalence of tic disorders suggest that from 2.9–5.9 per 10,000 individuals are affected (Apter et al., 1993; Burd, Kerbeshian, Wikenheiser, & Fisher, 1986; Caine et al., 1988); the male to female sex ratio is approximately 9:1 (Burd et al., 1986), and a typical onset is between the ages of 5 and 7 years (Leckman et al., 1987; Rapoport & Ismond, 1996).

Transient Tic Disorder is defined by the DSM-IV as single or multiple motor and/or vocal tics that occur many times a day, nearly every day, for at least 4 weeks, but for no longer than 12 consecutive months. In general, transient tics are the most common of all tic disorders. Fortunately, they also are the most benign of all tic disorders; they have a high rate of spontaneous remission, and little association is found with learning and behavioral disorders (Lerer, 1987). Chronic Motor or Vocal Tic Disorder is distinguished from Transient Tic Disorder primarily by its chronicity, that is, Chronic Tic Disorder is defined as either a motor or vocal tic, but not both, that occurs either continuously or intermittently throughout a period of more than 1 year (American Psychiatric Association, 1994).

Tourette's Disorder, the most severe of the tic disorders, is characterized by the presence of both motor and vocal tics with a course that lasts at least 1 year. Often, Tourette's Disorder begins with a single facial tic, usually eye blinking or eye rolling, between the ages of 5 to 9 years (Leckman et al., 1987), that later becomes complex and in-

volves multiple muscle groups of the torso or legs (Lerer, 1987; Shapiro et al., 1988). Motor tics may involve echokinesis (imitation of movement of others) and copropraxia (vulgar or obscene gesturing). Vocal tics typically develop later than motor tics, between the ages of 9 and 12, and commonly include grunting, sniffing, snorting, barking, whistling, coughing, throat clearing, and humming (Bruun, 1988). More complex vocal tics, including coprolalia (involuntary utterances of obscene words), echolalia (repetition of others' words or phrases), and palilalia (repetition of one's own words or phrases), occur much less frequently; echolalia and palilalia occur in less than 17% of children with Tourette's Disorder (Leckman et al., 1987). Coprolalia, one of the most commonly recognized symptoms of Tourette's Disorder and often the most disruptive symptom for the child, occurs even less frequently, and typically does not emerge until early adolescence (Shapiro et al., 1988; Shapiro & Shapiro, 1982).

Reviews of the literature on Tourette's Disorder have indicated that approximately half of the children with this disorder experience other emotional or behavioral difficulties such as Obsessive-Compulsive Disorder, Attention Deficit Hyperactivity Disorder, and learning disabilities (Bruun, 1984; Lerer, 1987; Pennington & Smith, 1988). Often children are referred for treatment due to the comorbid disorder rather than for the Tourette's Disorder itself, and this may lead to increased estimates of comorbidity in clinic samples (Apter et al., 1993). For example, a community-based sample of children with Tourette's Disorder found that only 12% of nonreferred children met the criteria for ADHD, compared to 50% in clinic-referred samples (Apter et al., 1993). Conversely, from 30–40% of children with Tourette's disorder are diagnosed with Obsessive-Compulsive Disorder in both clinic-referred and community samples (Apter et al., 1993; Peterson, Leckman, & Cohen, 1995).

The exact pathogenesis of Tourette's disorder is unknown. It is generally accepted, however, that the disorder requires a genetic predisposition and this may be a shared predisposition with Obsessive Compulsive Disorder (e.g., Sallee & Spratt, 1998). There is also evidence for neurochemical abnormalities in children with Tourette's Disorder, specifically in the dopaminergic pathways. Therefore, it is not surprising that the most effective treatments for Tourette's Disorder are dop-

amine antagonists (e.g., haloperidol and pimozide) (Towbin & Cohen, 1996). Use of these medications results in a significant reduction in symptoms for the vast majority of patients (70–80%) (Shapiro, Shapiro, Young, & Feinberg, 1988). However, these medications do not completely eliminate symptoms, and there are numerous side effects associated with dopamine antagonists even at low doses, including tardive-dyskinesia and extrapyramidal symptoms, which can affect from 34–42% of treated children (Sallee & Spratt, 1998).

Due to the side effects of most medications used in treating tic disorders and due to the continued presence of symptoms even under the best medical management, it is not surprising that psychosocial interventions are often advocated in combination with medication. Self-monitoring is frequently used to determine the frequency and severity of tics, and this procedure may result in some reductions in symptomatology (Thomas, Abrams, & Johnson, 1971). Other behavioral techniques that have been recommended for reducing tics include massed negative practice, contingency management, relaxation training, and habit reversal (Teichman & Eliahu, 1986; Walter & Carter, 1997). Schroder and Gordon (1991) present a comprehensive treatment protocol for treating tic disorders that includes many of these individual components, including self-monitoring, competing-response training, relaxation training, and contingency management.

Selective Mutism

Selective mutism is characterized by the consistent failure of a child to speak in one or more social situations (American Psychiatric Association, 1994). In the DSM-IV-R, this disorder was termed elective mutism, and the definition included a “persistent refusal” to speak (American Psychiatric Association, 1987). However, in the change to the DSM-IV, the emphasis was changed to a “consistent failure” to speak, which is consistent with the current conceptualization that selective mutism is a disorder that originates from fear or anxiety, as opposed to a voluntary, oppositional disorder (Rapoport & Ismond, 1996).

In general, few empirical studies have investigated selectively mute children. However, two studies have found that school is the most common

place for a child to be mute; nearly all children (88–89%) are selectively mute at school (Steinhausen & Juzi 1996; Wilkins, 1985). In addition, almost all selectively mute children were mute with adult strangers (89%), whereas less than half were mute with general groups of other children (42%), specific other children (34%), or family members (13%) (Steinhausen & Juzi, 1996). The typical onset of selective mutism is from 4–5 years of age, and boys tend to have a somewhat earlier onset than girls (Rapoport & Ismond, 1996; Steinhausen & Juzi, 1996).

Although a transient form of mutism is not uncommon in children, particularly when a child starts school (Brown & Lloyd, 1975), more persistent forms of selective mutism are quite rare, and estimates are as low as 0.8 per 1,000 (Fundudis, Kolvin, & Garside, 1979). Unlike most other behavioral disturbances in childhood, selectively mute girls outnumber boys at a ratio of approximately 1.6:1. Steinhausen and Juzi (1996) and Wilkins (1985) found several typical factors in selectively mute children. For example, approximately one-third of mute children evidenced pre-morbid speech and language disorders, and one-third to one-half were also diagnosed with separation anxiety disorder. In fact, comorbid internalizing problems are typically found with selectively mute children, and 85% are reportedly shy, 66% are reportedly anxious, and 36% are reportedly depressed (Steinhausen & Juzi, 1996).

Given the limited research on this form of psychopathology, it is not surprising that little is known about the clinical course and treatment of selective mutism. Kolvin and Fundudis (1981) found that a substantial proportion (approximately 42%) of their sample of selectively mute children showed significant improvement before the age of 10. Children who remain selectively mute after age 10 tend to have a very poor prognosis, and relatively few children improve with (Dummitt, Klein, Tancer, Asche, & Martin, 1996) or without treatment (Wilkins, 1985).

In general, the most common form of treatment is psychotherapy; psychotherapy as an intervention is offered to 42% of selectively mute children (Steinhausen & Juzi, 1996). Recently, fluoxetine has been used in clinical trials with some efficacy; however, the efficacy varied by age (Dummitt et al., 1996). Specifically, 93% of children under age 10 improved, whereas only 33% of children over age 10 improved, again suggesting that prognosis

is much worse for selectively mute children over the age of 10. Past research has also shown the efficacy of operant procedures in treating children with selective mutism (Kratochwill, 1981; Lahey, 1973).

Summary

In this chapter, we tried to provide an overview of some of the more common forms of childhood psychopathology. For some disorders, such as ADHD and Disruptive Behavior Disorders, there is a fairly substantial literature on the phenomenology, etiology, course, and treatment of the disorder. For other disorders, such as childhood depression, there is much less research. Generally, externalizing disorders have been the focus of more research than internalizing disorders because children with externalizing disorders are much more disruptive to those around them which leads to their more frequent referral to child mental health clinics. However, it is becoming increasingly clear that internalizing disorders, such as anxiety and depression, are more chronic and impairing in children than was once thought, making research on these disorders an important goal of child psychologists.

Another important issue that has become clear from research on childhood psychopathology is that comorbidity is the rule rather than the exception. Children who show significant emotional, behavioral, social, or learning disturbances are quite likely to have problems in multiple domains. This suggests that factors that make a child vulnerable to one type of disturbance also make a child vulnerable to other difficulties. However, some authors have suggested that the high degree of comorbidity among disorders could be an artifact of our imperfect methods of classifying psychopathology that create artificial boundaries among disorders (Lilienfeld, Waldman, & Israel, 1994). Whatever the reason for the high degree of comorbidity among the various forms of psychopathology, it is clear from our review of the research that comorbid conditions can greatly affect the presentation, course, and treatment of the primary disorder.

Another theme that emerged from this review is the fact that research is beginning to recognize the importance of classification for guiding advances in causal theories and for guiding advances in

treating childhood psychopathology. Specifically, it has become increasingly clear that many disorders are not homogenous conditions with single causal pathways that lead to the disorder (e.g., Frick, 1998a,b). Instead, many disorders result from multiple causal pathways; each involves a distinct constellation of causal processes. As research begins to uncover more homogenous groups within the various childhood disorders, causal theories can be developed to explain the different causal mechanisms that underlie the behavior of the different subgroups, and treatments can be developed that are more specifically focused on the needs of children within a diagnostic category.

Finally, and perhaps most importantly, in summarizing the research on childhood psychopathology, it is clear that it is critical to embed theoretical models within a developmental context. Many disorders of childhood share common features with related disorders found in adults. However, throughout this chapter, we attempted to highlight important developmental differences in the way the disorders are manifested in children. Most of these differences can be understood within the context of the developmental challenges and tasks that children and adolescents face that lead to variations in presenting the disorders across development. Furthermore, advances in our causal theories of these conditions are likely to come from integrating our knowledge of normal developmental processes into our theories of the way these processes can deviate and lead to psychopathological conditions. Such a developmental perspective for understanding childhood psychopathology is critical for guiding future research in this area and for providing a sound scientific basis to develop more effective prevention and treatment programs for all of the childhood disorders.

Psychopathology in the Aged

Jane E. Fisher, Antonette M. Zeiss,
and Laura L. Carstensen

Introduction

Our understanding of the influence of aging on psychopathology has undergone significant revision in the past few decades. Early negative stereotypes about increased rates of problems that occur in old age have been challenged by empirical accounts of reduced incidence and prevalence rates of many psychological problems in elderly cohorts or a nonlinear relationship between age and psychological problems (Dick & Gallagher-Thompson, 1996; Gatz, Kasl-Godley, & Karel, 1996; Kessler, Foster, Webster, & House, 1992; Kessler et al., 1994; Vaillant, 1996). In general, recent research on psychological functioning in old age suggests that, despite exposure to increasing numbers of uncontrollable changes and losses associated with aging such as health problems (Aldwin, 1995; Zeiss, Lewinsohn, Rohde, & Seeley, 1996) and bereavement (Zisook & Schuchter, 1991), the majority of older adults report greater levels of contentment that at any point in the life-span. These findings suggest that a lifetime of exposure to the inevitable stresses of life results in enhanced coping abilities and adaptation, not in

cumulative negative effects (Brandstedter, Wentura, & Greve, 1993). These recent findings present challenges for the field of clinical gerontology. As negative stereotypes of aging are debunked by empirical findings, new theoretical accounts of psychological functioning across the life-span will be needed.

In this chapter, we examine the theoretical assumptions and empirical status of research on psychopathology in old age. In studying the relationship between psychopathology and aging, the topic must be examined from several positions: (1) disorders may develop for the first time in old age; (2) disorders first evident earlier in adulthood may continue in old age and remain basically unaltered by the aging process; (3) disorders that begin in early or middle adulthood may continue into old age but be significantly altered by the aging process; (4) and disorders that begin in early or middle adulthood may remit in old age. As we examine the effects of aging on psychological problems, we will find that each of these positions is reflected in the literature across a variety of problems.

The study of psychopathology in old age is complicated by several methodological problems such as the confounding of age and cohort effects, the lack of standardized measures normed on an elderly population, and nonrepresentative sampling associated with selective dropout and differential mortality. For each of the disorders we examine in the chapter, we have attempted to address the relevance of these problems. Before reviewing research on the prevalence, etiology, and assessment of specific disorders, we attempt to provide a

general orientation by examining some major issues relevant to this field of study.

Composition of the Older Adult Population

The phrase “the graying of America” aptly reflects the fact that changes in the age composition of the U.S. population will be quite considerable during the next 30 years. As a group, the elderly are the fastest growing segment of the population. Changes in the age composition of the population are expected to have profound economic, medical, and social impact.

Gerontologists divide the 65-and-over age group into three groups: early old age (65–74 years), middle old age (75–84 years), and advanced old age (85 and above). In 1900, individuals over the age of 65 made up only 4% of the population; now, in the United States, persons age 65 and over comprise 12% of the population. Not only is the population over 65 increasing, but the number of persons who are 85 and over will double in the next 10 years. The age group over 85, sometimes referred to as the “old old,” is the fastest-growing segment of our entire population. Between 1960 and 1990 the population of individuals over the age of 85 increased by 237%. Between 2000 and 2010, the segment of the population aged 75 to 84 will increase by 57%, and the number of those age 85 and over will grow by 91% (U.S. Bureau of the Census, 1990). The fastest growing population in most countries is persons 80 and over (World Health Organization, 1998). By the year 2030, it is expected that the elderly will comprise approximately 21% of the population.

There are gender and ethnic differences in the aging trends, at least in the United States. In terms of gender, differential longevity continues to occur, and women outlive men. The average life-span for men was 72 in 1993 and for women 79, up by almost 30 years since 1900. For those who have managed to make it to age 65, the figures are even more promising: men of 65 can expect to live, on average, to age 77; women can expect to live, on average, to age 81. Ethnic minority elderly account for a significant proportion of the overall increase in older adults; their rates of growth are expected to exceed those of Whites during the next 50 years. For example, the percentage of minority group elderly is projected to increase from 10.2% in 1990 to 15.3% in 2020, and to 21.3% in 2050 (Angel &

Hogan, 1994). Demographic trends suggest that the number of African-Americans over age 65 is increasing, and the largest shift will occur in persons 85 years of age and older (U.S. Bureau of the Census, 1996).

Contrary to stereotypes about dependency in old age, the vast majority of the elderly reside in the community. Only about 5% of the elderly reside in nursing homes or convalescent centers at any time, although the lifetime probability of placement in a nursing home is 25–30%. As people age, the risk of nursing-home placement increases from 1 in 20 to 1 in 7 after the age of 80; in other words, 15% of the people over 80 years old reside in nursing homes (AARP, 1998). With advancing age comes an increased likelihood of dependence on government programs as safety nets for income and health care. The proposed projections of a dramatic increase in the proportion of the “oldest old” during the next 30 years is driving increased concern regarding the adequacy of current public policies for assisting older adults because benefits to this group already account for 40% of federal expenditures (Binstock, 1999).

Methodological Issues in the Study of Aging and Psychopathology

A limitation of many epidemiological studies is that they place all subjects over the age of 65 into one group, whereas subjects age 18–64 are typically categorized into three to four separate age groups. For many disorders, this approach to age categorization presents an overly simplistic or distorted view of the relationship between aging and psychopathology (Kessler et al., 1994). Several inconsistencies have been identified in the methodology of studies of psychopathology in different age groups. Studies of elderly nursing-home residents, for example, may aggregate subjects ranging in age from 55 to 100. Feinson (1985) suggested that this practice indicates that age distinctions are viewed as important for young and middle-aged adults but not for older adults. Feinson and Thoits (1986) reviewed epidemiological studies of mental health problems among older adults and found prevalence rates of any psychopathology that varied from 6–37%, depending on the specific old age category. According to these authors, cross-

sectional studies reported either positive, negative, or no association, depending on the methods and measures used.

Cross-Sectional Versus Longitudinal Studies

Research on aging and psychopathology has typically relied on cross-sectional studies. In a cross-sectional study, samples of individuals of different ages are observed for the variables of interest at a single measurement time. A limitation of this approach is that it does not allow one to rule out the effects of cohort or time-of-measurement effects. For example, a researcher interested in the effects of aging on depression may find a sudden decline in mood at age 65. Although this finding may be "age-related," it may also be a reaction to an event such as retirement or an announcement that the government is reducing Medicare benefits. In these examples, the effects of age and history are confounded. Other cohort related factors that may impact psychological functioning in old age include differences in divorce rates, lifetime exposure to violence, gender-based employment opportunities, and exposure to risk factors from substance use and sexually transmitted diseases.

Another example of the limitations of cross-sectional designs is seen in the conclusions that were drawn from early research on intellectual functioning in old age. In the 1930s, 1940s, and 1950s, numerous investigators administered intelligence tests to individuals of different age groups. The results led investigators to conclude that intelligence increases up to early adulthood, reaches a plateau in the person's 30s, and begins to decline progressively around the age of 40. These conclusions went unchallenged until the appearance of the first longitudinal studies. In a longitudinal study, the variable(s) of interest are observed for the same individuals at two or more measurement times. Longitudinal studies found that different intellectual domains showed different rates of decline (e.g., Baltes & Schaie, 1976; Schaie, 1994, 1996; Schaie & Labouvie-Vief, 1974; Schaie & Stone, 1982); on measures of vocabulary and other skills associated with educational experience, for example, individuals maintained their levels of functioning into their 60s and 70s. Longitudinal studies also showed evidence for individual differences. Many people show no significant intellec-

tual decline into the eighth decade (Field, Schaie, & Leino, 1988), and the patterns of decline also vary across individuals (Schaie, 1989, 1990); few showed decline in all areas. Indeed, some individuals continue to show increases in intellectual abilities into old age (Field et al., 1988). One major reason that longitudinal results were so different is that cross-sectional studies of intelligence did not control for effects of cohort (e.g., education; for thorough reviews of methodological issues in developmental research, see Schaie, 1994, 1996).

When studying changes in psychopathology during the life-span, it also is important to consider the role of age-associated selection biases. Differential mortality is particularly problematic when sampling from the population of individuals in advanced old age (75 and older). There is good reason to assume that those who survive into advanced old age were previously more psychologically vigorous and/or physically healthy than the members of their cohort who died. Studying these individuals can result in overly optimistic inferences about age-related remission in psychopathology. This problem is especially relevant for studying behaviors that can have a direct impact on physical health (e.g., alcohol abuse, eating disorders, sexual behavior).

Selective dropout is another source of sampling bias that impacts research on psychopathology and aging. This problem is particularly relevant for longitudinal research. Subjects who die, move, or withdraw from the research are more likely in lower class populations and produce increased bias toward middle class samples during the course of a longitudinal study. Given that certain problems (e.g., schizophrenia, polysubstance abuse) occur at higher rates in lower classes (Susser & Wanderling, 1994), longitudinal research is particularly difficult to carry out for these disorders.

Problems in Measurement

One of the most pervasive problems in studying psychopathology in old age is the lack of standardized instruments that have been normed on an elderly sample. Differences in the reliability, validity, and cutoff scores of assessment instruments normed on younger groups should be considered when they are applied to the elderly. Reliability, for example, may be affected by changes in memory. Further, although an assessment instrument may be reliable and valid for this population, the

cutoff scores for elders may differ from those for younger adults. These issues will be explored more specifically in examining assessment procedures for each of the disorders discussed in the following sections.

Mood Disorders

Prevalence

Controversy has surrounded the study of the prevalence of depression among the elderly. Findings from recent reviews of epidemiological studies of depression in the aged (Kessler et al., 1994; Newman, 1989) suggest that the relationship of age to depression depends, in part, on the screening instrument used to measure depression. Most depression inventories include items that assess somatic symptoms of depression. Many of the somatic symptoms of depression, though, are changes that occur naturally in old age. These include increased fatigue, decreased appetite, and decreases in sleep. When somatic symptoms are included in surveys of depression in the elderly, the result may be an overestimate of prevalence because of the confounding of physical health status and emotional distress (Aldwin, Spiro, Levenson, & Bosse, 1989; Roberts, Kaplan, Shema, & Strawbridge, 1997). When clinical diagnostic criteria are used to estimate prevalence rates (e.g., Myers et al., 1984; Roberts, Kaplan, Shema, & Strawbridge, 1997; Weissmann et al., 1985) the rates of depression are lower in old age (see Newman, 1989, and Kessler, 1995, for critical reviews of this issue).

Depression-spectrum disorders, including subclinical depression, dysthymia, and adjustment disorder with depressed mood, may account for reports of increased rates of depression when *symptoms* of depression rather than diagnostic criteria are used to estimate prevalence rates. These disorders are more prevalent than major depression among the elderly (Lasser, Siegel, & Sunderland, 1998; Lyness, King, Cox, Yoediono, & Caine, 1999).

In considering the course of depression across the life-span, Lewinsohn, Zeiss, and Duncan (1989) found that the probability of relapse following recovery from a first episode of depression is equal for individuals who are over 40 and those under 40 at the time of the first episode of depres-

sion. The likelihood of experiencing a first episode of major depression in old age is very low. In studying the age distribution for first episodes of unipolar depression, Lewinsohn et al. (1986) found a peak between 45 and 55 years, followed by a decrease with increasing age to a risk of zero at 80 years or older.

Studies of lifetime prevalence rates of major depression indicate the operation of a cohort effect. In reviewing ten epidemiological studies, Klerman and Weissman (1989) noted that all of the studies found an increase in lifetime rates of major depression in younger age cohorts (i.e., those born after 1940) and a decrease in the lifetime prevalence in older cohorts.

Although overall rates of major depression are lower in the elderly, the rate of depression among nursing-home residents is much higher than the rate for the community-residing elderly (Futterman et al., 1995; Robins et al., 1984). Among the elderly who receive residential care, increases in clinical depression have been predictive of death (Parmelee, Katz, & Lawton, 1991).

The seriousness of geriatric depression becomes salient when one examines the disproportionately high rates of suicide in this age group. Suicide rates increase with age and are the highest among adults aged 65 and older (Center for Disease Control, 1999). The suicide rate for the general population is 12.4/100,000, but rates in 80- to 84-year-olds are 26.5/100,000. Suicide is particularly a problem for White men over the age of 85 who as a group have the highest suicide rates in the United States, 65.3/100,000. Risk factors for suicide among the elderly differ from those of younger adults. Leading risk factors for suicide in older adults include social isolation and physical illness.

Bipolar Disorder

Bipolar disorder in older adults has not been studied extensively, presumably because of its very low base rate in this population. Results from NIMH catchment area studies indicated a prevalence rate for manic episodes of zero for the 65-plus age group. It has been suggested, however, that this disorder is often misdiagnosed in adults over the age of 60 and that its prevalence is underestimated. Young & Klenman (1992) reported that individuals who develop late-onset bipolar disorder have more frequent episodes than those with

early onset. Research further suggests a poorer prognosis for older patients relative to younger adults with bipolar disorder due to more extensive neurological and cognitive deficits (Shulman, Tohen, Satlin, Mallya, & Kalunian, 1992).

Theories of Etiology of Depression in the Elderly

Etiological theories of geriatric depression should address three areas: (1) the finding of decreased incidence of depression in old age; (2) the causes of depression in old age; and (3) the factors associated with maintaining depression throughout adulthood in certain individuals. For the most part, etiological theories of geriatric depression have been based on the assumption that the prevalence of depression actually decreases in old age (Dick & Gallagher-Thompson, 1996; Klerman & Weissman, 1989), it is apparent that new etiological theories of depression in old age are needed.

Medical Illness and Depression. Recent research has provided new insight into the relationship between health and depression in old age. When one compares the prevalence rates of depression and physical illness, it is clear that the majority of physically ill elderly does not develop major depression.

Reich, Zautra, and Guamaccia (1989) studied disabled elderly subjects and found that they exhibited significantly higher distress and lower levels of well-being compared with recently bereaved subjects and nonbereaved healthy subjects matched in age, socioeconomic status, and gender. Follow-up assessment conducted 13 to 16 months later revealed almost full recovery of the bereaved subjects and an absence of significant improvement in mental health for the disabled subjects. More recently, Zeiss and colleagues (Zeiss, Lewinsohn, Rohde, & Seeley, 1996) showed that medical illness *per se* is not a risk factor for depression in community-dwelling older adults, but that loss of function did increase the risk of becoming depressed. Illness may be the imminent cause of functional loss, so in a statistical sense, medical illness is likely to be associated with depression, but when illness and functional loss are examined separately, functional loss is the key factor. It is likely that this functional loss leads to depression through its psychological impact, particularly as functional changes limit valued activities and/or change an older adult's roles and opportunities.

It has also been suggested that major depression in the aged may result in greater morbidity and mortality from medical causes (Parmelee et al., 1991). The relationship between depression and medical illness in the aged is clearly complex and warrants further attention.

Psychological Theories of Depression in Old Age. *Psychodynamic Theories.* Psychodynamic theories of late-life depression typically focus on a combination of two factors: stress (particularly that associated with loss) and age-associated rigidity or lack of adaptability. Freud did not focus much attention on old age in his writings but generally viewed this period of life as one of ego rigidity and diminished cognitive ability. In discussing the applicability of psychoanalysis in advanced adulthood, he wrote,

Near and above the fifties the elasticity of the mental processes on which the treatment depends is lacking. Old people are no longer educable and on the other hand the mass of material to be dealt with would prolong the duration of treatment indefinitely. (Freud, 1924, p. 228)

Freud viewed grieving as a painful process involving the withdrawal of ties to the "love object"; this process is termed decathexis. The ego resists this withdrawal through denial by becoming preoccupied with the deceased and through loss of interest in the outside world. Eventually, mourners review memories and expectations of the deceased and gradually detach themselves from the lost love object. The grieving process ends when the individual is able to "cathect" or invert emotional energy in other relationships (Freud, 1917/1957). According to Freud, some individuals do not pass through the grieving process in this way, but instead develop a melancholic depression that may last for an extended period. This melancholic depression resembles normal grieving in many respects. According to Freud (1917/1957), there is one striking difference: Whereas normal mourning is limited to the loss of an external object, melancholia is associated with an internal loss and a sense of personal worthlessness. According to Freud, the elderly encounter the losses of old age with a fixed character structure. Characteristically, later psychoanalysts disagreed with Freud. Kaufman (1940) stated that the psychoses and neuroses of later age were definitely of a pregenital type. In discussing the treatment of depression in old age, he referred to an "inverted Oedipus complex" that makes dependent elderly individuals regard their

children as they once regarded their parents. According to Kaufman (1940), this phenomenon results in much confusion when elderly individuals attempt to interact with their children. Grotjahn (1951) described aging as a narcissistic trauma that represents and repeats a castration threat. Therefore, depressive neuroses in old age represent a defense against castration anxiety. Hamilton (1942) suggested that the change from a mature to an aging personality is characterized by regression to the earlier life stages (i.e., childhood and adolescence). In the beginning of senescence, there is a weakening of unconscious urges that may be brought about by retirement and inactivity. The demands made by the ego, coupled with a reduced ability to cope with the instinctual urges of the id, result in feelings of inferiority, insecurity, guilt, and feelings of hostility toward younger people. Hamilton suggested that the preexisting and chronically unresolved conflicts of childhood that were repressed during maturity become reactivated in old age and lead to neurotic behavior. Several psychodynamically oriented theorists have suggested that regression plays a role in the development of psychological disturbance in old age (Modell, 1970; Zarsky & Blau, 1970). According to Modell (1970), the term regression can refer to a variety of processes, including the reemergence of earlier developmental stages and the emergence of more primitive defense mechanisms. It has been suggested that regression may be an adaptive response to the losses and stress of old age (Newton, Bauer, Gutmann, & Grunes, 1986). Regression is considered a pathological phenomenon if unconscious material is dominated by unresolved problems that originated in childhood and defenses developed in adulthood do not have sufficient integrity to be effective in protecting the elderly individual against primitive drives (Newton et al., 1986). Psychodynamic theories of depression in old age have not been adequately tested and therefore should be judged with the considerable skepticism due such speculative statements. It is also noteworthy that the dynamic theories generally predict an increased prevalence of depression with old age, whereas the opposite is actually true.

Behavioral and Cognitive Theories. Behavioral researchers have focused on age-associated changes in reinforcement frequency and magnitude to understand depression and other problems in old age. In contrast to the psychoanalytic conceptualiza-

tion of psychological problems, behavioral approaches are based on empirical evidence of behavioral plasticity in old age (Hussian, 1983; O'Donohue, Fisher, & Krasner, 1986). Reductions in reinforcement frequency associated with the loss of roles (e.g., because of retirement, relocation, or the death of significant others) and reductions in the magnitude of reinforcement stemming from sensory losses (e.g., taste, visual, and hearing deficits), it has been suggested all contribute to the development of depression in the elderly (Teri & Lewinsohn, 1986). Support for the role of reduced reinforcement in geriatric depression is seen in the findings of research on depression and bereavement (Gallagher, Breckenridge, Thompson, & Peterson, 1983) and studies of treatment that have involved increasing rates of reinforcement to reduce depression in the elderly (Hussian, 1983; Gallagher-Thompson, et al., 2000). It is unclear whether such reductions in reinforcement are actually relatively rare and result in the low prevalence of depression or whether elders use more effective coping strategies than younger adults when placed in low-reinforcement environments. Behavioral theorists have just begun to grapple with these issues (e.g., Lewinsohn, Zeiss, & Duncan, 1989). The applicability of the reformulated learned helplessness model (Abramson, Seligman, & Teasdale, 1978) to depression in old age has been partially supported by recent research (Hybels & Miller, 1987). The theory predicts that certain patterns of attributions regarding negative and positive events develop in those who have experienced noncontingent reinforcement and are depressed. In studying eighty-four nonpsychotic, non-demented elderly women, Hybels and Miller (1987) operationalized uncontrollable stress as physical impairment. In examining the relationship between attribution style and depression, they found that clinically depressed subjects made more external attributions for good events and more internal and global attributions for bad events than nondepressed subjects. This relationship held only for severely depressed subjects; when mildly depressed subjects were included, only the globality of attributions for negative outcomes remained significant. The authors suggested that, as in other research on the reformulated model of learned helplessness, their measure of attributional style may have been sensitive only to the extreme ends of the continuum. Research on the efficacy of cognitive therapy for depression in

the aged indicates that a cognitive model of depression has some validity and utility for understanding depression in this population. Gallagher and Thompson (1983) described several cognitive distortions that are commonly held by the elderly. These include the beliefs "I'm too old to change," "If only X would change, I wouldn't be depressed," and "If only I had done X or Y earlier in my life, I wouldn't be depressed now" (p. 177). Cognitive theories will be more compelling, however, when they also begin to explore which cognitions may help protect most elders from becoming depressed in the face of losses, chronic illness, reduced reinforcement schedules, and so forth. Thus, a complete theory would identify effective coping strategies of typical elders and the factors that lead to the breakdown of cognitive coping in the minority of elders who become clinically depressed.

Depression and Bereavement. Bereavement is a common experience in old age. Depression and bereavement often coincide. Gilewski, Farberow, Gallagher, and Thompson (1988) found that 28.7% of bereaved elderly subjects scored in the depressed range of the Beck Depression Inventory (BDI) one month after the spouse's death. The reasons for individual differences in response to spousal bereavement are unclear. Factors that have been investigated in attempting to explain individual differences in response to spousal bereavement include gender (Farberow, Gallagher-Thompson, Gilewski, & Thompson, 1992; Hays, Kasl, & Jacobs, 1994; Nolen-Hoeksema, Parker, & Larson, 1994), differential social support (Feld & George, 1994; Harlow, Goldberg, & Comstock, 1991; Prigerson, Frank, Reynolds, George, & Kupfer, 1993), marital satisfaction before bereavement (Futterman, Gallagher, Thompson, Lovett, & Gilewski, 1990; Zisook & Shuchter, 1991), coping style (Herth, 1990; Nolen-Hoeksema et al., 1994), the suddenness of death (Byrne & Raphael, 1994; Carey, 1977; Lundin, 1984), and the age of the survivor (Zisook & Shuchter, 1991).

In considering age differences in responses to bereavement, recent research suggests that exposure to grief-related stimuli may have a significant impact on long-term response to bereavement. It is reasonable to expect that widows and widowers would attempt to avoid feelings of depression associated with bereavement. Further, such avoidance is often culturally sanctioned in the United States. Hayes (1994) writes "... it is not uncom-

mon for a person facing the sadness associated with a death in the family to be told to think about something else, to get on with life, to focus on the positive things, to try to pour themselves into work, or to otherwise avoid the aversive properties of an inherently aversive event." (p. 15). Such advice advocates the denial of grief and decreases "... the ability of the individual to be present with their psychological reactions in difficult circumstances." (Hayes, p. 15). In considering the impact of avoiding grief, the possibility emerges that individual differences in adapting to bereavement may be related to variation in the willingness to confront the emotional correlates of loss. Experiential avoidance functions to help the individual escape aversive or anxiety-provoking internal stimuli result in a reduction in distress. This reduction in distress then strengthens the avoidance response through negative reinforcement.

It has been argued that experiential avoidance has long-term negative consequences for individuals who rely on it as a coping strategy (Hayes, Wilson, Gifford, Strosahl, & Follette, 1999). Avoidance, like thought suppression, produces a rebound effect in which individuals may successfully suppress their emotional experience until they return to the context in which suppression occurred. When presented with stimuli associated with suppression, classical conditioning leads to a recurrence of the suppressed private experience potentially at even more intense levels (Hayes et al., 1999). Therefore, individuals do not truly escape the experience that they attempted to avoid and may actually magnify the feared aspects of the experience.

Support for the detrimental effects of experiential avoidance following loss can be found in the bereavement literature. Research indicates that individuals whose primary coping strategies involve experiential avoidance have greater psychological distress, compared to individuals who rely on alternate strategies. Herth (1987) examined the relationship between eight different coping styles and grief resolution in an elderly sample. Grief resolution was measured by the Grief Resolution Index (Remondet & Hansson, 1987) which was designed to assess psychological distress and adjustment to the environment without the deceased. Remondet and Hansson (1987) defined the resolution of grief "... as psychological and physiological reactions to the loss and a degree of social reintegration ..." (p. 31). Sample items on the Grief Resolution

Index include "Accepted the death of my husband" and "Was able to think through what my husband's death meant to me." (p. 32). Items on this scale are rated on a five-point scale ranging from "1-very poorly" to "5-very well" (p. 32). The eight coping styles examined in this study were as follows: (1) evasive style-evasive and avoidant activities; (2) fatalistic style-pessimistic approach; (3) emotive style-expressive emotion; (4) confrontational style-constructive problem solving; (5) optimistic style-positive outlook; (6) palliative style-stress reducing methods; (7) self-reliant coping style-self-initiated activities; and (8) supportive style-reliance on supportive systems. Reliance on each of these coping styles was measured by the revised Jalowiec Coping Scale (Jalowiec, 1987, cited in Herth, 1987), a self-report questionnaire.

The results of the Herth (1987) study indicated that evasive, fatalistic, and emotive coping styles were significantly negatively correlated with grief resolution, whereas the remaining five coping styles were significantly positively correlated with successful grief resolution. The implication of these findings is that individuals who rely on confrontational rather than evasive coping techniques are more successful in resolving grief. These findings support the hypothesis that experiential avoidance is detrimental to return to preloss functioning.

Nolen-Hoeksema et al. (1994) studied the impact of ruminative coping styles in 253 individuals (aged 20–86) who had experienced the loss of a family member. Ruminative coping was defined as a passive focus on one's negative emotions and the meaning of these emotions. Rumination can be conceptualized as a form of emotional avoidance where the bereaved individuals focus predominantly or exclusively on a single aspect of the grief experience (e.g., perseveration around feelings of guilt), thus suppressing other aspects of their private experience of the loss (e.g., depression and loneliness). A self-report measure, the Response Styles Questionnaire (Nolen-Hoeksema & Morrow, 1991) was used to measure ruminative coping. This questionnaire was designed to assess responses to depression that are self-focused (e.g., "Why do I react this way?"), symptom-focused (e.g., "I think about how hard it is to concentrate"), or focused on possible consequences of their mood (e.g., "I think I won't be able to do my job if I don't snap out of this") (Nolen-Hoeksema et al., 1994). Nolen-Hoeksema and her colleagues

found that people with poorer social support, more concurrent stressors, and higher levels of postloss depression reported more rumination than people with better social support, fewer stressors, and lower levels of initial depression. Further, rumination was significantly associated with depression at both 1 and 6 months following loss. Unfortunately, because this study was correlational, the direction of influence between depression and rumination is unknown. However, the finding of a significant correlation indicates that rumination is likely to be detrimental to recovery and is consistent with the thought suppression literature.

Gass (1987) studied the relationship between coping strategies and psychological and physical health in 100 widows ages 65–81. Subjects in this study had lost their husbands between 1 and 12 months before data collection and were not remarried. Gass defined coping as "cognitive and behavioral efforts made to master, minimize, alleviate, or reduce external and internal demands" (p. 30). Coping was measured with the Ways of Coping Checklist developed by Folkman and Lazarus (cited in Gass, 1987) to assess a broad range of behavioral and cognitive coping styles that a person uses in a specific stressful situation. Physical and psychological health were measured using the Sickness Impact Profile developed by Gibson et al. (1978; cited in Gass, 1987). The results of the Gass (1987) study indicated that widows evaluated a variety of avoidance activities that they had tried as ineffective coping strategies. These strategies included consumption of medications or alcohol, sleeping more, blaming oneself, and avoiding or getting mad at people. Conversely, 23% of the sample reported that the avoidant strategy of forgetting (e.g., getting rid of their husband's belongings shortly after death) helped them cope. However, Gass reported that widows who attempted to forget were in more psychological turmoil and, in general, had poorer physical and psychological health than widows who fostered memories.

Further support for the hypothesis that exposure affects grief involves the age of the survivor. Psychological symptoms of grief are more severe among young widows and widowers, compared to elderly survivors of spousal bereavement. Zisook and Shuchter (1991) reported that the average age of bereaved individuals with depression was significantly lower than those without depression. Further, widows and widowers older than 65 were significantly less likely to be depressed than

younger individuals. Differences between age groups in reaction to the loss of a spouse may be due to increased exposure to grief and related facilitated acceptance of grief in elderly populations.

There are several reasons to believe that the elderly have more exposure to grief than younger populations. First, as a result of their advanced age, there is an increased chance that the elderly have experienced the loss of parents and friends. Second, older individuals are more likely to have anticipated the death of their spouse than younger individuals. As discussed earlier, anticipation may provide the opportunity for exposure and acceptance before bereavement and may lead to better postloss adjustment. Third, Thorson and Powell (1988) reported that the elderly had less fear of dying than younger populations. Because exposure is a vital component in treating anxiety, it is possible that the lower level of anxiety about death in the elderly reflects increased exposure. However, lower levels of fear related to death may also reflect a cohort effect unrelated to exposure.

A methodological limitation of the extant research investigating response to bereavement is that it is largely cross-sectional (Feld & George, 1994). The longitudinal studies have recruited subjects just before the death of a significant other and followed the sample for up to two years. Recruiting subjects immediately before the death of a loved one is problematic because it precludes gathering information about an individual's psychological functioning and methods of coping before the stressful experience of the loss or the receipt of information regarding impending death.

Assessment of Mood Disorders

Depression in the elderly often presents a different symptomatic picture than that observed in younger groups. The task of the evaluator frequently involves determining whether complaints involve natural concomitants of aging, an underlying physical disorder, or symptoms of depression (Radloff & Teri, 1986; Gaylord & Zung, 1987). Several screening instruments that have been used with the elderly are reviewed later. The Beck Depression Inventory (Beck, 1967) has been studied extensively with the elderly. Because the format of the BDI makes administering it to cognitively impaired elderly rather cumbersome and because the large number of somatic items may inflate de-

pression scores for medically ill elderly, there has been some skepticism regarding its utility. It has worked out well in practice, as the following studies demonstrate. Gallagher et al. (1982) examined the test-retest reliability and internal consistency of the BDI with clinical and nonclinical samples of elderly subjects. Test-retest periods ranged from 6 to 21 days. The test-retest correlation for the entire sample was .90, the coefficient alpha was .91, and the split-half index was .84. These results indicate that the BDI has adequate reliability for use with the elderly. In an attempt to assess the concurrent validity of the BDI, Gallagher, Breckenridge, Steinmetz, and Thompson (1983) examined the relationship between BDI cutoff scores and selected diagnostic classifications of the Research Diagnostic Criteria (RDC; Spitzer, Endicott, & Robins, 1978) for a sample of 102 elderly persons who sought treatment for depression. Results indicated that the diagnosis for 91% of the subjects who scored 17 or greater on the BDI was that they were experiencing an episode of major depression disorder based on the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978) and the RDC classification criteria. Further, 81% of the subjects who scored 10 or below did not meet criteria for any RDC depressive disorder. These findings were replicated in two other studies (Kilcourse, Gallagher, Thompson, Tanke, & Sheikh, 1988; Norris, Gallagher, Wilson, & Winograd, 1987). Norris et al. (1987) compared BDI cutoff scores with interview ratings based on the DSM-III criteria. They reported that 84% of the subjects who scored below 10 were correctly identified as not depressed and 84% of those with BDI scores greater than 17 were correctly identified. The Geriatric Depression Scale (GDS) (Yesavage et al., 1983) is a thirty-item questionnaire on which individuals respond "yes" or "no" to questions about the presence of depressive symptoms. Early validity studies involved comparing GDS ratings with those of other depression scales (e.g., Biggs, 1978; Hedlund & Viewig, 1979). Given the similarity of the items on the different depression scales, the significant correlations may be more accurately viewed as indicating the reliability rather than the convergent validity of the scale. More recently, Norris et al. (1987) reported that GDS ratings were consistent with RDC and DSM-III diagnoses for 84% and 77% of cases, respectively. Norris et al. suggest that, although BDI scores were slightly more

consistent with RDC and DSM-III diagnoses than GDS scores, the simpler format and comparatively few (one vs. six) somatic items of the GDS may make it more useful for use with the medically ill and cognitively impaired elderly. A short version (fifteen items) of the GDS has also been developed. Sheikh and Yesavage (1986) reported that the short form correlates significantly ($r = .84$) with the long form and may be an attractive alternative to lengthier scales. The Zung Self-Rating Depression Scale (SDS; Zung, 1965) is one of the most widely used self-rating scales for assessing depression. Zung (1967) was the first to study the SDS in an elderly population. He assessed depressive symptomatology in normal subjects over the age of 65. When compared with younger groups, elderly subjects had significantly higher SDS scores. The higher scores of the elderly population were attributed to greater endorsement rates for somatic items; affective items were less likely to be endorsed in the elderly samples, compared with the younger groups. This response pattern has been found consistently in studies of the SDS. Zung and Zung (1986) reported that the findings of a number of studies indicate that starting at the age of 60, there is a linear increase in the mean SDS index from 43 to 49. The pattern of SDS scores suggests that it should be less valid for diagnosing depression in the elderly. In an effort to assess the concurrent validity of the SDS, Okimoto et al. (1982) compared SDS ratings with DSM-III diagnoses made by psychiatrists who were blind to the SDS results. The authors concluded that cutoff scores for the SDS vary, depending on the purpose of its application. Kitchell, Barnes, Veith, Okimoto, and Raskind (1982) attempted to evaluate the validity of the SDS by comparing Hamilton Depression Scale and SDS scores from forty-two elderly hospitalized medical patients. Both scales discriminated between depressed and nondepressed subjects diagnosed by the DSM-III criteria. The accuracy of the SDS for classification, however, was only 74%. Kitchell et al. (1982) suggested that readjusting scoring may produce higher sensitivities and improve the accuracy of classification of the SDS. Zung et al. (1974) used the SDS as a measure of treatment outcome and reported that it is sensitive to treatment effects. The SDS has also been studied with cognitively impaired elderly subjects. Heidell and Kidd (1975) measured depression levels in samples of cognitively impaired and healthy individuals over the age of 60. The results demonstrated that moderately cognitively

impaired subjects scored significantly higher on the SDS than unimpaired subjects. These findings support the use of the SDS as a measure of treatment outcome for use with the cognitively impaired. In sum, research on depression scales used with the elderly provides support for the reliability and validity of several instruments. The Beck Depression Inventory currently enjoys the greatest support. Its use is recommended except for older populations known to have high cognitive impairment or serious chronic illness.

Anxiety Disorders

Prevalence

Epidemiological studies of anxiety present a complex picture of the prevalence and incidence of anxiety in advanced age. Recent epidemiological surveys have consistently found lower rates of anxiety in elderly cohorts and the highest rates among cohorts of young adults (Kessler et al., 1994; Robins & Regier, 1991). In the NIMH Epidemiological Catchment Area studies (Myers et al., 1984), the prevalence rates for all of the anxiety disorders were lowest for the 65-plus age group. In the ECA study, prevalence rates over a 6-month period for simple phobias averaged 3.3% for males older than age 65 and 7.0% for females older than age 65. The prevalence of agoraphobia averaged 1.6% for males and 3.0% for females older than age 65. The prevalence rates during a 6-month period for obsessive-compulsive disorder averaged 1.3% for males and 1.0% for females older than age 65. No males older than age 65 met the diagnostic criteria for panic disorder; the prevalence rates for panic in women older than age 65 averaged 0.2%. Assuming independence of disorders, this would be an overall total of 6.2% of men and 11.2% of women who reported an anxiety disorder. Feinson (1985) surveyed 313 randomly sampled older adults and found that anxiety was the only problem significantly associated with increased age. In this study, subjects older than age 85 reported higher rates of anxiety than individuals in the 65–84 age group. This finding is consistent with the age-associated differences in anxiety reported by Himmelfarb and Murrell (1984). It might at first appear to differ with the low prevalence rates found in the NIMH Epidemiological Catchment Area studies; however, recall that the ECA studies lumped together elders older than 65

into one age group, whereas the Feinson study presents a breakdown within that broad age range. Using a sophisticated sampling procedure, Himmelfarb and Murrell (1984) surveyed 713 males and 1338 females older than age 55 to assess the prevalence of anxiety symptoms among community-residing elderly. They found that 17.1% of males and 21.1% of females surveyed experienced sufficiently severe anxiety symptoms to warrant intervention. These investigators found several interesting interactions among anxiety and age, gender, and health. Anxiety scores decreased from ages 55–59 and reached a low point in the 65–69 age group; the scores increased in the 75–79 age group. These findings are consistent with the less detailed analyses presented by Feinson (1985). When gender was examined, it was found that never-married males had the highest anxiety scores among the males, whereas never-married women reported the lowest levels of anxiety within the female sample. Physical health and anxiety had the strongest association. High anxiety was significantly associated with the presence of several medical conditions, including hypertension, kidney or bladder disease, stomach ulcers, hardening of the arteries, stroke, and diabetes. Significant relationships were also found between anxiety and taking prescription medication; needing care from a doctor, hospital, home health agency, or mental health service; and not having medical needs met within the last 6 months. Wisocki (1988) surveyed ninety-four community-residing elderly to examine the prevalence of worrying. Respondents ranged in age from 60–90 and the mean age was 72. Wisocki found that few of the elderly (14%) in this sample reported significant levels of worrying. Worries concerning health were the only type that were correlated with age; marital status did not differentiate type or frequency of worrying. Respondents reporting the most worries were significantly more anxious and rated themselves in poorer health than the less worried respondents. The participants in this survey were sampled from senior citizen centers and meal sites and therefore may be representative of healthier elderly who are actively involved in the community. Because worry levels were not reported by age decades, precise comparability to earlier studies is also difficult. The overall level of worrying is comparable to the rates of anxiety reported in the general population older than 65 in the British (Ray, Beamish, & Roth, 1964) and American (Myers et al., 1984) epidemiological studies.

Etiology of Anxiety

Etiological theories of anxiety and aging need to address (1) the decreased prevalence of anxiety in old age; (2) factors associated with increased vulnerability to developing anxiety in old age; and (3) environmental precipitants of anxiety in the aged. Systematic investigation of the prevalence and incidence of anxiety is needed before development of an adequate etiological theory. To date, there have been no longitudinal studies that investigated the natural history of anxiety or changes in worrying and coping across the life-span.

Anxiety and Medical Illness. Anxiety in older adults often occurs simultaneously with physical illness (Cohen, 1991; Himmelfarb & Murrell, 1984; Raj, 1993). The relationship between physical illness and anxiety in old age is not well understood. It is unclear, for example, whether the onset of the anxiety and the physical disorder occur simultaneously or whether one predates the other and has a possible causal influence. Physical disorders that are frequently accompanied by anxiety include angina, cerebral arteriosclerosis, epilepsy (particularly psychomotor), Parkinson's disease, hypoglycemia, hyperinsulinism, hypoxic states, hypothyroidism, and amine-secreting tumors. Hypothyroidism in the elderly, for example, may produce symptoms similar to those of anxiety, including sweating, tachycardia, cardiac arrhythmias, and restlessness. Detailed thyroid tests are necessary to rule out this condition.

In studying the effects of disability and bereavement, Reich et al. (1989) found that subjects recently disabled by an illness or accident reported higher levels of anxiety than both recently bereaved and nonbereaved healthy control subjects. All groups reported decreases in anxiety over time. The disabled subjects were found to have experienced significantly more health problems before the study, compared with either control group. These findings suggest that anxiety may occur simultaneously with or as a consequence of illness in the elderly. Because the psychological status of the disabled subjects before the onset of their disability was not known, however, the causal relationship between anxiety and illness cannot be determined.

Anxiety and Cognitive Impairment. The relationship between anxiety and cognitive impairment has not received much attention from researchers. Studies that have been reported have addressed either the relationship between anxiety

and dementia or the impact of anxiety on the cognitive functioning of healthy older adults.

A difficulty associated with the study of anxiety in dementia patients involves the lack of validated measures of emotion for use with this population. When anxiety is reported, it is typically inferred from behavioral observations of agitation and/or escape behaviors. Swearer, Drachman, O'Donnell, & Mitchell (1988) found that 63% of caregivers of dementia patients who resided in the community reported that the patient exhibited one or more behavioral symptoms of anxiety, including general fearfulness, restlessness, pacing, a fear of specific objects of events, and worry over insignificant matters. In a study of forty-two Alzheimer's disease patients who resided in long-term care facilities, Fisher, Goy, Swingen, and Szymanski (1994) found that nurses described all of the patients who exhibited aggression as distressed before and during aggressive acts. In this sample, the aggressive behavior was consistently reported to be associated with an effort to escape from an aversive stimulus or with a high level of environmental stimulation. These findings suggest that aggressive behavior may function to terminate an anxiety-provoking stimulus for some dementia patients (see Fisher & Noll, 1996, for further discussion).

Psychological Theories of Anxiety in Old

Age. *Psychodynamic Theories.* Psychodynamically oriented theorists have not addressed anxiety in old age to the extent that they have researched depression. In discussing anxiety in general, Freudian theorists have emphasized the role of intrapsychic forces in the form of forbidden instinctual drives that threaten to escape conscious control. Verwoerd (1980) suggested that anxiety associated with the anticipation of loss of external resources may best characterize anxiety in old age. This form of anxiety is known as secondary or depletion anxiety and is distinguished from anxiety that results from an overpowering influx of stimuli or anxiety that is a response to unacceptable impulses. Anxiety from helplessness and dependency are cited as common examples of depletion anxiety. Although we could not locate any reports of direct empirical tests of Verwoerd's assertions, indirect support might be found in the research on anxiety and medical illness described earlier.

Behavioral Theories. Learning theorists have presented several explanations of anxiety disorders. Mowrer (1948) and Dollard and Miller (1950) pro-

posed that anxiety develops through a two-stage process. The two-factor theory posits that in the course of an individual's experience, a neutral stimulus is paired with an aversive stimulus and through respondent conditioning arouses anxiety. The individual is motivated to reduce the fear and thus avoids the conditioned stimulus. This avoidance results in relief from anxiety and thus, through negative reinforcement, becomes habitual. Although this model has considerable clinical relevance because it suggests that behaviors that reduce fear are reinforcing, many studies suggest that it is insufficient as an explanation. For example, it has been found that fear continues even after avoidance responses have stopped (Riccio & Sylvestri, 1973). Further, fears are often acquired through modeling (Rachman, 1977). In an attempt to address the limitations of the two-factor theory, learning theorists have focused on the role of cognitive events in developing and maintaining anxiety. Cognitive theories of anxiety assume that the expectancy of harm mediates anxiety responses, that these expectancies are learned, and that the intensity of anxiety is a function of the perceived likelihood of anxiety. Chorpita & Barlow (1998), for example, in describing a model of the development of panic disorder, suggests that the psychological changes that accompany panic attacks become conditioned stimuli for further panic attacks. When these anxiety-associated psychological changes begin to occur, even for ordinary reasons, the individual begins to anticipate an attack. The fear of the attack intensifies the psychological response, and in a spiraling fashion, the fear and psychological reactions increase until an attack occurs.

It seems plausible that several age-associated changes in learning could affect anxiety in the aged. To date, learning theorists have not empirically investigated the effects of conditioning, psychological, and cognitive factors on anxiety in this population. A few researchers (Borkovec, 1988; Wisocki, 1988), however, have begun to speculate on the relationships between these age-associated changes and anxiety. In attempting to explain the low rates of worrying observed in a healthy sample of elderly, Wisocki (1988) offered some interesting hypotheses. She suggested that an age-associated biochemical change may result in a decline in cognitive acuity that may in turn reduce the impact of potentially worry-eliciting stimuli; she noted that now there is no clear evidence to support this hypothesis. Alternatively, Wisocki

suggested that the elderly may develop effective coping strategies that allow them to adapt to environmental conditions. Borkovec (1988) suggested that if the latter is an accurate explanation of the frequency of worrying among the elderly, then their coping strategies should be investigated, as these may provide insight into better coping mechanisms for worry and anxiety in the general population. He suggests three mechanisms that might be operating: (1) long-term habituation that results in a lessening of the impact of stressful events; (2) development of realistic expectations regarding the probability of events and effective ways of coping with events as a result of experience; and (3) developmental changes in the attitudes and behaviors necessary to reduce worrying. Borkovec (1988) noted that these speculations rest on the assumption that the elderly do in fact worry less than younger age groups. Current data suggest this, but are not yet definitive.

Assessment of Anxiety

As with other disorders, it is important to assess whether anxiety in an older person involves a continuation of a problem first seen in earlier adulthood or one that developed in old age. Anxiety symptoms with a rapid onset may be attributable to a physical disorder or to a toxic reaction to medication. The high consumption of prescription and nonprescription drugs and the prevalent practice of polypharmacy in the elderly makes it essential to assess the possibility of a toxic reaction as the precipitant of anxiety. There are very few anxiety-screening measures that have been normed on an elderly population. The State Trait Anxiety Inventory (Spielberger, 1983) includes norms for working males and females from ages 50–69. Spielberger (1983) compared data from norm studies of three age groups (19–39, 40–49, and 50–69) and found that although the mean anxiety scores for the two younger groups were quite similar, the scores for the oldest group were significantly lower. It should be noted, however, that these ratings were done with a group of relatively young, high-functioning, and healthy older adults.

Psychotic Disorders in Late Life

The gerontological literature on psychotic disorders in later life has consistently reported an

increase in the prevalence of psychotic symptoms in old age (Forsell & Henderson, 1998). Psychoses in later life may involve a continuation of a chronic disorder first evident earlier in adulthood or, more commonly, the development of psychotic symptoms associated with an underlying medical condition. The increase in psychotic *symptoms* is largely associated with underlying medical conditions such as delirium, dementia, and other neurological conditions (Ballard, Chithiramohan, Bannister, Handy, & Todd, 1991; Ballard & Oyebode, 1995; Forsell & Henderson, 1998). Older adults who experience neurological disorders may be at increased risk of psychotic symptoms when cognitive impairment is coupled with sensory deficits and social isolation (Thorpe, 1997).

The sparse literature on schizophrenia in old age reflects, in part, the long-held belief that this disorder follows a chronic deteriorating course. Until recently, many felt that the study of schizophrenia in old age would do little more than document an obvious pattern, namely, that deterioration continues until death. However, several longitudinal studies of psychiatric patients have provided evidence that calls into question previous thinking about psychopathology in old age (e.g., Ciompi, 1985; Harding, Brooks, Ashikaga, Strauss, & Breier, 1987; McGlashan, 1988). Contrary to expectations, evidence of stability and even improvement in some symptom patterns has been observed. Comparable gains in understanding have not been made in the domain of late-life paranoia. Here, our knowledge base about age-specific characteristics remains quite limited. Clinical wisdom and case study continue to be our principal informants. In this section, we consider prevalence, etiology, and symptomatology separately for schizophrenic and delusional disorders. We caution the reader, however, that as a result of the poor diagnostic classification of psychosis in much of the geropsychiatric literature, there is a certain arbitrariness in the delineation.

Schizophrenia

Virtually all clinical scientists believe that schizophrenia is a disease of the central nervous system (U. S. Department of Health and Human Services, 1988). It is considered a psychiatric disorder (as opposed to a medical disorder) because the manifestations are almost entirely cognitive or behavioral. Schizophrenia affects nearly every aspect of information processing and renders the afflicted

individual impaired in the entire spectrum of mental processes from attentional abilities to speech generation and comprehension to eye-movement control. Thought content may be bizarre, marked by fixed delusional systems or simply faulty beliefs. Emotional response is often inappropriate, some times aberrant and exaggerated, but more often absent (i.e., flattened or subdued). Perceptual disturbances range from basic deficits in processing external information to visual and auditory hallucinations. Not surprisingly, schizophrenia typically results in serious impairment in social relationships. Symptoms of schizophrenia are typically subtyped as either positive or negative (Andreason, 1982; Carpenter, Heinrichs, & Wagman, 1988). Positive symptoms are florid symptoms such as hallucinations and delusions; negative symptoms, in contrast, refer to symptoms associated with the loss of normal functions, personal neglect, apathy, and slowed or absent movements (Strauss, Carpenter, & Bartko, 1974). It is difficult, if not impossible, to tease apart the effects of institutionalization, chronic use of major psychotropic medications, and aging *per se* on late-life symptomatology, but it appears that the aging process exerts a beneficial influence on positive symptoms of the disorder. In a study of patients hospitalized 28 years or more, Lawton (1972) found that patients were "less active, less agitated, less disorganized and more conforming" (p. 141) on follow-up than according to earlier records. Longitudinal research published during the past decade suggests that age in both hospitalized and nonhospitalized patients is related to reductions in the frequency and severity of positive symptomatology (Ciompi, 1985; Varner & Gaitz, 1982). General slowing and decreasing energy associated with normal aging may lead to the diminution of florid symptoms. Some researchers interpret these findings optimistically and even suggest that schizophrenia remits in old age (Harding, 1986), but others caution that such claims are premature (McGlashan, 1988). The exact processes that underlie decreases in positive symptoms also exacerbate negative symptoms and place older schizophrenics at risk of social isolation from friends and neglect by the mental health system. Among the elderly, just as in younger adults (Hooley, Richters, Weintraub, & Neale, 1987), negative symptoms (and not positive symptoms) predict social support and level of functioning (Meeks et al., 1990). Most of the current cohort

of geropsychiatric patients experienced the radical changes in treatment that developed after the discovery of major tranquilizers in the 1950s. For many, it meant discharge from what would have been lifelong institutionalization. As this patient population aged, however, many patients faced a return to communities unprepared to meet their needs. And tardive dyskinesia, a serious motor disorder that stems from long-term use of antipsychotic medication, now afflicts a substantial proportion of older chronically mentally ill patients.

As in young people, the treatment for schizophrenia in old age is symptomatic. Psychotropic medication is considered the treatment of choice. Dosages, however, can be decreased; many times, they can be discontinued altogether.

Prevalence. The incidence of schizophrenia in the over-60 age group is slightly less than that in the general adult population. The decrease reflects the extremely low rate of new cases, coupled with a relatively high mortality rate among diagnosed schizophrenics largely the result of suicide and trauma (Post, 1980). In more than 90% of cases, onset occurs before the age of 40 (LaRue et al., 1985). Thus, most older schizophrenics are chronic patients grown old, not newly diagnosed schizophrenics. Rarely does schizophrenia appear for the first time in old age (Gurland & Cross, 1982). In fact, in the DSM-III, an initial onset of symptoms beyond age 45 precluded the diagnosis of schizophrenia. This criterion was disputed by some and dropped in the subsequent revision of the manual, but the fact that it was initially included speaks to the rarity of onset in late life. Studies of psychiatric hospitalizations show that the number of admissions attributable to schizophrenia is also relatively low in older age groups. Approximately 1% of first psychiatric admissions involve schizophrenia, less than half the number among younger psychiatric patients (Kastrop, 1985).

Etiology. It is widely accepted that genetic inheritance plays a causal role in the development of schizophrenia (Gottesman & Shields, 1972), even though the mode of transmission is indeterminate at present (Gottesman, McGuffin, & Farmer, 1987). Family, twin, and adoption studies have demonstrated that risk increases linearly with the degree of shared genetic inheritance with the afflicted proband (Gottesman & Shields, 1972). Just as widely accepted is the belief that environmental influence is essential to the onset of the disorder

(Stromgren, 1987). Most behavioral scientists subscribe to some variation of a diathesis-stress mode of transmission (e.g., Zubin & Spring, 1977). These models view genetic inheritance as a necessary but insufficient precursor to the disorder. Environmental stressors that serve as triggers for the onset of symptoms are also essential. The low incidence of initial-onset cases in old age may reflect the fact that, if one is vulnerable, one will have succumbed to the disease long before old age.

Paranoia

As mentioned earlier, the most common form of psychosis in old age is paranoia. The term paranoia originated in Greek law; it referred to the deteriorated mental state in old men that allowed their sons to take over the management of their fathers' affairs (Post, 1987). The central feature of paranoia is an unshakable delusional belief system. These false beliefs may be limited to a circumscribed set of persons and circumstances or may be more elaborate and incorporate multiple people and multiple motives. It is important to note that we refer in this section only to the clinical syndrome of paranoia; paranoid symptoms that characterize early stages of Alzheimer's disease occur with considerable frequency in old age, but in such cases the cardinal feature is progressive cognitive decline. In paranoid psychosis, serious cognitive deterioration is not evident, and daily functioning is well preserved.

It is clear that paranoid delusions at any age seriously disrupt the ability to function and maintain social networks. For old people, especially those who require extended assistance from others, the consequences are potentially dire. Persecutory beliefs that target the very family members and professionals who are trying to help the patient can be so unsettling that assistance is discontinued. This usually leads to greater social isolation and an exacerbation of symptoms. Frequently, a central objective in treatment is reducing the anger and guilt that family members experience when their relative is suspicious of their motives.

There have been many attempts to establish classification systems for subtypes of paranoid disorders in old age, yet none has been widely accepted in the empirical literature. An unfortunate consequence has been an overabundance of terms in the literature that carry limited informa-

tion about prevalence, course, or treatment. Examples of subtypes frequently used include senile paraphrenia, simple paranoia, paranoid hallucinosis, and transitional paranoid reaction, none of which appear in the DSM classification system.

Treatment for paranoia typically involves psychotropic medication. This course of treatment, however, is sometimes precluded by the patient's refusal to take medication. There is some evidence that behavioral interventions are also effective (Carstensen & Fremouw, 1981).

Prevalence. Paranoia is second only to depression in the frequency of occurrence among the elderly. It is considered the most common form of psychosis in the senium; unlike schizophrenia, new cases continue to appear well into old age. Accurate estimates of prevalence, however, are absent as a result of the classification problems referred to before. Some researchers, for example, differentiate paranoia from schizophrenia on the basis of late-life onset, whereas others attempt to differentiate one from the other on the basis of symptom patterns.

Using the DSM-III criteria for diagnosis, Varner and Gaitz (1982) estimated that 2% of outpatients and 4.6% of inpatients among the elderly suffer from paranoia. Still, quite commonly, paranoia fails to receive psychiatric attention; therefore, population estimates are assumed to be much higher.

Etiology. Most geriatric clinicians believe that interpersonal as well as biological loss play a role in the etiology of paranoia in old age. LaRue et al. (1985) cite several premorbid risk factors for late-onset paranoia, including never having married, being childless, being socially isolated, and suffering significant hearing loss. Impairment in hearing presents greater risk than vision impairment. A positive family history of schizophrenia and paranoid or schizoid premorbid personality also contributes to risk.

Assessment of Psychosis

The troublesome lack of attention to (and agreement about) classification is central to the relative dearth of information about psychosis in old age. This limits the interpretation of many early studies. For example, numerous articles about paranoia consider cases of increased suspiciousness toward family members and cases involving complex delusional systems under the same rubric. Distinc-

tions between schizophrenia of the paranoid type and paranoia are rarely made. There is no scientific justification for this pattern. Paranoid symptomatology in old age can indicate schizophrenia, dementia, or paranoid psychosis; the prevalence and prognosis are different for each.

Schizophrenics are no more likely than normals to develop dementia in old age (Ciompi, 1985). Even though the two disorders can co-occur, cognitive impairment usually indicates dementia rather than paranoia. Differentiation of drug-induced symptoms from psychotic symptoms is of paramount importance in assessment. Geriatric patients are more susceptible to toxic reactions from a wide range of prescription and nonprescription medications. It is essential to consider delirium whenever a new patient is assessed.

By and large, the same assessment instruments used with younger psychiatric patients are used with geropsychiatric populations. The Brief Psychiatric Rating Scale (BPRS), the SCL-90, and the Minnesota Multiphasic Personality Inventory (MMPI) are very commonly used. The Kincannon, a brief form of the MMPI, is sometimes preferred to the original form because it can be administered verbally.

Summary

Psychotic disorders continue to appear in late life. Most geropsychiatric patients, however, are chronically mentally ill persons grown old. In some aspects, the long-term outlook for psychosis is good. Specifically, there is a muting of positive symptoms; because positive symptoms dampen or remit in advanced years, medications can frequently be reduced or discontinued. Remaining symptoms, however—particularly social withdrawal—place older patients at risk of an exacerbation of problems in the development of now-secondary problems because of the absence of adequate nutrition, insufficient medical care, and increasing social isolation. For this reason, it is essential to assess carefully and to treat negative symptoms, even when diminished positive symptoms suggest improvement.

Psychoactive Substance Use Disorders

Prevalence surveys of psychoactive substance abuse have varied in sampling methods and in the

definition of substance abuse. Most prevalence studies, for example, have sampled an urban population and have examined alcohol abuse rather than drug abuse. Bailey, Haberman, and Alksne (1965) surveyed households in Manhattan and found a bimodal peak prevalence for alcoholism. The peak prevalence for alcoholism occurred in the 45–54 age group (23 cases per 1000); prevalence declined to 17 per 1000 in the 55–65 age group, but it increased to 22 per 1000 in the 65–74 age group. This second peak was followed by a precipitous drop to 12 per 1000 for the 75-and-over age group. The highest rates were found among elderly widowers: 105 cases per 1000. These prevalence rates indicate that alcoholism is a serious problem for this particular group of elders, given that the prevalence rate for the entire population is 19 per 1000.

In a study of 1990 referrals to a geriatric outreach program, Reifler, Raskind, and Kethley (1982) found a 10% prevalence rate for substance abuse. The majority of the cases (82%) involved alcohol abuse rather than drug abuse. These authors reported a decline in alcohol and drug abuse between the ages of 60 and 90 or more years. For the age group of 60–69 years, the prevalence was 21%, whereas the prevalence rate after age 90 was 1%. These data are consistent with the findings of Daniel (1972) and Bailey et al. (1965) who also reported an age-associated decline in alcohol-related problems. Reifler et al. (1982) suggested that the observed decline may be attributable to the increased mortality associated with substance use disorders. Note that both Reifler et al. (1982) and Daniel (1972) sampled from elderly persons already involved in the mental health system; the prevalence rates reported by these investigators may be underestimated if elderly substance abusers do not find their way into the mental health system. This is highly possible, given that studies of patterns of mental health service utilization suggest that visits to mental health clinics by individuals older than 65 are rare (Shapiro et al., 1984). The prevalence may be overestimated, however, if substance abusers are more likely to develop problems that bring them to the attention of the health care system.

Medical care for the problems associated with long-term alcohol abuse is usually necessary for the elderly early-onset alcoholic. The prognosis for elderly alcoholics who began drinking in early adulthood is likely to be poorer. For those elderly who begin abusing alcohol in later life, the onset

of the abuse is likely to be associated with a stressful event (Martin & Streissguth, 1982). Life events common in old age that may contribute to late-onset alcohol abuse include retirement, relocation, bereavement, and financial concerns. Stress associated with these circumstances may contribute to the development of anxiety or depression; the elderly individual may in turn attempt to obtain relief by self-medicating with alcohol. Valinis, Yeaworth, and Mullis (1988) surveyed bereaved and nonbereaved older adults and found, for example, that only 5.6% of bereaved males abstained from alcohol use, compared with 46% of nonbereaved males.

Cognitive Impact of Alcohol Abuse in Old Age

Jones and Parsons (1971) suggested that the severe cognitive deficits typically seen in elderly alcoholics relative to younger alcoholics are attributable to the greater susceptibility of the aging brain to the effects of alcohol abuse. This is known as the increased susceptibility hypothesis. A second hypothesis, known as the premature aging hypothesis, developed from observations of the cognitive functioning of long-term alcohol abusers. It has been found that alcoholics can often perform tasks that require highly overlearned responses, but that they demonstrate severe deficits in tasks that require abstract reasoning, memory, learning, or visuo-perceptual skills (Ryan, 1982). Ryan and Butters (1980) reported that in various learning and memory tasks, alcoholics typically perform at a level comparable to normal controls who are 10 years older. This relationship, it was found, held across the life-span. Noonberg, Goldstein, and Page (1985) suggested that a limitation of this research has been the disregard for whether the cognitive tests used are sensitive to both aging and the effects of alcohol. A study reported by Holden, McLaughlin, Reilly, and Overall (1988) provides support for the hypothesis that the effects of alcohol abuse on cognitive functioning are similar to the effects of aging. These investigators calculated mental age function from WAIS-scale score profiles for 164 alcoholics who ranged in age from 35–74. They found that the mean mental age for subjects in the alcoholic sample was approximately 7 years advanced over age-matched controls.

Noonberg et al. (1985) suggested that a significant interaction between alcoholism and age is not

necessary to support the premature aging hypothesis. These authors contend that the premature aging hypothesis predicts that the performance of alcoholics will be inferior to normal controls across the life-span. In contrast, the increased vulnerability hypothesis predicts that young alcoholics will not display significant decrements relative to normal controls. Furthermore, according to the increased susceptibility hypothesis, alcoholics should become susceptible to the effects of long-term alcohol abuse only in advanced old age (Holden et al., 1988). The increased susceptibility hypothesis developed from findings that there were no parallel relationships in the developmental curves of alcoholics and normal controls. Bertara and Parsons (1978), for example, found that alcoholics performed more poorly than normals in a scanning task at all ages, but a relationship between age and performance was found only for the alcoholic group. Common findings of cognitive deficits observed in young alcoholics (e.g., Holden et al., 1988; Ryan & Butters, 1980) do not support this hypothesis. There is evidence, however, that recovery from the effects of alcohol abuse may be age-dependent. Reilly, Kelly, Pena, Overall, and Faillace (1983) reported that a deficit in visual evoked-potential latencies in newly detoxified alcoholics was reversible in younger alcoholics but progressively less so at older ages. At present, it is not clear whether recovery in cognitive functioning is also age-dependent. Zimberg (1987) developed a scale of alcohol abuse that he reports is useful in diagnosing alcohol abuse in the elderly and in measuring changes in the severity of abuse over time. He suggested that lower scores are indicative of abuse, compared to score levels for younger groups, because there is typically less evidence of addiction in the elderly and fewer physical sequelae. Unfortunately, he does not report any data that support the reliability and validity of the scale.

Zimberg (1987) suggested that classifying elderly alcoholics according to whether the problem drinking began early in life or whether the onset occurred in old age can have implications for treatment planning. Further, he noted that this approach to classification allows examining the effects of the stresses of aging that contribute to alcohol abuse. These factors can be compared with the characteristics of the early-onset alcoholic that are unrelated to the problems of aging. **Assessment.** Assessment of alcohol abuse in the elderly is hindered by an absence of standard-

ized instruments with norms based on an elderly sample. It has been suggested that alcoholism in the elderly may be underidentified because elderly alcoholics typically drink relatively small amounts, compared to younger alcoholics (Willenbring, Christiansen, Spring, & Rasmussen, 1987). Elders who consume smaller amounts of alcohol are still considered alcohol abusers because they cannot metabolize alcohol as readily as younger adults (Saltman, Vander Kolk, & Shader, 1975). Older alcoholics are usually brought to the attention of the medical community because of the medical and cognitive complications that often accompany alcohol abuse in old age, rather than because of family or occupational difficulties, as is often the case with younger alcoholics. Willenbring et al. (1987) argued that the differences in symptomatology between older and younger alcoholics may limit the validity of screening instruments that have been normed on younger groups.

Willenbring et al. (1987) assessed the validity of four versions of the Michigan Alcoholism Screening Test (MAST) for elderly males. They reported that, using a cutoff score of 6 or more, the MAST correctly classified all cases and 90% of the controls. The brief versions of the MAST also have acceptable sensitivity and specificity for this population.

Sexual Disorders

The film "Cocoon" exemplifies many of the myths and realities about aging and sexual dysfunction; a major goal of this section is to help clarify the realities and dispel some of the myths that the movie dramatizes. In this film, three older men (two married and one unmarried) are restored to youth, unknowingly, by swimming in a pool containing alien "cocoons" that are imbued with a mysterious "life force" by their alien rescuers. On their way home, all three share that each has a strong erection, the first in a long time. The two married men return home to initiate sex with their wives (who need no restoring "life force" to be eagerly receptive sexually). The unmarried man stops avoiding contact with an interested woman and becomes willing to date her and to begin a romance. The messages are clear, though implicit. First, and most positively, the film suggests that sex is not disgusting or inappropriate for elders; it is a joyful activity for both the men and the women

in the film. The other messages, however, are more problematic. The second message is that older men do not get spontaneous erections; only men "restored to youth" can do that. Third, only when men get spontaneous erections does sexual contact occur for couples. In fact, this expectation is so strong that the unmarried man avoids all personal, potentially intimate, social contact with women until he can get an erection. Fourth, older women are shown as dependent on their male partners' decisions to initiate or avoid sexual contact; they can accept but cannot make overtures.

Prevalence

What does the literature suggest about the accuracy of these stereotypes of sexual functioning and dysfunction in elders? Unfortunately, well-designed epidemiological studies of functioning across a full range of healthy and ill elders of various ages and demographic characteristics are nonexistent; however, a patchwork of studies that examined various aspects of function is available.

The earliest studies to examine the prevalence of sexual problems in the elderly suggested that there was a general decline in sexual activity across the life-span. For example, Kinsey and his associates (Kinsey, Pomeroy, & Martin, 1949; Kinsey, Pomeroy, Martin, & Gebhard, 1953) found lower levels of sexual activity of all types with each increasing decade of age. They also reported a greater incidence of male dysfunction (particularly, difficulty obtaining or maintaining an erection) with each increasing decade of life, particularly starting around age 50. Similar findings have been reported by a number of investigators (e.g., Freeman, 1961; Newman & Nichols, 1960; Pfeiffer & Davis, 1972; Pfeiffer, Verwoerd, & Davis, 1972; Pfeiffer, Verwoerd, & Wang, 1969; Verwoerd, Pfeiffer, & Wang, 1969a,b).

The major problem in all of this prior research has been the exclusive use of cross-sectional methodology. Thus, the effects of age have been confounded with cohort in these studies. In addition, when combining across individuals at each age, a smooth curve may be the picture of decline, when the actual longitudinal events may be more acute rather than gradual, that is, individuals may sustain a particular level of function throughout their lives without any decline until some dramatic event, such as the onset of a severe illness, changes the picture.

Studies of Prevalence. George and Weiler (1981) tested these possibilities using data from the Duke Longitudinal Study of Aging and followed 278 men and women, ages 46–71 and all married (though not necessarily to each other), for approximately 6 years. Using this longitudinal design, they found that “levels of sexual activity remain more stable over time than previously suggested” (George & Weiler, 1981, p. 918). They found that as people aged, the best predictor of their level of sexual behavior was their level of behavior when they were younger. For some couples during the period of study (8.3% of the men and 14.8% of the women), however, a dramatic decline in activity occurred. In most cases, the cause of this change was some physical change in the male partner that altered his interest in sex or his ability to be an active sexual partner (e.g., development of erectile failure attributable to medications). These authors concluded that “it is crucial to distinguish between aggregate trends and intraindividual change” (George & Weiler, 1981, p. 918), particularly when considering the clinical implications of these findings.

Since these findings have been reported, a handful of additional studies has become available. Among these is only one longitudinal study (Persson & Svanborg, 1992). These authors studied men in Sweden who were married and sexually active at age 70; men were again interviewed at age 75 regarding sexual activity. They found cessation of sexual activity among about half of the sample: 20 still had intercourse with their wives, whereas 21 did not. For men who had ceased sexual activity, cardiovascular causes were the most commonly cited reason. In addition, various life stresses, such as financial problems, were also typical of men who had ceased sexual activity. The authors further reported that there seemed to be additive effects of stress and cardiovascular disease, particularly hypertension. It is interesting to note that the authors of the study and, apparently, the men in the sample did not mention substituting other sexual activity when intercourse was no longer feasible. When the male partner had difficulty with erectile function, sexual activity of all kinds ceased.

Weizman and Hart (1987) reported maintenance of sexual interest and activity in healthy men ages 60–71. Similarly, Martin (1981) showed that individual differences in sexual functioning before middle age are likely to be maintained past middle

age and to persist into old age. Laumann, Paik, and Rosen (1999) studied a large national probability study of men and women, but unfortunately covered only ages from 18–59. However, within this age range, they report the intriguing finding that the effects of age are different for men than for women. For women, increasing age led to a decreased prevalence of sexual problems across the spectrum of desire, orgasm, and pleasure experienced in sex. For men, the opposite was true: increasing age was associated with increased prevalence of difficulty, especially in relation to sexual desire and the experience of erection.

Bortz, Wallace, & Wiley (1999) surveyed men aged 58–94 to obtain information on sexual attitudes and activity. They found, as others have, that age was related to increased sexual dysfunction and decreased sexual activity. However, many of these men (along with those without difficulty) continued to engage actively in sexual behaviors and to report positive attitudes about sex. Health status was a major predictor of the presence or absence of dysfunction. Perceived partner responsiveness was also an important moderator of age effects.

Following on the importance of health status, two studies targeted physically healthy older adults. Bortz and Wallace (1999) obtained information from older men and women who attended the Fifty Plus Fitness Association, a group committed to an active life-style. They found that, in this select group, both male and female members had high levels of sexual activity and satisfaction. Sexual satisfaction was correlated with the degree of fitness. Steinke (1994) conducted studies, using the Aging Sexual Knowledge and Attitude Scale (White, 1982), of members of an older adults' wellness group and of a random sample of older adults. Both groups reported a moderate level of knowledge and permissive attitudes; there were no significant differences between men and women. There was a wide range of sexual activity, from 0 to 30 episodes of sexual activity per month. Surprisingly, there were no dramatic differences between the wellness group and the randomly selected older adults.

Socioeconomic status is another variable that appears to affect sexual attitudes and behavior in older age (Cogen & Steinman, 1990). In a study of older men (ages 61–84) who attended a VA geriatric clinic, these authors found that 59% of the men had erection difficulties that ranged from complete

loss to frequent difficulty obtaining an erection significant for intercourse. Generally, these men were from lower socioeconomic backgrounds, and they reported infrequent use of manual or oral stimulation, even when intercourse was not possible. In fact, with one exception, all of the men who could not obtain erections adequate for intercourse ceased all sexual activity. This figure contrasts with the report from men of higher socioeconomic status of a high prevalence of using (up to 56%) alternative activities for sexual stimulation (Brecher, 1984; Starr & Weiner, 1981).

Unfortunately, the well-constructed NIMH Epidemiologic Catchment Area program (Regier et al., 1984) did not include questions about sexual function, so that there are still many unanswered questions regarding the prevalence of particular sexual dysfunctions in community-dwelling elders. There are some reports on the prevalence of sexual dysfunction in men (but unfortunately not in women) who have various medical problems (Slag et al., 1983).

Medical Problems and Sexual Dysfunction.

One influential study (Mulligan, Retchin, Chinchilli, & Bettinger, 1988) reported on 1180 men who received care in a Veterans Administration medical outpatient clinic; although the age range of the sample is not clearly reported, it is primarily an elderly sample judging by the mean ages for various groups (which ranged from 56.5 years old to 66.9 years old). In this group, which was preselected for medical problems and was likely to be using medications, 34% reported erectile dysfunction. Another study that examined medically ill elderly veterans (Mulligan et al., 1988) also reported high rates of inhibited sexual desire (31% in those ages 65–75 and 50% in those older than 75) and erectile dysfunction (27% in those ages 65–75 and 50% in those older than 75).

Much of this research supports the implication from earlier studies (e.g., George & Weiler, 1981; Persson & Skanborg, 1992) that it is not age *per se* but age-related physical illness that leads to sexual dysfunction in the elderly. It is also possible that normal age-related changes may contribute to dysfunction, however, that psychological attitudes may make ill elders more vulnerable to dysfunction, or that there may be complex interactions among normal age-related changes, medical conditions, psychological, and cultural factors in the etiology of sexual dysfunction in the elderly.

Etiology and Assessment. Masters and Johnson (1966) described the major age-related changes

in physical response to sexual stimulation. Generally, these changes result in slowed and slightly diminished response to stimulation at every stage of the sexual arousal cycle, but at no stage of the cycle is responsiveness qualitatively changed, nor is the reduction in response great enough to prevent arousal, a wide range of sexual activity (including intercourse), or orgasm. Specifically, men need more direct penile stimulation to reach erection, and the erection may be 70–80% of the size and rigidity attained at a younger age. Longer, more intense stimulation is likely to be needed for orgasm (a boon to those who experienced premature ejaculation as young men), and a longer post-orgasm refractory state will be experienced. For women, menopause results in reduced lubrication and vaginal elasticity, so that intercourse may be painful unless estrogen replacement or an artificial vaginal lubricant is used. Women may also need more intense stimulation to become fully aroused and to experience orgasm. Older women (like younger women) are potentially multiorgasmic and do not experience a refractory period. Underlying these changes are various endocrine, vascular, and metabolic changes; those best understood are the gradual decline of testosterone production in men (e.g., Davidson et al., 1983; Tsitouras, Martin, & Harman, 1982) and subclinical atherosclerotic changes that result in diminished genital vasocongestive capacity (e.g., Gewertz & Zarins, 1985; Kaiser et al., 1988).

In addition to these normal changes, a huge array of medical conditions and medications can physiologically disrupt various aspects of the sexual arousal cycle. An exhaustive description of all of them is far beyond the scope of this chapter; summaries can be obtained in Segraves and Schoenberg (1985), Schover and Jensen (1988), and Davis et al. (1985). The following, however, are worthy of special note.

Antihypertensives are a common cause of erectile difficulties (e.g., Segraves, Madsen, Carter, & Davis, 1985; Zeiss, Zeiss, & Dornbrand, 1989), and there is an age-related increase in hypertension and in the use of antihypertensive medication. A variety of neurological diseases, including multiple sclerosis, Parkinson's disease, stroke, and Alzheimer's disease, also affect sexual functioning (Coslett & Heilman, 1986; Mancall, Alonso, & Marlowe, 1985; Singer, Weiner, Sanchez-Ramos, & Ackerman, 1991; Zeiss, Davies, & Tinklenberg, 1990). Although some of this may be mediated by psychological distress about neurological symp-

toms (e.g., Zeiss, Davies, & Tinklenberg, 1990), sexual dysfunction usually increases for both males and females in direct proportion to the length and stage of disease (and thus is indirectly age-related).

It is also well-known that diabetes results in erectile difficulties in men in a large proportion of cases (often cited as 50%, although careful studies are lacking). Interestingly, problems with desire, ejaculation, or orgasm are almost never reported in men with diabetes, even when no erection can be obtained (e.g., Jensen, 1985). The degree of contribution of psychological factors is questionable (e.g., Jensen, 1986; Renshaw, 1985), but erectile problems do seem to be related to physiological indexes, particularly the presence of peripheral neuropathy. Recent research with female diabetics suggests that type II diabetes has negative effects on female sexual desire, orgasmic capacity, lubrication, sexual satisfaction, sexual activity, and relationship with the sexual partner (Schreiner-Engel, Schiavi, Vitorisz, & Smith, 1987) but that type I diabetes is not associated with dysfunction. Other research, however, suggests that psychological factors as well as physical factors may play an important mediating role in the impact of diabetes on sexual function in both men and women; acceptance of the disease and the presence of somatopsychological responses to the disease are important predictors of its impact on sexual function (Jensen, 1986; Newman & Bertelson, 1985).

Operations for prostatic problems are especially common in older males. A radical prostatectomy directly impacts sexual function because pubic nerves are severed during the surgery. Most surgery for enlarged prostates is now done via the transurethral resection of the prostate (TURP) procedure, which theoretically should have no direct negative physical consequences for erectile function (although retrograde ejaculation is often a physical consequence of the surgery). A series of studies by Libman and her associates, however, has demonstrated that older men are at elevated risk of developing sexual problems after a TURP, compared to men not undergoing surgery and to younger men undergoing TURPs (Libman et al., 1987). This elevated risk, however, seems to be most closely related to the man's sexual adjustment and couple satisfaction before surgery (Libman, Fichten, Jacobson, Creti, & Brender, 1986). In addition, older men who undergo inguinal hernia repair have negative consequences after surgery similar to those who undergo a TURP, so that

the physical procedures involved in the TURP are less crucial than the negative physical and/or psychological impact of surgery *per se*.

Psychological factors involved in sexual dysfunction in the elderly include cultural stereotypes (which affect elders' expectations and their willingness to express sexual feelings), interpersonal issues (such as changes in couples' role relationships at retirement), and intra-personal factors (such as anxiety engendered by awareness of aging or failing health). A complete review of these factors is also outside the scope of this chapter, but reviews can be seen in Renshaw (1985), Schover (1986), and Weg (1983). The issues in psychosocial functioning are particularly well described by Renshaw (1985):

Consider the woman whose 56-year-old husband has a partial erection for the first time. He panics and impotence might follow, not because he is aging but as a result of his anxiety. This is emotional impotence based on misperceptions that erections will be high and "instant" forever. If his wife has no greater knowledge, she may out of compassion avoid him sexually: "I would rather not be in bed with him. It upsets him because he cannot ..." The couple then has no loving contact at all, which may aggravate their distress and lead to physical as well as needless emotional distance. (P. 637)

This passage also illustrates the complex interaction of psychological factors (which lead to the loss of "instant" erections or full erections every time) and psychological factors (which compound the intrapsychic anxiety and the loss of the couple's closeness and result in a full-blown dysfunction).

The difficulty in talking about sexual experience by at least the current cohort of elders is another cultural factor that has psychological impact. At a younger age, the couple did not need to discuss sex, because their expectations for spontaneous arousal were physiologically supported by young, healthy bodies. As age-related normative changes and/or illnesses take their toll, however, the need to discuss concerns, engage in problem solving as a couple, and develop alternative strategies to enhance arousal and comfortable intercourse is essential. When the couple cannot discuss sex, this essential problem solving is impossible, and dysfunction results (Weg, 1983; Zeiss, Zeiss, & Dornbrand, 1989). Again, it is futile to argue whether this is essentially a psychologically caused problem (because the couple's mode of interpersonal functioning prevents finding an innovative solution) or a physical problem (because physical factors lead to the need for innovative problem solving).

Implications

In reviewing the factors cited in the prevalence research at the start of this chapter, it is important to remember that the physical changes that lead to disruption of sexual functioning are those that affect the male partner's interest in sex and/or his ability to obtain an erection. This provides another example of the intricate interplay of physical and psychological factors in elders' sexual problems. It appears that the culturally induced emphasis on male sexual assertiveness and control underlies sexual problems for many elders. For example, both diabetic men and their partners could have mutually satisfying sexual activities resulting in orgasm for both, whether or not the man obtains an erection. Because the cultural expectation, however, is that the man's erection signals the start of sexual activity and is the defining basis of the most accepted activity, sexual intercourse, the loss of spontaneous erections all too often signals the loss of sexual intimacy and shared physical pleasure.

Numerous authors (e.g., Schiavi & Schreiner-Engel, 1988) have made similar points regarding the complex interplay of physical and psychosocial factors in the elderly. The developing consensus is well described in the following: "The data also strongly suggest that organogenic and psychogenic are not dichotomous categories and that a multi-faceted assessment of erectile potential, psychological factors, and the current social and interpersonal context of sexual behavior is necessary for successful medical or psychological treatment planning" (Sakheim, Barlow, Abrahamson, & Beck, 1987, p. 379).

It is instructive now to look back at the example from the movie "Cocoon" that began this section. What are the major lessons to be drawn from it? First, the film is quite correct in suggesting that older men do not get spontaneous erections, at least as often or as firmly as younger men; this probably has a physiological basis. It is also correct that an erect penis does seem to be the major criterion for active sexual participation in older couples; this emphasis is probably culturally mediated. Couples limit themselves because of their lack of knowledge regarding normal age-related changes and reversible medical problems or the effects of medication. They also limit themselves because of their difficulty in discussing sex and in planning effective solutions to minor problems. Finally, the double standard by which this cohort

of elders was raised, which dictated that only men should actively seek sexual activity and guide its expression, seems to cause problems. It leaves couples vulnerable to a shift from sustained sexual activity to a sudden cessation or sharp decline of sexual intimacy when major (or even minor) health problems affect the male partner's ability or willingness to sustain the burdens of that role.

Eating Disorders

Eating disorders within the DSM-IV are classified under the heading of "disorders usually first evident in infancy, childhood, or adolescence." Stelnicki and Thompson (1989) suggested that this classification system may result in attributing disordered eating behaviors in the elderly to an underlying physical disorder. Consequently, the prevalence of eating disorders in this population may be underreported. The incidence of eating disorders in the elderly has not been studied systematically. Many cases reported in the literature involved individuals who displayed dysfunctional eating behaviors before reaching old age. It has been noted that the prevalence of eating disorders such as anorexia nervosa is much higher in younger cohorts (Stelnicki & Thompson, 1989). As these cohorts age, we may see an increased prevalence of such disorders in the elderly. Significant weight loss associated with anorexia, however, is already a common problem in old age. The problems of decreased food intake and malnutrition are considered of epidemic proportions among the institutionalized elderly in some areas (Morley & Silver, 1988). A survey of nursing homes in Florida, for example, indicated that up to 58% of residents experienced some degree of malnutrition (Pinchofsky-Devin & Kaminski, 1986). The majority of reports of eating disorders in the elderly are case studies. A review of the literature revealed no systematic prevalence surveys or group treatment studies with community-dwelling, noninstitutionalized populations. Price, Giannini, and Colella (1985) reported a case of anorexia nervosa in a 67-year-old widowed woman. The subject had lost 21 pounds during the course of a year, although she had no health problems. She reported that she was dieting and using laxatives and described herself as "fat and ungainly." She displayed no signs of a mood disorder. A behavioral treatment program that involved reinforcement contingent on weight

gain was implemented; after approximately 1 year, she returned to her normal weight of 125 pounds.

Ronch (1985) described the case of an institutionalized 75-year-old man who displayed symptoms consistent with a diagnosis of anorexia nervosa. Assessment revealed a long history of disordered eating habits and several hospitalizations for treatment of malnutrition. He weighed 80 pounds, engaged in laxative abuse, and refused to eat sugars, fats, and carbohydrates. He also had several food phobias, frequently hoarded food, and occasionally induced vomiting after eating. A program of forced use of food supplements and intravenous feedings resulted in weight gain up to a high of 102 pounds, but treatment gains were not maintained. In an effort to improve treatment maintenance, a cognitive-behavioral program was implemented. The program focused on treating depression and nutrition reeducation. This resulted in a moderate weight gain (up to 92 pounds) and eliminated many of the anorexic behaviors. The subject continued to report "feeling fat" at treatment termination. Another reported case of bulimia nervosa involved a 70-year-old woman with a long history of fear of becoming obese (Kellett, Trimble, & Thorley, 1976). The subject gorged herself with fattening foods and then induced vomiting and used laxatives to purge herself. A few cases of pica in elderly individuals have also been reported (e.g., Nash, Broome, & Stone, 1987). All of these involved individuals with a diagnosis of mental retardation or dementia and therefore will not be reviewed here because these disorders are covered extensively in other chapters. Of interest is the finding that the prevalence of pica among the mentally retarded is highest on the group over the age of 71 (39% of cases). The groups ages 41–60 and 11–40 account for 14 and 29% of cases, respectively (Danford & Huber, 1982).

Etiology

Several age-related physical changes may contribute to reduced calorie intake in the elderly. These include decreased demand as a result of lower metabolic rate and reduced activity; changes in taste, smell, and vision that occur with normal aging; teeth and denture problems; and decreased feeding drive, possibly related to alterations in neurotransmitters (especially endogenous opioids; Morley & Silver, 1988). Because it is a concomi-

tant of normal aging, anorexia may also be associated with a variety of disease processes that are common in old age. These include conditions that cause pain on eating (e.g., abdominal ischemia) and recurrent infections (Morley & Silver, 1988). For example, it has been suggested that the anorexia-causing chemical cachetin (or tumornecrosis factor) is released during infection or cancer and may play a causative role in the excessive weight loss found in nursing-home patients who often experience repeated bouts of infection (Morley & Silver, 1988). Depression and dementia in the elderly are often associated with anorexia. Zung (1967) reported that decreased appetite is one of the most common symptoms seen in depressed elderly. A Finnish study (Kivela et al., 1986) found that a significant proportion of elderly depressed men reported problems that interfered with eating. These included a history of diarrhea (20%), constipation (36%), stomach pains (37%), nausea (17%), vomiting (10%), and loss of appetite (22%).

It has been suggested that deficiency of norepinephrine (NE) may play a role in anorexia associated with depression. As mentioned earlier, several studies demonstrated a significant age-related reduction in NE (Veith & Raskind, 1988). This age-related reduction in NE, coupled with NE deficits associated with depression, may account for the high prevalence of decreased appetite in geriatric depression. Corticotropin-releasing hormone (CRF), it has also been suggested plays a role in the anorexia of elderly depressives. Morley and Silver (1988) reasoned that because NE inhibits the release of CRF, NE reduction should be associated with an increased release of CRF. These authors noted that CRF acts within the central nervous system as a potent inhibitor of food intake, and thus excess CRF probably functions in anorexia associated with depression. Furthermore, it has been suggested that CRF plays a role in the development of anorexia nervosa (Morley, Silver, Fiatarone, & Mooradian, 1986). Dementia is commonly associated with significant weight loss and malnutrition. The causes of anorexia in individuals suffering from a dementing disorder may include reduced interest in eating, forgetting to eat, and impaired judgment that results in failure to recognize the need to eat (Sandman, Adolfsson, Nygren, Hallmanns, & Winblad, 1987).

Problems associated with eating have serious consequences for individuals with a dementing disorder. For example, Chenoweth and Spencer

(1986) found that among caregivers of demented individuals who resided in the community, behavior problems such as the inability to self-feed accounted for 18% of the reasons given for deciding to institutionalize. Several studies have found that the nutritional status of demented individuals is often seriously deficient. Sandman et al. (1987) found energy and/or protein malnutrition in 50% of demented subjects examined; the mean reference weight of subjects was 82% of ideal body weight. Patients with dementing disorders also have lower levels of zinc, vitamin B12, and serum iron (Greer, McBride, & Shenkin, 1986). These findings suggest that the nutritional status and self-feeding behaviors of individuals with dementing disorders warrant careful attention because they are at serious risk of malnutrition. At present, little is known about the role of neurotransmitter abnormalities and anorexia in dementia. The neuropathological changes associated with dementing disorders, coupled with the resulting behavioral deficits, present complex questions for researchers in attempting to understand and reduce nutritional deficits in this population.

Conclusions

In this chapter, we reviewed the literature on psychopathology and aging. It is clear that early research and theory assumed that the incidence of psychological disorder increased with age. This was attributable, in part, to negative societal attitudes about the aging process and the methodological limitations of early research strategies.

In recent years, we witnessed improvement of sampling methods in epidemiological research and increased use of longitudinal designs. These methodological changes have dispelled some of the myths about aging and old age. Unfortunately, changes in theory have not kept pace with empirical findings. New etiological theories of depression, for example, are needed to account for the consistent finding of decreased incidence of depression in late adulthood. The knowledge base has increased significantly, and researchers are now faced with the challenge of identifying the relevant mechanisms. Although information about normal and pathological aging is developing at a significant pace, our understanding of the aging process is still in its infancy.

 across cultures, 110–111, 115, 117, 119
 activity-withdrawal dimension, 99
 biological variables and biopsychological aspects, 97–
 101, 341–344, 361–362
 aberrations in pathophysiology, 424–427
 brain stem and middle-latency components, 361
 brain structure and activity, methods of measuring, 344
 Crow’s hypothesis, 99, 100, 351–352
 dopamine hypothesis, 98–100, 391, 424–426
 EEG, 346–347, 349
 ERPs, 353–356, 360–362
 frontal and prefrontal dysfunction, 353–356
 lateralization and laterality/asymmetry, 349–353
 motor cortex, 361
 MRI, 347
 neurodevelopmental mechanism, 385
 neurodevelopmental *vs.* neurogenerative disorder, 373–
 374
 neuropsychological profiles, 348–349

Schizophrenia (*cont.*)

- biological variables and biopsychological aspects (*cont.*)
 - PET measures, 347–348
 - physiological anomalies, 379–380
 - prefrontal cortex, 353
 - receptor-site theories, 424–427
 - soft, neurological signs, at-riskness, and brain anomalies, 420–422
 - temporal lobe, 356–361
 - viruses, 381–382
- childhood/early onset, 393, 899–900
 - etiology, 900
 - prognosis and treatment, 900–901
- chronic vs. episodic course, 98
- comorbidity
 - alcohol-related disorders, 604
 - conversion reactions, 227
- definitions, 13, 36, 58–59, 110
- diagnosis, 19, 35–37, 39, 44–45
 - differential, 33
 - DSM-IV, 405–408, 410
 - historical background, 404–405
- diagnostic state of affairs, current, 410–411
- diathesis-stress model, 98, 371–372, 393–394
- DSM-IV alternative dimensional descriptors for, 410
- in elderly, 933–934
- environmental evidence and etiologies, 75, 380–385, 396–397
 - Dutch famine, 381
 - family history and place and season of birth, 382–383, 422
 - signals from childhood, 384–385
 - traumatizing events, 422–424
- epidemiology, 900, 934
- etiologic considerations, 411–412, 934–935
- etiological heterogeneity, 342
- evidence indicating transmission within families, 375
 - adoption studies, 378–379
 - family association studies, 375–376
 - twin studies, 376–378
- future research priorities, 397–398
- genetic analysis, problems with, 395–396
- genetic contributions, 58–64, 98, 412–413
 - degree of heritability, 394–395
- genetic models, behavior
 - phenotype and endophenotypic variables, 75, 412, 416–418
- genetic studies/research, 375, 385–387, 393
 - adoption studies, 378–379, 414–415
 - candidate genes, 391–393
 - family association studies, 375–376
 - genome-wide scans, 387–388
 - linkage analysis of specific chromosomes, 388–391
 - molecular, 75–76, 415–416
 - repeat trinucleotides, 393
 - twin studies, 376–378, 413–414
- heterogeneity, 341–342, 374–375

Schizophrenia (*cont.*)

- intrafamilial subculture and, 418–420
- latent, 61, 62
- methodological issues in the investigation of, 341–342
 - brain-behavior isomorphism, 343–344
 - concept of defect, 342–343
 - sequential emergence of manifest phenomena, 343
 - traits and states, 343
- multifactorial polygenic model, 98, 386–387
- obstetric complications, 383–384
- paranoia and, 329, 546
- premorbid functioning, 409, 410
- prevalence/incidence, 934
- the search for markers, 344–346
 - signals from childhood, 384–385
- sleep disorders associated with, 695–696
- symptoms
 - delusions, 329–330, 410
 - positive and negative/deficit, 99–100, 360, 373, 409, 410
 - Schneiderian first-rank, 406–407
- taxonomies, 372–375
- treatment, 427
 - drug therapy, 99, 427–429
 - ECT, 427
 - psychotherapies and psychosocial therapies, 429–433, 900–901
- types and subtypes, 16–17, 408–410, 532
 - classical, 408–409
 - familial vs. sporadic, 374
 - process vs. reactive, 409, 410
- Schizophrenia spectrum disorders, 61–64; *see also*
 - Schizotypal personality disorder
 - history and diagnostic criteria, 532–533
- Schizophrenic patients
 - assessment, 48
 - deficits, 406
 - memory, 351, 353
 - perseveration, 351
- Schizotypal individuals, 345–346
- Schizotypal personality disorder (SPD), 62–63, 345, 346, 494, 531, 549; *see also* Schizophrenia spectrum disorders
 - description and diagnostic criteria, 536–537
 - epidemiology, 541
 - etiological theories, 545
 - history, 533–534
 - treatment, 547
- Schneider, Kurt, 406–407
- Schreber, Daniel Paul, 324–325
- Season of year effects, and schizophrenia, 382–383
